That issue can be clearly understood from the language of expert witnesses. In Beckh *v.* Sinclair,[1] Mr. Donald Armour said that a modern surgical operation was a ritual in which every detail must be carried out with meticulous care; those who were present were a team, each member trained in his own duties; the surgeon as a rule did not interfere to see whether the others did their jobs; the modern nurse was a highly trained technician. Similarly, in the same case, Mr. H. S. Souttar said that, unless there is a separation of functions at an operation, it would be impossible to carry on modern surgery; the surgeon cannot allow his attention to stray. Giving evidence at Shrewsbury for Dr. Dunlop, Prof. Leonard Gamgee explained the exact duties of the theatre sister and the grave disadvantage to the patient if the surgeon is distracted from his difficult and delicate task. He could himself testify to the dangerous strain on the surgeon conducting an operation in emergency, without trained assistance, through the extra duty of counting swabs. He spoke also of the grave risk of infection if the surgeon is to touch swabs which have been used, so as to keep a tally of them himself. Mr. Justice Branson put the issue clearly. "One of the great points between the two sides in this case is whether it is the duty, in a case of this kind, of the surgeon himself to bear in mind, either consciously or subconsciously, the number of swabs that he has used, so that he can have his own idea as to whether he has removed them all or not; or whether, acting according to the ordinary practice of operating surgeons in this country, he is entitled to take the answer given by the theatre sister and to rely upon that without charging his own mind with keeping a record of the number of those dressings which he has used. That is a question of fact." Unhappily the jury at Shrewsbury decided this question of fact in a manner inacceptable to the ideas of modern surgery and blind to the interests of the patient. In the South African case of Van Wyk *v.* Lewis, where the surgeon was more fortunate, three main points were established. First, as in English law, the surgeon who contracts to operate undertakes that he will perform his task with average technical skill and reasonable care. Secondly, the relation of surgeon to trained nurse is not that of master and servant, or anything like it; she is an independent assistant, though under his control as respects the operation. This point has been obscured in English law by Lord Justice Farwell's observations in Hillyer *v.* St. Bartholomew's Hospital, which are sometimes quoted as relieving the hospital of responsibility on account of the surgeon's general control of the nurses at an operation. Thirdly, regard must be had to the prevailing professional practice. How long is it to be before judges and juries in England take something like the South African view? Meanwhile the position is serious. The necessary delegation of duties at a modern surgical operation is ignored. Further, even if a jury was satisfied that the responsible trained nurse had assured the surgeon that all swabs were removed, the Court of Appeal suggests that the surgeon must still make his own independent search. Lord Justice Scrutton says that the surgeon puts the swabs in, knows where they are, and is responsible for taking them out again. This view seems to assume that the surgeon will easily find the swab exactly where he first put it. He knows, of course, that the swab is within the abdominal cavity, but will the exact location be immutable? The court hardly seems to appreciate the possible covering over by the intestines or other organs and the disturbing effect of artificial respiration. The surgeon apparently is to grope searchingly. The nurse's assurance, it seems, is merely an additional confirmation, not authoritative information by itself. "No doubt," said Mr. Justice Branson to the jury, "the most efficient way would be for each swab to be counted in by everybody present and counted out by everybody present," but then, as he proceeded to explain, some of those present have other things to do. This latter fact is elementary and vital. The law must not suppose that a surgical operation upon an anæsthetised patient can proceed at the same majestic pace as the day's work in the law courts.

[1] THE LANCET, 1927, ii., 1040.

THE GLASGOW CONGRESS.

AT the eighth British Congress of Obstetrics and Gynæcology, reported elsewhere in our columns, the main subject of discussion was ovarian neoplasm. Oöphorectomy was one of the earliest successful surgical interventions, its technique has been developed to a nicety, there is a wide uniformity in treatment, and most surgeons deal alike with the difficulties they encounter. But on a few points there is divergence. In answer to the question whether the bulk of a large cyst should be diminished by tapping before its removal, some say that since malignant change never occurs in cystadenoma or papillomatous cysts, there is no reason why fluid should not be withdrawn in order to diminish the size of the incision. Others advocate removal intact through a large incision owing to their fear of dissemination of tumour material. Had those who favoured puncture at the Congress analysed their results from this point of view it would have been helpful. It is difficult to understand how continental writers on ovarian tumours can record so high a percentage of malignant change in innocent tumours if they have no definite proof. Innocent cysts are found with frank malignant disease in one part only. On the whole, apart from folliculomata which received a fair amount of attention, speakers kept chiefly to the clinical point. Prof. Blair Bell suggested a classification of ovarian neoplasms for the guidance of later speakers, whose collected evidence should on further scrutiny throw light on other points. What is clearly lacking is a satisfying knowledge of the ætiology and ontogenesis of ovarian neoplasm, the cause of some of its physical signs, for example ascites in some cases, and the reason for the secondary involvement of the ovaries from carcinoma of the breast and gastro-intestinal tract, when there is no mass ulcerating into the peritoneal cavity to cause transcœlomic implantation and permeation of lymphatics. That the ovary forms an excellent nidus for growth is shown by the ease with which grafted tumours can be propagated in the ovaries of rabbits. A feature in treatment which does not seem to have been fully appreciated before is the high mortality from surgical intervention in ovarian tumours, as compared with hysterectomy for fibroids. Apart from this main topic some of the other subjects touched on should bear early fruit. The great army of women referred to the gynæcologist on account of backache may look forward to some relief at the hands of the orthopædic surgeon. The effective plea to bring the teaching of obstetrics and gynæcology into line with that of medicine and surgery should do something towards reducing maternal mortality and disablement.

ANNOTATIONS

NATAL AND NEONATAL MORTALITY IN INDIA.

Dr. Christine J. Thomson has recently undertaken, under the auspices of the Lady Irwin Research Fund, an inquiry into the causation of stillbirths and neonatal deaths in India. Her report[1] consists of three main sections: the first summarises 200 post-mortems, the second deals with the results of an all-India questionaire to obstetric institutions, while the third part sums up the conclusions and appendices give all the results in tabular form.

In the post-mortem series 19·5 per cent. of the deaths were due to the complications of labour, but this is an under-estimate, because so many of the cases were macerated fœtuses. Tears of the dural septa were found in 20·9 per cent. of the fresh cases, half of which were breech deliveries, one-third being spontaneous vertex deliveries. Gross visceral hæmorrhages were present in 35 cases. There were 27 cases of antepartum hæmorrhage, 11 being placenta prævia. Eclampsia caused 14 per cent. of the infant deaths in Calcutta, 8 per cent. in Madras, and 1·4 in Bombay; the incidence of "certain" syphilis was 14·5 per cent., which suggests that this disease as a primary cause has been over-estimated. It is a distinct surprise that only 10·5 per cent. of the deaths could be attributed to tropical diseases, but the figure of 2·5 per cent. for malaria is regarded as an obvious under-estimate. Fœtal states accounted for 8 per cent. and there was a curiously high incidence (8 cases) of malformation or disease of the urinary system. Placental disease was found in 5·5 per cent., all of the cases being premature. Placental leucocytosis appeared to be commoner in India than in the west (10·4 per cent. of the placentas examined).

The questionaire revealed a significantly higher stillbirth-rate among Mohammedans than among Hindus, while Christians showed the lowest figure. The especial prevalence of osteomalacia in North India was revealed by the preponderance of multiparæ over primiparæ in cases of death due to contracted pelvis. In most districts there was considerably less antepartum hæmorrhage than the average British figure of 18·9 per cent. The figures for toxæmias of pregnancy vary so much that comparison is impossible; the incidence was 1 per cent. in Delhi and 17 per cent. in Calcutta. The incidence of deaths from acute maternal disease was from 11 to 18 per cent., much higher than in the west, and Bombay showed a large proportion of deaths from malaria and dysentery. A considerably higher percentage of children seemed to die from marked prematurity in India than in the west. Data on neonatal states in the questionaire must be regarded with caution in the absence of pathological examination, and there are practically no figures of placental disease.

In order to pave the way for further work Dr. Thomson attempts certain tentative generalisations and recommendations. Apart from obvious administrative reforms such as improved instruction in midwifery and education of the general public and the provision of more antenatal clinics and hospital beds, she suggests certain lines of action and research. Medical students and pupil midwives, she says, might attend special lectures on the causation and pathology of stillbirth and neonatal death, to focus attention upon an important field of obstetrics. Modern methods for the resuscitation of the asphyxiated infant might be more widely applied in hospitals; the installation of up-to-date apparatus for oxygen and carbon dioxide inhalation would certainly save life. Pædiatricians should be appointed on the consulting staffs of maternity hospitals and given special nurses and accommodation for treating birth injury, prematurity, and neonatal disease. The lines along which research could be profitably directed include the relation of poverty and malnutrition to the condition of the Indian child at birth; the scientific study of diet in relation to pregnancy; the establishment of standards of fœtal maturity for the various communities and districts and the effect of tropical diseases upon the stillbirth and neonatal death-rate. The curious geographical distribution of eclampsia obviously calls for investigation, as do also syphilis and placental disease. Malaria parasites should be sought in the placenta, and as placentas are easily obtainable there is a rich store of material to hand. The realm of research is almost unlimited and the results of the work may not only save countless lives in India but may produce valuable knowledge which can be applied all over the world.

ERUPTIONS OF THE AUDITORY MEATUS.

THE external auditory meatus is a tract of common land whose oversight is claimed by otologist and dermatologist. The views of both overseers were heard at the Royal Society of Medicine on May 1st, when Mr. A. R. Tweedie took the chair, and Dr. H. W. Barber spoke on eruptions involving the meatus. Dr. Barber classifies such eruptions into those due to external infections, those due to infective organisms reaching the skin through the blood stream, allergic conditions, and those due to the involvement of cutaneous nerves or nerve ganglia; a few conditions such as nævi, new growths, verruca vulgaris, and acanthosis nigricans cannot be classified under any of these groups.

The first group includes eruptions due to pityrosporon, the pyogenic cocci, and the acne bacillus, the tubercle bacillus, and fungi such as monilia, saccharomyces, and aspergillus. If the skin becomes sensitised to one of these organisms it is possible to confirm the diagnosis by intradermal injection of an emulsion of the causative organism, both a local and a focal reaction developing in the course of a few days. Infection with pityrosporon produces first a seborrhœic dermatitis which passes on to eczematisation and to secondary infection, usually with *Staphylococcus aureus* or *Streptococcus longus*. The treatment, Dr. Barber considers, should include the infected scalp; a campaign against the uncleanliness of hairdressers might help to reduce the incidence. The acne bacillus gives rise to comedos and pustules in the meatus, and staphylococcal infections to boils and eczema. Streptococcal infections once acquired are extremely persistent and characterised by fissure formation in the folds of the skin; the angle of the retro-auricular fold appears to be a favourite site. The adoption of a parasitic mode of life by these organisms was favoured, Dr. Barber said, by a seborrhœic condition of the skin, particularly in the cases of pityrosporon, the staphylococci, and the acne bacillus. Moisture favoured the growth of monilia, infection with which was common on the fingers of washerwomen and barmen whose hands were continually wet. Where the resistance of the epidermis had failed, especially against invasion with streptococci, the production of antibodies could be stimulated by the intradermal injection of graded doses of a vaccine made from the causative organism. When a local reaction to this treatment ceased to occur it was usually found that the resistance of the skin had conquered the infection.

---

[1] Stillbirth and Neonatal Death in India: A Preliminary Enquiry. London: H. K. Lewis and Co. Pp. 165. 1s. 6d.

Mr. T. B. Layton believes that moisture predisposes so strongly to the infection of the meatus that he has abandoned the use of watery ear drops for middle-ear suppuration in favour of applications made up with spirit or glycerin. He considers that treatment is carried out more effectively if undertaken by the patient himself, and finds that children as young as 6 years of age can become expert in mopping out their own ears. His view that watery applications should be abandoned was shared by Mr. E. Watson-Williams, but Mr. L. Graham Brown considers that syringing is invaluable for removing debris, after which applications of glycerin or spirit can be used with more hope of success.

CORONARY THROMBOSIS.

DURING the past few years many papers on coronary thrombosis have appeared in the English and American journals. The clinical features of the syndrome are now well recognised, and it is only in atypical cases and in those in which the symptoms are short-lived that any difficulty arises in the diagnosis. Eight such cases are described by Dr. R. L. Levy in a recent paper[1] which constitutes an important contribution to the subject. All the patients were under 50 years of age, and two of them were only 37. In five there was a family history of heart disease, terminating in sudden death. This is an important point from the aspect both of diagnosis and prognosis. Most cardiologists know of families in which two or more members have died suddenly, sometimes in what appears to have been their first cardiac seizure. The term diathesis is no longer fashionable, but this is one instance in which it might aptly be applied, for a known family tendency to coronary disease must always carry much weight in prognosis, even where the symptoms appear to be relatively trivial. Levy noted the excessive use of tobacco in six of his eight patients. It has been suggested by previous writers that tobacco may be an accessory factor in the causation of coronary degeneration; but this thesis is exceedingly difficult to prove, and it must be admitted that at present it is purely speculative. Excessive smoking, especially in women, is often one manifestation of a somewhat highly strung and restless temperament, and it may be that it is not the tobacco but rather the habit of living at top speed which puts an undue strain on the arterial system and induces premature degenerative changes. All Levy's cases were in people who were working under high pressure.

The diagnosis in these atypical and apparently mild cases must be based on the character and distribution of the pain, the associated febrile disturbance, the leucocytosis, and the electrocardiographic changes. As in the more severe cases the attack is generally followed by a pronounced fall in blood pressure. The most surprising feature in Levy's cases was the rapidity with which the patients recovered. In several instances they felt quite well and insisted on resuming their normal activities within a few days of the attack. One of these patients died in a second attack four years later, and two others had further attacks within 12 months. Syphilis was not a factor in any of Levy's cases, but infections of various types—e.g., sinusitis and colitis—constituted a notable feature in the histories. Of the seven surviving patients, two appear to have made a complete recovery, while in the other five the cardiac reserve is definitely impaired.

VIEWS ON SPINAL ANALGESIA.

IN the *American Journal of Surgery* for March are nine papers on spinal and other modern forms of anæsthesia, and they contain some remarkably dogmatic statements. We do not deny that most of these are logically upheld by their context, but at first sight they are somewhat startling. Meyer Saklad, discussing spinal analgesia, says that the low pulse-rate is the saving factor, that controllable agents are of no advantage, that ephedrine by its cardiac acceleration "places the patient in a condition closer to circulatory exhaustion," and that "intravenous infusion, unless indicated by loss of fluid out of the circulatory system, is of no value and may result injuriously." Gaston Labat, whose experience of spinal analgesia entitles his words to respect, says that "if a patient receives a spinal anæsthetic and is placed immediately in the Trendelenburg position, and if that position is maintained during the entire operation, the transfer of the patient from the table to the bed and for three hours at least after the patient has been placed in bed, I see no reason why death should occur." He stated that so far he had had no fatality and had used the method in many bad surgical risks. F. T. Romberger has sought to increase the benefits of percaine by giving it in combination with novocain, so that the latter, which acts quickly, can counteract the disadvantage which percaine possesses of taking some time to be effective. Moreover, the combined solution is heavier than simple percaine solutions, and it is therefore unnecessary to put the patient prone in order to get the posterior roots soaked. Romberger writes on the experience of a small series of cases only, but is so far well pleased with the method.

VALUE OF SERUM IN DIPHTHERIA.

A PAPER whose title will appeal both to the epidemiologist and the clinician has been published by Ida Mary Stevens[1] based on investigations at the Johns Hopkins University and with the California State board of health. In answer to 4694 inquiries issued, histories of 3122 diphtheria patients were obtained, each including the patient's age, the date of onset of the illness, the date of the doctor's first visit, the reasons for delay, the date on which antitoxin was administered, the number of units of antitoxin given, the method of administration, the number of doses, the laboratory findings, and the issue of the case. The information furnished by these histories suggested studies of: (1) the effect of delay in administering antitoxin on the case-fatality-rate; (2) the variations in the case-fatality-rate in communities of different sizes; and (3) the variations in the case-fatality-rates among different age-groups. As was to be expected, the evidence in favour of early administration of antitoxin was plentiful. In the first place comparison of the death expectancies of each day's survival in a series of cases from Providence, R.I., in the pre-antitoxin era with the California group showed that the chances of recovery were much greater to-day in the early stages of the disease, though more patients seemed to die in convalescence. Secondly, a comparison of the percentage distribution of deaths for these two periods showed that in the California series a smaller proportion of deaths occurred in the earlier stages of the illness. Thirdly, a classification of the cases according to delay in treatment showed that the greater the delay the higher were the fatality-rates and the greater the number of deaths. Fourthly, a comparison of the death expectancies for groups treated for the first time on each successive day with the death expectancies in the Providence series showed that after the fifth day the chances of death were approximately the same for both groups and that treatment delayed till then had little if any therapeutic value. As regards the differences in the fatality-rates for communities of different sizes the highest rates were found in the rural territory for all ages under 20 and for all methods of treatment, including the size or number of doses, routes of injection, and dates of injection. Finally, as regards the differences in the fatality-rates among the different age-groups it clearly emerged that except for infants under 1 year treated within the first 48 hours, the younger the child the higher was the death expectancy regardless of the size of the dose, method of administration, or delay in treatment. It will be seen from this summary that the paper, though it does credit to the writer's industry, does not convey much new information. The suggestion that antitoxin is of no value in diphtheria after the fifth day, though frequently repeated, especially in textbooks, is not borne out by practical experience. It is advisable to regard the presence of membrane in the throat, nose, or elsewhere—however late in the disease—as an indication for serotherapy.

ENDOCRINE REMEDIES IN SKIN DISEASE.

A QUESTIONAIRE[1] on the use of hormones in dermatology has elicited replies from six authorities in Germany, Italy, and Russia. It can be accepted that in so far as we lack reliable tests for endocrine deficiencies, and means of accurately standardising the products of the manufacturing chemist, our advances must be slow and must be based on the results of clinical trial. These are notoriously meagre. In no other department of medicine, perhaps, is the physician so often confounded and the patient disappointed. We can hardly wonder then that an enumeration of their few successful cases forms the major portion of the replies to this inquiry. Thus E. Bizzozero (Turin) reports two cases of inveterate psoriasis which eventually cleared up on a prolonged course of ovarian and thyroid injections, and the same result in a similar case associated with arthritis—on thyroid and testicular extracts. P. L. Bosellini (Rome) emphasises the extreme complexity of the problem in most cases of suspected endocrine dysfunction, excepting those in which the classical symptoms of, for example, myxœdema or Addison's disease are present. Even when the dermatologist establishes his suspicion he must remain in doubt which gland or glands are at fault, and he has always to remember that the failure of one secretion may involve a partial or complete disorganisation in the output of others. Even then his difficulties are not ended, for he has still to theorise on the nature of the dysfunction—whether it is temporary and functional, congenital and permanent, or brought about by some chronic inflammatory or malignant changes in the gland parenchyma. Examples of such difficulties are legion. Pigmentary changes, for instance, may be engendered by disturbances of the hypophysis cerebri, the suprarenals, the thyroid, or the genital glands; and it may be stated broadly that a pluriglandular dysfunction may lead either to excessive or reduced pigmentation of the skin. Finally, it has to be borne in mind that with few exceptions such as adrenalin, insulin, and thyroxin, the endocrine extracts we administer are highly complex, and have no standardised or even ascertained composition. Some of them, moreover, contain biologically antagonistic substances.

Prof. A. Buschke (Berlin) whose work on thallium acetate made its therapeutic use an accepted practice, has employed this drug in alopecia areata, which had defied all other measures, to produce complete temporary depilation. On regrowth of the hair it was found that previously denuded areas of alopecia had recovered. A similar success is claimed in a case of monilethrix, an infection peculiarly resistant to treatment. It is held by Buschke and others that thallium acetate acts by way of the endocrine glands, although the biochemical mechanism is far from clear. Irradiation of the thyroid gland with X rays is sometimes followed by at least temporary cure of psoriasis, and Buschke has found an ovarian product occasionally successful in cases of dermatitis herpetiformis and a pituitary preparation worth a trial in inveterate cases of urticaria. Thyroid should always be used in cases of sclerœdema, but its effects are more uncertain in scleroderma. All dermatoses associated with diabetes are benefited by insulin, and some successful results are reported in essential pruritus, even in the absence of hyperglycæmia.

The possibility of acquired or congenital luetic infection of the endocrine system should always be borne in mind, although it is probably not so common as French writers would have us believe. A. P. Jordan (Moscow) reports one strikingly successful case of prurigo treated by ovarian substance. The patient developed the symptom after double oöphorectomy and complete hysterectomy. The prurigo always returned when the drug was withdrawn and was immediately relieved on its resumption. The endocrine ætiology of this case seems to be clearly proved, but such cases are so rare as to be relatively unimportant. We shall all agree with R. von den Velden (Berlin) that we cannot be too careful in drawing general conclusions from isolated clinical reports.

MENTAL ILLNESS IN TWINS.

No more fundamental or momentous question has ever exercised the mind of man than that of the relative importance of environment as against heredity in shaping individual and racial destinies. As if she sympathised with our very natural perplexity on this subject, Nature now and then performs an experiment in genetics from which we can learn much. She produces uniovular twins. Such twins, being derived from the same zygote, have the same genetic constitution; hence the measure of their differences is the measure of the power of environment to modify hereditary type. The study of uniovular twins was the subject of an address entitled Genetic Problems in Psychiatry, given by Dr. A. J. Lewis at a member's meeting of the Eugenics Society in the Linnean Society's rooms on April 28th. There is, he said, no sphere of medicine in which ætiological significance of heredity has been more disputed than psychiatry. Thus estimates of the relative incidence of primary and secondary amentia vary within wide limits; psycho-analytic theory has, in recent years, undergone significant modifications in regard to the weight it gives to hereditary factors as causal agents in the various neuroses; and in the sphere of the psychoses there are profound divergencies of opinion as to the ætiological value of acquired toxæmias and endocrine disturbances. Hence in no branch of medicine would a knowledge of the principles of heredity be more useful than in psychiatry. Unfortunately, there is no branch in which the investigation of these principles is more difficult. Three such difficulties were pointed out by Dr. Lewis. There is no constant and recognisable relation between mental abnormality and bodily structure, which last can only admit of truly impersonal determination; psychiatry does not deal in unitary and circumscribed diseases, but rather in fluid syndromes, indefinite symptom-complexes, and unstable reaction types that frequently merge into and succeed one another; lastly, there is not yet complete agreement as to what should be included within the scope of a given diagnostic label. Of what, then, it may be asked, are we seeking to ascertain the inheritance? To this question the study of uniovular twins presents the most satisfactory available reply. The more unlike the environment in which two such twins have been reared, the more convincingly will be the similarity of any disease picture which they subsequently exhibit in common prove the hereditary nature of this disease. A common genetic denominator will have been demonstrated which, in the sphere of psychiatry can, perhaps alone, be rightly called unitary. Dr. Lewis is at present conducting an investigation of twins in the mental hospitals of Great Britain. He concluded a valuable and stimulating address by an appeal for assistance from any of his audience who might know of a twin or twins who had suffered or was suffering from any form of mental illness. This appeal we are happy to hand on to a wider circle.[1]

AN INFANT WELFARE JUBILEE.

ON March 24th, 1906, Mrs. Arthur Luff arrived at the St. Marylebone General Dispensary with the first baby for a welfare consultation, and last week the Mayor of St. Marylebone, the Parliamentary Secretary to the Ministry of Health and other distinguished people assembled there to celebrate the little jubilee of this event. Dr. Eric Pritchard, who has established an indisputable claim for priority to this first infant welfare consultation, told the meeting what it was that put into his head the idea of starting it. He was then senior physician to the Dispensary, and was also pædiatric correspondent of THE LANCET. In this capacity he had become acquainted with the work of Pierre Budin and his system of *gouttes de lait* at the Clinique Tarnier; he had learnt of the school for mothers at Ghent; of the babies' welfare opened by Miss Margaret Boileau at Wakefield; of Mr. Benjamin Broadbent's scheme to encourage mothercraft and breast-feeding in Huddersfield; he had knowledge of the Nathan Straus pasteurisation of milk in New York City, of the Walker-Gordon system in London, and of the milk depôts in St. Helens, Liverpool, Battersea, and Finchley. These ideas crystallised into a scheme to suit conditions in St. Marylebone which appealed to the management of the Dispensary and to the St. Marylebone Health Society lately founded. Dr. Pritchard was happy in his comrades. Dr. Janet Lane-Claypon was his first clinical assistant. Dr. Stuart (now Lady) Robertson helped him for several years. Dr. Wynter Blyth was medical officer of health for the borough. Dr. E. B. Hulbert, resident medical officer at the Dispensary, was in Dr. Pritchard's words the finest sanitary policeman known in the history of St. Marylebone, the only individual who ever succeeded in opening a Harley Street window. With the help of these and others whom he named, an army of voluntary health visitors was enrolled, many of whom were fitted for service by possessing a nurse's training. There was naturally at first some little difficulty in inducing the mothers to bring their babies for inspection. It took time to accustom them to the idea of submitting their infants to a medical examination when they appeared to be perfectly well, but these difficulties were surmounted, and the St. Marylebone example proved rapidly infectious. In the following year Dr. J. F. J. Sykes started a school for mothers in St. Pancras, and there are now over 2900 welfare centres in England, Wales, and Scotland. Miss Susan Lawrence in her address spoke of the widening scope of child welfare work to include the supervision of pregnant women, of the child between 1 and 5 years of age, and of the early manifestations of rheumatic infection. It was to be hoped, she said, that the example of the St. Marylebone Dispensary would be followed in this as it had been followed in the pioneer days of infant welfare centres.

A knighthood in the Royal Victorian Order has been conferred on Mr. Henry Martyn, F.R.C.S., Surgeon Apothecary to H.M. Household at Windsor. Mr. Martyn is surgeon in charge of the ear, nose, and throat department of the King Edward VII. Hospital, Windsor. He has been attending the King during his recent indisposition.

AT a meeting of the British College of Obstetricians and Gynæcologists, reported in our news columns, it was announced that Lord Riddell has offered to give the College £600 a year for seven years. Lord Riddell has previously made a gift of £1000.

WE regret to record the death of Dr. H. B. Weir, pathologist to the National Hospital for Diseases of the Heart.

As already announced in these columns the Royal Institute of Public Health is holding its annual congress this year from May 19th to 24th at Frankfurt a.M., under the presidency of Lord Reading. The work of the congress will be conducted in six sections, and visits will be paid to centres in and around Frankfurt and in the Rhine country. The address of the Institute is 37, Russell-square, London, W.C.1, and the meeting is open to all interested in public health.

DONATIONS AND BEQUESTS.—Lady Houston has given £5000 to the Appeal Fund of the National Council for Maternity and Child Welfare.—Subject to his widow's interest, the late Mr. W. Rhodes, of Weeton, Yorks, left, among other bequests, £2000 to Harrogate Infirmary; £1000 to Leeds Maternity Hospital; and the residue of the property to Leeds General Infirmary.—The late Mr. E. R. Jaeger, of Birmingham, left £1500 to the Children's Hospital, Birmingham, and £1500 to the Royal Cripples' Hospital, Birmingham, for the endowment of "Ernst Jaeger" beds, and £2000 to the German Hospital, London.

---

SPECIAL ARTICLES

IMMUNITY IN VIRUS DISEASES.*

By C. H. Andrewes, M.D., M.R.C.P. Lond.,
MEMBER OF THE SCIENTIFIC STAFF, NATIONAL INSTITUTE FOR MEDICAL RESEARCH, HAMPSTEAD.

II.

The available methods for producing active immunity against viruses may be considered under three heads: (*a*) immunisation with living virus, whether attenuated or not; (*b*) combined use of virus and immune serum; (*c*) immunisation with apparently killed virus.

Methods of Immunisation with Living Virus

may be grouped under the headings in Table II.

Table II.—*Methods of Immunisation with Living Virus.*

(1) Subinfective doses.
(2) Unusual route of inoculation—
    Poliomyelitis; Borna disease; herpes simplex; rabies; variola.
(3) Virus attenuated—
    By passage through usual host—variola.
    By culture—pleuro-pneumonia of cattle.
    By passage through unusual host—vaccinia and animal poxes; fowl-pox; rabies.

(1) SUBINFECTIVE DOSES.

It might seem to be a good plan to give a very small dose of living virus in hopes of giving a very mild disease which would be followed by an immunity. In practice this hardly ever works. One seems either to give so little virus that nothing happens at all either in the way of infection or of immunisation, or else the little dose of virus starts to multiply and one obtains the full-blown disease.

(2) UNUSUAL ROUTES OF INOCULATION.

Attempts have been made to immunise by giving living virus by an unusual route. This has met with a little success with some of the highly neurotropic viruses. Monkeys can be immunised against poliomyelitis by giving the virus intradermally; but the method is not always successful, and it is at present of no practical value. Borna disease is an acute encephalomyelitis affecting horses; small animals can be infected experimentally; and the virus is highly neurotropic. Here it is possible to give some immunity by injecting the virus subcutaneously, intramuscularly, or intravenously instead of directly into the nervous system. Again, the result is uncertain. Such success as there is is perhaps due to the fact that the disease has a very long incubation period, so that a general immunity can develop before the virus has propagated too much in the nervous system.

With some strains of herpes simplex virus it is possible to immunise rabbits by subcutaneous inoculations; they will then resist an intracerebral test dose which is fatal to controls. Similarly, rabbits may be rendered immune to rabies fixed virus in a fair proportion of trials by subcutaneous immunisation.

(3) ATTENUATED VIRUS.

Before the days of vaccination—in the East almost from the dawn of history—it has been sought to immunise against small-pox by variolation—that is, by deliberate inoculation with a small amount of material from a case of the disease. The method sometimes led to the occurrence of fully virulent small-pox, but as a rule the disease was milder than that naturally acquired. This was due in part perhaps to the introduction of virus directly into the skin, that is by an unusual route, as discussed in the last paragraph; in part to the propagation of pure virus unmixed with the streptococci which often accompany it; in part to the selection of mild cases for the transfer of material. Probably the actual attenuation of the virus was very slight.

The virus of pleuro-pneumonia of cattle becomes attenuated on keeping and can be used for producing immunity. This virus is of some interest as it is practically the only virus which has hitherto been cultivated in a cell-free medium. Many people because of this deny that it is a virus; but it seems hardly justifiable to do this unless you are going to exclude every organism from the category of viruses as soon as it becomes possible to cultivate it. The cultures, after a certain number of subcultures, will no longer produce the typical disease on inoculation into cattle, but they will continue to give rise to an acute local reaction following which the animal is immune to pleuro-pneumonia. This instance encourages us to hope that immunisation against other viruses would be much easier if only we could grow them on cell-free culture media.

The method of prophylactic immunisation by means of virus modified by animal passage has found very little application except in the group of animal poxes—very probably because it has not been found easy to modify other viruses in such a way that they will not readily revert to their original condition. Apart from variola and cow-pox, there are sheep-pox, goat-pox, swine-pox, horse-pox, camel-pox, and fowl-pox. The literature is full of contradictions as to whether the members of this group are convertible one into another, and whether they will immunise one against the other. It seems probable, however, that fowl-pox is separate and the others very closely related in the sense of being modifications of one virus. Inoculation of any of the group into the rabbit tends after passage to give a disease like vaccinia, which is perhaps to be regarded as the basal, least elaborated member of the group. At any rate it seems clear that vaccinia never tends to undergo the reverse modification into small-pox; this suggests that variola loses something when it is passed through the calf or rabbit, something it cannot regain. Cow-pox differs from the other poxes in having but little tendency to produce a generalised rash. Apart from its use in prophylaxis against variola, vaccinia has been used successfully to immunise pigs against swine-pox. Immunisation of poultry against fowl-pox can be carried out with pigeon-pox virus, which is probably very closely related to it.

Immunisation against rabies differs from the other kinds of immunisation we have to consider in that it is immunisation after infection. Such immunisation after infection is also possible with vaccinia; inoculated vaccinia has a much shorter incubation period than naturally acquired variola and may thus succeed in immunising a person if given after his exposure to a case of small-pox. With rabies there is a larger margin of safety, as the disease has a very long incubation period while the virus is travelling up the nerves from the site of inoculation to the central nervous system. Immunisation is made possible by the fact that the naturally occurring "street virus" in the mad dog, when passed through rabbits, undergoes a modification into so-called "fixed virus." This kills rabbits far more quickly than does street virus, but when given subcutaneously is practically harmless for man or dog. If begun early enough, intensive inoculation of this modified virus will immunise a man infected with street virus before that virus can reach his brain and kill him. Pasteur's method of attenuating the fixed virus by drying apparently acts, not by producing any qualitative change in its properties, but simply by reducing the number of living virus particles. It is possible to use dilution as a means of graduating the dose instead of the classical method of giving rabbit cords dried for shorter and shorter periods. In the East, virus inactivated by phenol is used very widely; this will be referred to later under the heading of immunisation by apparently killed viruses.

---

* Two lectures (abridged), delivered at University College Hospital Medical School on March 17th and 24th, 1931.

Combined Use of Virus and Serum.

By the combined use of serum and virus one aims at producing a very mild disease which shall be followed by solid immunity. We have seen that giving very small doses of live virus is not a method which can be relied upon to give a very mild infection; immune serum, on the other hand, has considerable powers of keeping a diseased process under control.

If you mix virus with immune serum and, if necessary, incubate the mixture until it is no longer infective *by any route*, you will find that it is no good at all as an immunising agent in any virus disease. To produce immunity along these lines you must use a slightly under-neutralised mixture. This method is used in France to immunise sheep against sheep-pox. (See Table III.)

TABLE III.—*Immunisation by Combined Use of Virus and Serum.*

(1) Virus-serum mixtures—sheep-pox.
(2) Simultaneous side-to-side inoculation.
  Cattle plague.
  Swine fever.
  African horse sickness.
  Blue tongue (sheep).
  Dog distemper.*
  Yellow fever.
(3) Virus first: serum later.
  Measles.
  Dog distemper.*

* An account of this method of producing immunity to distemper by P. P. Laidlaw and G. W. Dunkin will be appearing shortly in the Jour. of Comp. Path. and Therap. They have kindly allowed me to refer to it here.

Much commoner is the "simultaneous side-to-side inoculation" of virus and immune serum into different parts of the same animal. This allows the production of a very mild form of disease. It is necessary, however, with some viruses to grade the dose of virus and serum very carefully so that the disease is just mild enough and not completely extinguished; with distemper and cattle plague an excess of immune serum seems to be immaterial. In Table III. are shown some of the diseases in which the simultaneous side-to-side method is used. Against cattle-plague and swine-fever it is employed abroad on a very large scale. The history of its origin in the prophylaxis of swine-fever is of interest. It was found that pigs passively immunised by serum were apparently permanently immune, and investigations indicated that such pigs must have come into contact with the virus while they were in a state of partial immunity; they then developed a mild unrecognised infection which left them with a solid active immunity. Now this state of affairs is deliberately brought about by simultaneous inoculation.

It may be asked, why, if this method is so successful in controlling certain virus diseases of livestock, is it not more used against the viruses attacking man, such as the specific fevers of childhood. The answer is that the farmer who uses this method of prophylaxis is prepared to lose a certain small number of his inoculated animals, but he realises that the loss will be very small compared with his probable loss if no inoculation is done. Obviously we cannot use such a method for the widespread immunisation of children until it can be controlled with some certainty, until we can be sure that when properly inoculated none will develop the disease as a result of the immunisation. One difficulty is that in many instances we could not titrate either the virus or the serum on a susceptible animal, and should be working blindfold; even measles does not "take" in monkeys with any certainty.

SERUM AFTER VIRUS.

It may happen that a serum is so effective that it can completely stop the disease from developing at all when it is given along with the virus. In order to obtain an active immunity it may be necessary to give virus first and serum a little later. This method of immunising is obviously only applicable where a disease has a long incubation period. Consider measles. An immune serum of considerable potency in passively immunising against measles can be obtained from convalescent patients. In some places adults who develop measles in institutions are systematically bled when the temperature has returned to normal; the sera after Wassermann testing are pooled and are then available for use. It is, however, possible to obtain serum from normal adults who are known to have had measles; such sera are poorer in antibodies than convalescent sera, but are quite as effective if given in correspondingly larger doses. If measles contacts are immediately injected with 5 c.cm. of convalescent human serum they will mostly be protected, but they will not develop any active immunity. Some will develop a very mild disease and will be actively immune. If the serum is given a few days after exposure to infection, but not later than the middle of the incubation period, a mild disease will usually result and active immunity follow. Instead of giving 5 c.cm. of convalescent serum one may give larger quantities of normal adult serum; it is not so potent, but much easier to get hold of at a moment's notice. For reasons already discussed it is not practicable to immunise children systematically along these lines. All the same if the eldest member of a family brought back measles from school, it would be very reasonable to allow the younger ones to come into full contact with him and to give them some of your own blood intramuscularly (if you had had measles) after four days in the hopes that they would have a very mild infection. Of course, if the younger children were weakly one would prefer to give serum or blood as soon as possible, hoping to avoid the disease altogether for the time.

Immunisation with Apparently Killed Virus.

We now come to a point of much practical and theoretical importance: can one immunise with killed virus? It would obviously be of enormous importance to be able to immunise animals regularly with no risk of losing *any* of those inoculated, and to have a method which could safely be applied to immunising human beings. Everyone agrees that it is possible to immunise against many virus diseases with apparently killed virus, and that the immunity obtained is feeble compared with the immunity produced by live virus. So far we are on safe ground. What is greatly disputed is whether the apparently killed virus is really killed, or whether it contains living virus in very small quantity or modified in some way. Table IV. shows some of the diseases against which apparently dead virus can produce immunity and also the agents which have been used for inactivation. In not every instance have such vaccines been applied practically. The list is incomplete, but even so I have included some examples because of their theoretical interest, although they rest on isolated unconfirmed observations. Some points in the Table require further comment. First, none of these methods has as yet been applied practically to the immunisation of man. Only three human diseases appear in the list, and the experiments on yellow fever and poliomyelitis concern monkeys and are only in the very early preliminary stages.

TABLE IV.—*Immunisation by Apparently Killed Viruses.*

Agent use for inactivation.	Viruses.
Formalin	Foot-and-mouth disease ; distemper* ; cattle plague* ; yellow fever ; African horse sickness.*
Phenol and phenol-glycerin	Rabies* ; distemper ; fowl plague ; cattle plague* ; Borna disease ; yellow fever.
" Autolysis " ..	Cattle plague ; foot-and-mouth disease.
Bile	Dengue.
Chloroform	Cattle plague.*
Ether	Rabies.*
Aluminium hydroxide	Poliomyelitis.
Heat	Distemper ; fowl-pox.*

The vaccines marked with an asterisk have been used, apparently with success, in the field.

Second, some viruses, particularly cattle plague, can be made into a vaccine fairly easily, and a number of different methods seem to work. Even virus allowed to die off of its own accord in saline (" autolysis " in the Table) is said to immunise. On the other hand, other viruses, such as vaccinia, do not appear in the list; there is no agreement as to whether inactivated vaccinia will immunise at all.

The phenolised rabies virus is used on a large scale —almost entirely replacing living virus in the East for the treatment of bitten persons. It is used extensively in Japan, and also in Europe and America, as a true prophylactic for widespread immunisation of dogs. This is an obviously very advantageous method to have available in a country where rabies is widespread and where quarantine measures are not practicable as they are in England.

Formalinised virus has been found not to give a very durable immunity against dog distemper. It is therefore recommended that one dose of this vaccine should be given to dogs and that this should be followed up later by a dose of living virus. This dose of living virus may or may not be followed by a mild febrile reaction ; but it succeeds in converting the slight transient immunity which the dead vaccine confers into a solid lasting one.

Horse-sickness virus is not inactivated by a weaker dose of formalin than 1 : 1000. Vaccine made with 1 : 1000 formalin will not protect horses against living virus. But workers in South Africa have found it possible to protect by means of 1 : 1000 formalin against virus treated with 1 : 2000 formalin and then to follow up with virus treated with 1 : 3000 and 1 : 4000 formalin. Finally, living virus can be given with safety. If it should prove that the doses of partly inactivated virus do not simply represent minute doses of living virus, a very interesting field of speculation would be open. A similar story is told by some workers in Greece concerning immunisation against dengue by means of bile-treated virus. Virus completely killed by bile failed to immunise against living virus, but immunity could be established by giving doses of virus treated with successively weaker and weaker concentrations of bile.

ARE THESE VACCINES DEAD ?

Very large doses of, let us say, formalinised distemper virus fail to infect a dog. Why then, it may be asked, should some people still deny the possibility of immunising with killed viruses ? They do so because of a number of difficulties and anomalies which exist.

METHODS OF " KILLING " VIRUS.

One reagent will make a good vaccine from one virus ; quite a different one works with another virus ; it is difficult to lay down rules. Heat seems a bad method to use ; formalin is perhaps the most generally useful. It seems best to inactivate your virus slowly, using a concentration of reagent which will not inactivate for some time ; a similar principle applies to the making of anatoxin from toxin. As with toxin and anatoxin, too, one has to work within a fairly narrow range of formalin concentration. Too strong formalin will destroy all antigenic power ; too weak formalin will not completely inactivate. This is one of the facts which leads some to suspect that an effective vaccine may be not entirely " dead."

QUANTITY OF VIRUS INJECTED.

Toxin and anatoxin may not differ much in immunising value, but inactivated virus is enormously weaker than living virus. This is doubtless largely because the " killed " vaccine contains such a minute trace of antigenic virus protein, while the living virus can multiply perhaps a millionfold in the body and thus has a far better chance of immunising. Here, again, some think it hardly conceivable that the trace of virus in a " killed " vaccine can possibly immunise unless it can multiply to some extent. When virus is inoculated into a naturally refractory species one commonly finds that no specific neutralising antibodies develop. Virus so inoculated probably cannot multiply, and is for all intents and purposes dead. It is therefore easy to understand why it is so difficult to obtain antibodies ; such a very small amount of antigen has been introduced. It is not quite true to say that a virus cannot evoke antibodies in a non-susceptible species, for apparently horses will yield an anti-poliomyelitis serum. On the whole, however, it is a difficult thing to do. A complication is, of course, introduced by the fact that a horse immunised with poliomyelitis virus is receiving in addition to a tiny dose of virus a good deal of monkey protein, since infected monkey brain or cord is the only source of poliomyelitis virus available.

SPECIES OF ANIMAL FURNISHING VIRUS.

This same difficulty is seen in another connexion. Laidlaw and Dunkin proved that dog distemper virus would infect ferrets, and that these were in some ways very convenient to work with. A formalinised vaccine made from dog tissue gave protection to dogs, but was little use for immunising ferrets ; the same was true when ferret tissue was used to immunise dogs. A possible, but not proved explanation was this : the immunity mechanism of a dog injected with formalinised ferret spleen might be so busily occupied in making antibodies to the foreign ferret protein that it would, as it were, overlook the insignificant trifle of virus that was *there* and fail to make antibodies to that.

Similarly, cattle plague vaccine made from cattle tissue seems to be of no value in immunising goats. Here we have a difficulty of great practical importance. A formalinised virus has been found to give some immunity to yellow fever in monkeys; but as yet it has not proved to have any value in immunising man. It may be that the dog-ferret complication comes in here again; the human immunity mechanism may not respond well to virus contained in monkey tissue. If it is found impossible to immunise man against "killed" human viruses unless these are contained in human tissue, our progress will be considerably slowed up. We shall have to redouble our efforts to grow viruses on artificial media or else to purify them and get them separated from the animal proteins from which they cannot at present be freed. The difficulty I have outlined may not, however, occur universally, for it seems that rabies fixed virus which has been inactivated with phenol will immunise both man and the dog, though it is made from rabbit tissue.

TISSUE USED AS SOURCE OF VACCINE.

The last anomaly concerns the choice of tissue from which to make a vaccine. In cattle plague and in fowl plague blood is found to be extremely rich in virus, yet blood treated with formalin or phenol fails to make a good antigen. One has to use tissue, and in many diseases liver, spleen, and lymph glands seem to be best, though, of course, with a disease like rabies one naturally takes the tissue where the virus is present—the brain and cord. Why it is necessary to use tissue and not blood we do not know.

The enumeration of these complications seems to show that the story is by no means a simple one. In spite of the anomalies it appears to me most probable that it is really possible to immunise with virus which is quite dead; but at present it seems wise to reserve judgment. The analogy with the inactivation of toxins by agents such as formalin is, of course, very striking, but it is worth bearing in mind that the toxin-toxoid reaction is apparently a reversible one; it is just conceivable that the inactivation of a virus also might be reversible within the body.

To conclude, much progress has been made in active immunisation of the virus diseases of animals, but we do not seem to have advanced as rapidly in achieving *specific prophylaxis against the viruses* attacking man. There are, however, many indications of the lines along which further advances may be sought.

The field covered has been so wide that a bibliography to be complete would be of inordinate length. I have therefore deliberately omitted names and references. Most of the matter referred to may be found in the seventh volume of the Medical Research Council's "System of Bacteriology."

ST. BARTHOLOMEW'S HOSPITAL.—The income last year of this hospital was £216,305, an increase of £17,768; the expenditure was £219,138, an increase of £21,469. The annual report states that the completion of the surgical block marks the second stage in the scheme of reconstruction. The next stage should be the erection of a medical block to replace the south block which is nearly 200 years old and is no longer adequate. Equally urgent needs are the provision of additional accommodation for maternity patients and of a paying patients' department.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

WHEN SHOULD ANTI-TETANUS SERUM BE GIVEN?

I HAVE already referred to the need felt in France of an authoritative pronouncement on the conditions under which anti-tetanus serum should or should not be given. The commission appointed to report to the Académie de Médecine on this matter was composed of Roux, Vaillard, Bazy, Walther, Hartmann, Balthazard, Faure, Dopter, Vallée, Mauclaire, Auvray, and Gosset. After meeting three times, this commission reported to the Academy on April 14th. At the first meeting it was agreed that each member should submit a short memorandum to the commission's "rapporteur." These memoranda, which consisted to a certain extent of summaries of our knowledge of tetanus brought up to date, contained some expressions of opinion to which all the members of the commission were willing to subscribe. It was unanimously agreed that it was impossible to insist too strongly on the necessity for cleaning and disinfecting as thoroughly as possible every wound, especially lacerated wounds, and for removing foreign bodies. Anti-tetanus serum should be given for all lacerated wounds, and for less serious wounds complicated by foreign bodies or soiled by earth. This treatment is also indicated for all wounds, however slight, of the sole of the foot, and for subungual wounds, particularly of the feet. On the other hand, serum treatment need not be undertaken for superficial wounds easy to clean, uncomplicated by foreign bodies and not soiled by earth. So much for the unanimous recommendation of the commission which was accepted by the Academy, also unanimously. Among the memoranda submitted by its members to the commission was one by Roux the gist of which was as follows: It is impossible to enumerate all the circumstances under which tetanus may arise. Several of them are so rare that a doctor cannot be blamed for not having foreseen them. It is the duty of the doctor in charge to take the initiative with regard to the use of anti-tetanus serum, and the commission does not claim to lay down hard-and-fast rules. Roux referred to the special case in which a foreign body cannot be removed at once, the surgeon having to defer its extraction to a later date. In such a case he recommended active immunisation by Ramon's tetanus anatoxin. As soon as the wound has been dressed, the first injection of anatoxin is given. A quarter of an hour later the ordinary injection of anti-tetanus serum is given at some other point, and two weeks later a second injection of anatoxin is given. After another fortnight, the third and last injection of anatoxin is given. "It is superfluous to insist on the advantages of active immunisation should war break out."

THE SCIENTIST'S PROPRIETARY INTEREST IN HIS DISCOVERIES.

This question, raised in your leading article last week, was the subject of a report to the Académie de Médecine on April 21st by Dr. Lucien Klotz, who contrasted the poverty of the scientist, of hospitals, and of scientific libraries with the enormous benefit they confer on the community. He outlined a scheme according to which the starting-point of remuneration for scientific work should be the day on which its publication appeared. The scientist would then submit a memorandum, claiming a charge on the practical applications of his discovery, based on the publication thereof. He should be able to levy this charge for 50 years. A Supreme Council of Discoveries and Scientific Inventions would have to estimate the commercial value of a discovery or invention. Dr. Klotz argued that this scheme would not dishonour the scientist and would favour the provision of hospitals, and the protection and advancement of science which, as it provides milliards, deserves millions. At the conclusion of Dr. Klotz's report Prof. de Lapersonne, President of the Academy, carried the appointment of a commission charged with the preparation of a draft of a legal statute to deal with the rights of scientific discoveries. The members of this Commission are Madame Curie and Profs. Hanriot, d'Arsonval, Sergent, Léon Bernard, and Bezançon.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

PROPAGANDA AGAINST VENEREAL DISEASES.

THE Department of Health for Scotland has issued a circular dealing with health propaganda in general and with venereal diseases propaganda in particular. In 1916 a sum of about £1000 a year was granted to the Scottish Committee of the British Social Hygiene Council. This sum was under the direct control of the Board of Health and later of the Department. But, under the Local Government (Scotland) Act, 1929, this grant forms a part of the general money subsidy to the local authorities. Under this Act the local authorities have received powers to conduct propaganda for health education on the widest scale, including propaganda on venereal diseases, and each authority is entitled to its portion of the original £1000 granted in the standard year 1928–29. For example, the county of Aberdeen received £30 11*s.* 8*d.*; the County of Zetland, £4 19*s.* 9*d.*; while of the burghs, Glasgow received £219, and Edinburgh £87. The circular suggests that, instead of spending these amounts individually, the local authorities should pool their resources and enable the Scottish Committee to conduct the same type of propaganda as it formerly did under the central authority. It will be very difficult to get all the local authorities to consent to this, but an effort is to be made. The sum of £1000 is equivalent to 4*s.* 1*d.* per 1000 of the estimated population of the districts. There is no doubt that the control of the original money by the central authority enabled the Scottish Committee to do a great deal of independent work all over Scotland. The local authorities will tend to keep their expenditure entirely within their own districts. In the prevention of venereal diseases, it would have been wise to reserve to the central authority a certain sum that could be spent as the British Social Hygiene Council have spent it.

HONOUR TO DR. A. L. S. TUKE.

Dr. Alan Leonard Smith Tuke has been made an honorary freeman of the city of Dunfermline. This honour is in recognition of his public services, especially in connexion with the Dunfermline and West Fife Hospital, and with the local ex-Service men and their families. The freedom of Dunfermline, the old capital of the Kingdom of Fife, has not been frequently conferred and the distinction is therefore all the greater. In the earlier days of his practice there, Dr. Tuke did a great deal to develop the practice of physical education at the Carnegie Institutions. He took a full share in the war, serving in the Egyptian and Palestine campaigns and won the Military Cross in 1916. Recently he has given his full energy to the raising of £50,000 for the extension of the West Fife Hospital. On receiving the freedom, Dr. Tuke was able to sketch the progress of local medical events for forty years. Dunfermline, he pointed out, was the first town in Great Britain to introduce a complete and thorough system of school medical inspection, accompanied by organised and systematic physical training.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

EFFICACY OF LEGISLATION AGAINST VENEREAL DISEASES.

Prof. L. R. von Zumbusch, of Munich, discusses in the *Ärzteblatt* the efficacy of the law against venereal diseases which has been in operation since Oct. 1st, 1927. One of the purposes of that law was, as he points out, to diminish prostitution, and this object, in his opinion, has not been attained; on the contrary many women who were formerly prostitutes in secret have now become professionals so that street prostitution has become more evident. At the same time these women have become known to the police and have been referred to the municipal health offices for treatment and supervision. They have learnt that there is profit in being able to show a certificate of health and in Munich the number regularly examined has risen from 100 to 400 a week. Another advantage is that under the new law not women only but also men can be sent to hospital by the health authority, for they are just as likely to spread venereal diseases as are the prostitutes. The new law prohibits treatment of venereal diseases by unqualified persons, and does not allow the treatment to be discussed by other than qualified medical men in journals or at meetings not purely medical. According to Prof. Zumbusch this is the first serious step taken against unqualified practice. It is stated that venereal diseases have already diminished, although trustworthy returns are not yet available for the whole German territory.

THE PRESCRIPTION OF NARCOTICS.

In accordance with the law against abuse of narcotics the government has issued regulations more severe than those hitherto in force. By these new regulations narcotics can be prescribed only by qualified medical men and when their administration is medically justified. Compounds are not to be prescribed containing more than one narcotic nor compounds containing coca leaves, or opium, heroin, dicodid, eucodal, narcophin, and similar narcotics in substance. No medicine may contain more than 15 per cent. of morphia or heroin, nor more than 2 g. of opium, 0·2 g. of morphia, 0·4 of narcophin, laudanon, or pantopon, 0·2 g. of dicodid, or eucoidal, or 0·03 of heroin or dilaudid. In special cases a medical man may exceed these quantities but he is obliged to keep a register for such cases with accurate particulars of the disease. The prescription of cocaine in substance is prohibited, but a patient may receive a 2 per cent. solution for application to an eye and a 1 per cent. solution for other purposes. For use in the consulting room a medical man may prescribe not more than 1 gramme daily. A prescription given to a patient must bear the date, directions for use, the name and address of the patient, and the signature of the medical man. Where the allotted quantity has been exceeded the medical man must indicate on the prescription that he has entered the case in his register. Pharmacies are obliged to supply medicine only if it is prescribed in accordance with the above regulations, but in urgent cases a small quantity may be provisionally given even if the prescription is not in every respect in order. Apothecaries have to keep a book for registration of the prescriptions and this must be preserved for five years. It must be sent on request to the local health authority or to the German Health Office, or shown to an authorised representative of these authorities.

PERNOCTON ANÆSTHESIA.

Dr. Baisch reports in the *Archiv für Gynäkologie* on the results of pernocton anæsthesia. He has used the method in 1200 gynæcological operations and in 900 confinements. To produce deep narcosis in laparotomies on an average not more than 40 g. of ether and 5 g. of chloroform had to be used if pernocton was administered; in other operations the amount of ether was up to 30 g. and of chloroform up to 2 g. There is no contra-indication to the use of pernocton if it is given in a suitable dosage according to body-weight and if the intravenous injection is made very slowly, taking five or ten minutes. Even in cases of cardiac or pulmonary disease, and in advanced age—the oldest of Baisch's patients being 80—the drug was applied without risk. In parturient women pernocton was given instead of scopolamine. No death occurred which could be attributed to the narcosis, and bronchitis and broncho-pneumonia were very rare. The technique of giving pernocton—in contrast to avertin—is very simple. According to Baisch every operation from the easiest to the most complicated may be executed under pernocton anæsthesia.

MEAT-POISONING IN GERMANY.

According to statistical returns published by the German Health Office 2000 cases of meat-poisoning have been reported during the past three years, of which 60 were fatal. Most of the cases were of course recorded during the hot season from May to October and were traceable especially to cattle meat. More than half of the illnesses and a third of the deaths were caused by raw meat, while 10 per cent. were due to horse meat. Of the cases caused by consumption of sausage, 41 per cent. were due to liver sausage. Food control having become more effective, meat-poisoning has shown a considerable decrease compared with former years.

CHILDREN'S NURSES.

New regulations have been issued for the training and the examination of nurses for infants. There are two categories of nurses: those for healthy infants are called Säuglings-Pflegerin, and those for the sick are called Säuglings-Schwester. The former category are destined to the general care of infants in families, orphan asylums, &c. Their training lasts a year and includes the care and the up-bringing of babies and training in domestic work. The second category are trained for two years. In the first year the training is the same as for Säuglings-Pflegerin, but in the second year they are instructed in the nursing of sick children, infectious diseases, and first aid. Women of 18 to 34 years of age are admitted to the training and to the examination. For midwives and general nurses with a recognised diploma the training as an infant's nurse may be shortened.

MEDICAL BROADCASTING.

Lectures for medical men were broadcasted some time ago and the report of the Broadcasting Company says they are very much liked by the profession. This statement is however contradicted by several medical men in the *Ärzteblatt*. They say first that the time allowed for the individual lecture is too short to be of value and that therefore they cannot be an equivalent for medical lectures and congresses as suggested by the Broadcasting Company. Another drawback is that the lectures can be heard by the general public. People who have been listening for instance to a lecture on gall-stones or on the modern treatment of diabetes insist on their medical attendants applying the methods recommended by the radio lectures. As not only the symptoms of a disease, but also the differential diagnosis, the treatment, and (worse still) the prognosis is discussed, hypochondria is liable to be encouraged. A correspondent rightly remarks that medical radio lectures are like training medical students in public places where everyone can hear things destined only for the profession.

THE SERVICES

ROYAL ARMY MEDICAL CORPS.

Capt. E. G. Dalziel, from the secd. list, is restd. to the estabt.

Temporary Commissions.—The undermentioned Capts. to be Majs.:—E. M. J. O'Farrell, H. Jacques, and E. A. Tozer.

ARMY RESERVE OF OFFICERS.

Lt. F. R. How resigns his commn.

TERRITORIAL ARMY.

Lt. J. T. McOuat, from 6th Bn. Seaforth, to be Lt.

C. A. Ferguson (late Offr. Cadet, Glasgow Univ. Contgt., Sen. Div., O.T.C.) to be Lt.

J. W. Galloway (late Cadet Lce-Corpl., George Heriot's Sch. Contgt., Jun Div., O.T.C.) to be Lt.

R. B. Brew to be Lt.

INDIAN MEDICAL SERVICE.

Lt. H. S. Waters to be Capt. (*prov.*).

ROYAL AIR FORCE.

A. S. Burns is granted a short service commission as a Flight Lieutenant for three years on the Active List.

G. Kinneir is granted a temporary commission as a Flight Lieutenant.

Dental Branch.—J. E. Tyrrell is granted a non-permanent commission as a Flying Officer.

COLONIAL MEDICAL SERVICES.

The *following* appointments have been made by the Colonial Secretary during the month of April: Dr. A. C. Edwards, Supernumerary Medical Officer, Leeward Islands; Dr. C. Sturton, West African Medical Staff, Nigeria; and Dr. J. E. Macdonald, Medical Officer, Northern Rhodesia.

BIRMINGHAM DENTAL HOSPITAL.—Before the establishment of the Birmingham Hospital's Contributory Scheme three years ago this institution received annually about 6300 new patients. Since then there has been an enormous increase, and in 1930 there were 14,093 patients. Notwithstanding the rapid growth in the work of the hospital public donations provide only £600 of an expenditure exceeding £5000 a year.

ST. HELENS MATERNITY AND CHILD WELFARE HOSPITAL.—Last week this new hospital was opened by Dr. J. J. Buchan, formerly medical officer of St. Helens and now medical officer of Bradford. The building provides for 15 maternity cases and 22 ailing and debilitated children and has cost £18,500. Dr. Buchan recalled that the milk depôt established at St. Helens more than 30 years ago was "the very first thing done in any English-speaking country by any municipality to reduce the death-rate among infants."

CORRESPONDENCE

SWEEPSTAKES AND VOLUNTARY HOSPITALS.

To the Editor of THE LANCET.

SIR,—The success of the Irish sweepstakes and the transfer of such large sums of money from this country to Ireland have naturally aroused public interest, especially in connexion with the hospitals. "Why," it is asked, "if such substantial financial assistance can be given to Irish hospitals out of the sweepstakes cannot the same help be given on a larger scale to English hospitals which are so much in need of it."

So far as this particular part of the question is concerned it can easily be answered. It is certain that no one individual hospital would be allowed to run a sweepstake for its own exclusive benefit. If permission were given to one hospital there could be no reason for refusing it to any other hospital or charity, and as there are in England and Wales nearly 1000 hospitals and about 49,000 charities of different kinds there would be such a deluge of sweepstakes as to be self-destructive, and such an intolerable nuisance that even the generous and long-suffering British public would rise in revolt.

If it be granted that sweepstakes could only be legalised on the Irish basis and given a national character, there might then be three or four large sweepstakes organised during the year, say, on the Lincoln Handicap, Grand National, Derby, and Leger. The greater part of the money received must, of course, go to the prizewinners and the hospitals could not expect to get more than 20 or 25 per cent. Suppose that this resulted in a sum of £1,000,000. This would have to be divided, as I said above, among nearly 1000 hospitals which at once takes almost all the gilt off the gingerbread so far as each individual hospital is concerned, and then there are all the other charities to be considered. They would naturally clamour for some of the cake, and the end would be that the £1,000,000 would disappear in innumerable small grants which would be of little practical use to the hospital and would undoubtedly alienate many of its existing supporters. I am told that there is already a marked falling off in subscriptions to the Irish hospitals, subscribers rather naturally taking the view that as the hospitals are getting such a large subvention from the sweepstakes, their own subscriptions are not so much needed and can be reduced or cancelled altogether.

This is the purely material side of the question. There is also the moral side, but it seems to me unnecessary to dwell on it as the answer given to the material side is so conclusive. Hospitals would quite certainly lose by "sweepstakes for hospitals," and they would doubly lose if, in the eyes of not a few people, gambling were to climb into legality on the hospitals' backs.

But I have a suggestion to make. I received a letter a few days ago from the chairman of a small and very good provincial hospital. He said that a considerable part of their income was derived from a sweepstake got up every year and managed by the working people of the district, and for which all the prizes were in kind and were given. Surely this could not be called "gambling," and no one could possibly have any real objection to these people who are already interested in the hospital helping it in this way. The same position exists in connexion with "raffles" at bazaars and similar happy hunting-grounds of charities. These, as the law stands, are illegal, and any little girl raffling the indigestible-looking cake that auntie has made, and for which she has been told to get at least ten shillings, is bringing herself within the stern grip of the law. This is, of course, quite ridiculous, and if it hasn't led to "bootlegging" it can only be because we are, in the main, a patient and law-abiding race.

My suggestion is that these sweepstakes, lotteries, or raffles, by whichever name they may be called, shall be legalised, subject to the following conditions:—

1. The prizes shall all be in kind and no prize shall be in money.
2. The prizes shall all be given and shall not be paid for out of the money taken for tickets.
3. The whole proceeds shall go to the hospital or "charity" concerned subject to a very small deduction for expenses (such as the printing of tickets, &c.).

Surely the most determined opponent of gambling could see no offence in an arrangement of this kind. The winner gets the cake very cheaply, the seller gets a much better prize than would otherwise be obtainable, the charity gets the whole of the money, and the unfortunate holders of losing tickets are not likely to grudge their threepence or sixpence going to the charity in which presumably they are already interested.

I put this forward as a serious suggestion. I believe that it would result in very considerable aggregation of small sums for the benefit of hospitals and charities, especially the smaller ones, and I do not see how it could offend even the most sensitive conscience. I am, Sir, yours faithfully,

ARTHUR STANLEY.

Treasurer's House, St. Thomas's Hospital, S.E.

To the Editor of THE LANCET.

SIR,—You ask me, as chairman of the Hospital Saving Association, whether I think it wise to raise money for voluntary hospitals by sweepstakes.

The Hospital Saving Association exists to enable those who expect some day to be treated in hospital to save their money while they are earning wages, so that, when they fall ill, they may not have to depend on charity. Our contributors open their eyes and look bravely at one of the unpleasant facts of life. They realise that they and their dependants will, in the ordinary course of nature, fall seriously ill once or twice before they die, and they join together in our Association to prepare themselves and to organise mutual support for this emergency.

Illness is not a gamble, and it would not accord with the principles on which the Hospital Saving Association appeals to its members to base the finance of healing on the unstable foundation of gambling.

I am, Sir, yours faithfully,

5, Fenchurch-avenue, London. ALAN G. ANDERSON.

To the Editor of THE LANCET.

SIR,—In reply to your letter with reference to sweepstakes for hospitals, I think it is sufficient to say that sweepstakes in this country are at present illegal. In my capacity as treasurer of St. Bartholomew's Hospital, I would not be prepared to take part in any unlawful scheme. Ergo, I would not be prepared to organise a sweepstake on behalf of the hospital. But if the Government decided to legalise sweepstakes the position would be different, and it would be my duty to consider the desirability or otherwise, from the point of view of the best interests of the hospital, of the accepting of funds raised by this means. I am, Sir, yours faithfully,

St. Bartholomew's Hospital, E.C. STANMORE.

ORTHODOXY AND HETERODOXY IN SURGERY.

To the Editor of THE LANCET.

SIR,—In the address on this subject in your issue of April 25th Mr. Ogilvie says: "those operations that aim at making an anastomosis between the stomach and duodenum are based upon unsound physiology and are unprofitable in practice." Amongst such operations he mentions gastro-duodenostomy and duodenectomy—two very different things. Of the latter I have little first-hand knowledge, but of the former I have had a considerable experience, and I can assure Mr. Ogilvie, who states that "when an anastomosis is made between them (that is, the stomach and duodenum) bleeding is troublesome at the time, and leakage is not uncommon afterwards," that so far as gastro-duodenostomy is concerned these statements are entirely contrary to my experience. I never use a clamp on the duodenum and yet bleeding is no more troublesome than it is from the jejunum when doing a gastro-jejunostomy, where again I use a clamp only on the stomach. Nor have I ever seen a case where leakage has occurred from the anastomotic line. I think bleeding from the gastro-duodenal artery might be very troublesome in doing a duodenectomy for a posterior duodenal ulcer; one has even heard of an injury to the common duct in similar circumstances; if Mr. Ogilvie is referring to this operation it would be fairer if he made a distinction between duodenectomy, which for duodenal ulcer I consider a thoroughly bad operation, and gastro-duodenostomy, which my experience leads me to put at least equal to posterior gastro-jejunostomy as an operation. I think Mr. Ogilvie would find, on inquiry, that this is the kind of opinion he would receive about gastro-duodenostomy from most surgeons in the first rank—"in those cases where I have performed gastro-duodenostomy I have been well satisfied with the results; however, I usually do posterior gastro-jejunostomy because the conditions are more often favourable for the performance of this operation." In other words, the reason why gastro-duodenostomy is not more often performed is neither that the results are inferior nor that the physiology is less sound than that of gastro-jejunostomy as Mr. Ogilvie asserts.

One of the reasons given for the advocacy of gastro-duodenostomy according to Mr. Ogilvie is that the food leaving the stomach enters that part of the small intestine which is most used, to the presence of an acid medium; this, he says, is no more than an unsupported statement. It is not, however, in my opinion, quite the right way of stating the case. If he had said that the food enters that part of the intestine, into which nature intended it should pass from the stomach, more nearly than after gastro-jejunostomy, he would perhaps agree that mixing of the digestive juices and bile with the food has a sounder physiological arrangement than is the case after gastro-jejunostomy.

The real position seems to be this—there is only one good reason why gastro-duodenostomy is not more generally done, and that is the anatomical circumstances are more often unfavourable than otherwise, though in my opinion less often so than is generally thought; the results are certainly equal to those of gastro-jejunostomy, and the physiological arrangements are less disturbed by gastro-duodenostomy than by gastro-jejunostomy (what functional value, if any, there is in this it is not easy to determine).

The aspersions cast by Mr. Ogilvie on anastomoses between the stomach and duodenum are, in my experience, quite unfounded so far as gastro-duodenostomy is concerned. Indeed, I think he is damning an operation which has won for itself quite an honourable position in the treatment of certain cases of duodenal ulcer.

I am, Sir, yours faithfully,

Leeds, April 30th, 1931. E. R. FLINT.

INSULIN AND PRESERVATIVE.

To the Editor of THE LANCET.

SIR,—The doubts of Dr. Leyton and Dr. Poulton, as to whether the addition of antiseptic to insulin solutions would be a benefit, must be shared by the vast majority of physicians having long practical experience of the use of this substance. I can myself state that I have never come across any sign of ill-effect due to the absence of antiseptics in the solutions which have been in use up to the present time. It is perhaps doubtful whether the introduction of such substances could have any ill-effect, but it seems almost certain that no good can thereby be brought about, and it is also worthy of note that some manufacturers, advised by scientific experts of the highest authority, have such strong objection to the suggested change that the particular brands of insulin made by them may, in such circumstances, be withdrawn from the market. This alone would be most regrettable.

It is to be hoped the Ministry of Health will not proceed with the contemplated Bill until an opportunity has been given to all shades of medical opinion to express views as to the wisdom of the proposed measure. I am, Sir, yours faithfully,

London, W., May 2nd, 1931. T. IZOD BENNETT.

CAVERNOUS SINUS THROMBOSIS AND FACIAL INFECTIONS.

To the Editor of THE LANCET.

SIR,—Mr. Scott Brown in your issue of May 2nd (p. 960) points out the peril of thrombophlebitis of the cavernous sinus from seemingly trivial infections about the face. He agrees with observations recorded by many that infection usually occurs via the facial vein. Surely then the rational procedure is to forestall spread of infection by this route. This can be accomplished by ligating the angular vein. I have dealt fully[1] with this preventive operation. Secondly, I wish to reiterate the teaching of Ochsner that to incise or excise a carbuncle of the lip is most dangerous. Local treatment with ample hot moist dressings of magnesium sulphate preceded by peripheral auto-injections of whole blood is attended by far better results than excision. Lastly, when cavernous sinus thrombosis is established, but the patient has yet a good hold on life, may I draw attention to Eagleton's operation described in his thoughtful book, "Thrombophlebitis of the Cavernous Sinus" (New York, 1926).

I am, Sir, yours faithfully,

Harley-street, May 2nd, 1931. HAMILTON BAILEY.

ABERRANT MILK SECRETIONS.

To the Editor of THE LANCET.

SIR,—A group of workers at the London (R.F.H.) Medical School are anxious to obtain abnormal secretions of human milk for analysis and comparison. Secretions before pregnancy or any other aberrant milk secretions would be welcomed. We should be grateful if any of your readers who may come across such secretions would get into touch with us, in order that we might obtain specimens for analysis.

I am, Sir, yours faithfully,

SIBYL T. WIDDOWS.

London (Royal Free Hospital) School of Medicine for
Women (University of London), Hunter-street,
Brunswick-square, W.C., May 2nd, 1931.

POST-OPERATIVE VOMITING.

To the Editor of THE LANCET.

SIR,—Dr. Cook's paper on this subject in your issue of April 18th was both interesting and valuable. The percentage of cases which vomited after gas-oxygen, though favourable when compared with ether and other agents, seemed rather higher than one would expect. One would like to ask then whether the cases classified as "nitrous-oxide" and "gas" received ether in addition to reinforce the action of the anæsthetic? I think it is important to know this, and if Dr. Cook would use your columns to answer this question the value of her paper would be increased.

I am, Sir, yours faithfully,

Dundee, May 2nd, 1931. A. H. MACKLIN.

PANEL PRACTICE

Pregnancy and Sickness Benefit.

THE *National Insurance Gazette* continues its useful transcript of the evidence given by Sir Walter Kinnear, controller of national insurance, before the Royal Commission on Unemployment Insurance. In reply to a commissioner he agreed that pregnancy is not in itself sufficient to entitle an insured woman to sickness benefit under the Insurance Acts. Asked whether he would say that this was so in all stages up to the last, Sir Walter replied:

"The claims of married women, especially during pregnancy and after childbirth, is one of the problems of the health insurance scheme. The sickness claims of married women have risen by over 100 per cent. in the last ten years, and the disablement claims by over 150 per cent. The largest proportionate increase is in the case of married women of 45 years and under, and one of the most difficult questions the societies have to decide is when sickness benefit is properly payable during pregnancy. The society must be satisfied that the statutory condition of incapacity for work is fulfilled in these as in all other cases. A state of pregnancy does not necessarily give rise to incapacity. In the case of women in regular employment as wage earners (for instance, mill hands or factory workers), there is generally unfitness for the ordinary employment for some period before confinement, and if at the same time there is such a degree of bodily disablement as to prevent the woman from undertaking any other kind of work—except possibly household duties of the lightest character—the societies have little difficulty in regarding the statutory condition as fulfilled, and benefit is paid. Less easy of treatment, however, is the case where the woman, although admittedly unable to follow her ordinary occupation, is nevertheless capable of performing the ordinary work of her home. Where, in cases of this latter kind, the claim for benefit is submitted a substantial time before the expected date of the confinement, the society would feel considerable hesitation about admitting it—such hesitation being based on the ground that the performance of ordinary household duties may not unreasonably be regarded as an alternative occupation in the case of a married woman. Where, however, the claim is not made until a comparatively late stage, it would be much more likely to receive favourable consideration, inasmuch as societies in general are prepared to recognise the inherent probability of incapacity during the period immediately anterior to confinement."

Change of Doctor.

In the House of Commons on April 30th Mr. Albery asked the Minister of Health what provision was made for the medical attendance and treatment of an insured person who, at the commencement of a quarter, felt he could not any longer accept medical attendance and treatment from his insurance practitioner, and, when the consent to transfer by that practitioner was refused, was the insured person compelled to pay for his medical attendance and treatment by another doctor during the remainder of the quarter until the transfer was effected by giving one month's notice to the insurance committee.

In reply, Mr. Greenwood said that in these circumstances the insured person would normally be expected to apply for any necessary treatment to the insurance doctor on whose list he remained; and if he applied for treatment to another doctor any charges for such treatment would not be payable out of insurance funds. But in case of accident or other sudden emergency, application could be made by the insured person to another insurance doctor for treatment at the cost of insurance funds, if the doctor on whose list he remained (or his deputy) were not available.

LONDON HOMŒOPATHIC HOSPITAL.—When the Duke of York, the President, visits this hospital on May 20th he will receive the Royal Charter of Incorporation which has been granted to the hospital. The Duchess of York will also attend and receive purses for completion of the debt of £3126 on the extension of the nurses' home to 107 beds at a cost of £13,839.

RESEARCH FELLOWSHIPS IN TUBERCULOSIS.—The Dorothy Temple Cross research Fellowships in tuberculosis for 1931–1932 will shortly be awarded by the Medical Research Council, and applications should be lodged with the Council not later than June 6th. The object of these Fellowships is to give special opportunities for study and research to persons "intending to devote themselves to the advancement by teaching or research of curative or preventive treatment of tuberculosis in all or any of its forms." Candidates must be British subjects, and must possess suitable medical, veterinary, or scientific qualifications. The Fellowships will preferably be awarded to those who wish to conduct their studies or inquiries outside Great Britain. They will, as a rule, be awarded for one year, but in special cases may be renewed. The value of the Fellowships will depend upon the standing and qualifications of the candidate, but will not be less than £300 per annum, with travelling expenses in addition. It may also be possible to award a senior Fellowship of considerably greater value to a specially well-qualified candidate wishing to undertake an intensive study of some particular problem of tuberculosis at a chosen centre of work in another country. Further particulars and forms of application are obtainable from the secretary of the Council, 38, Old Queen-street, London, S.W. 1.

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS.

PHARMACY AND POISONS BILL.

THIS Bill was considered on Report in the House of Lords on April 28th.

THE TITLE OF CHEMIST.

On Clause 7 (Restriction on the use of certain titles, &c.) Viscount BERTIE OF THAME moved an amendment designed to prevent the use of the title "chemist" by unqualified dispensers in a hospital or in a laboratory of a manufacturing house. He said that such a use of the title "chemist" was not only misleading within the hospital itself, but might easily become a means whereby a person not entitled to do so could obtain possession of drugs, such as morphine, cocaine, or heroin, which under the Dangerous Drugs Acts might only be ordered by a medical practitioner, or a pharmacist, for hospitals.

Lord PONSONBY (Chancellor of the Duchy of Lancaster) said he thought Lord Bertie did not quite appreciate that the word "dispensing" really meant supplying. So far as dispensing in shops was concerned the point was already dealt with in the Bill. If it was intended, as he gathered from what Lord Bertie had said, that the amendment should cover the case of so-called dispensing in hospitals, the amendment would not have that effect. Therefore he could not accept it.

Lord BERTIE withdrew the amendment.

KEEPING OPEN SHOP FOR DISPENSING.

On Clause 18 (Prohibitions and regulations with respect to the sale of poisons) Lord PHILLIMORE moved a new paragraph making it unlawful for any person to keep open shop for the dispensing of prescribed medicines unless that person was an authorised seller of poisons. He said that Lord Ponsonby, when this amendment was moved in Committee, took objection to it on four grounds, one of which was that it would involve great hardships because there were many parts of the country where there was no registered pharmacist within reach. That this would not result from the amendment, if carried, was shown by the working of the National Health Insurance Act, under which all farm workers in fact came, and who were in most country districts supplied with medicine dispensed by a doctor. If this amendment was adopted, doctors being free to dispense, the same practice would prevail. Lord Ponsonby's second objection was based upon the fact that the Society's amendment, as originally drafted, would prevent the supply of simple uncompounded medicines. To meet that the wording of the amendment had been changed, and the word now used was "dispensed," which was the same word used in the National Health Insurance Act. The noble lord had also objected on the ground that the amendment would interfere with the possibility of persons holding the assistant's certificate of the Society of Apothecaries and ex-army compounders from dispensing in chemists' shops. As redrafted the amendment overcame that objection. A further objection was that it would lead to an increase in price, an argument with which he (Lord Phillimore) would be in very great sympathy, but he would point out that there would be over 10,000 shops which would be qualified to dispense in this country, and the ordinary rules of competition would probably ensure a sufficiently cheap supply. The noble lord also suggested that the amendment would interfere with the supply of veterinary medicines. With that point again he (Lord Phillimore) was in the greatest sympathy, and he had received from the Royal College of Veterinary Surgeons a suggestion that qualified surgeons should be added to the doctors and dentists qualified to dispense.

Lord PONSONBY said that as dispensing a medicine was defined in Clause 26 supplying a person "in accordance with a prescription duly given by a duly qualified medical practitioner," the effect of this amendment would be to prevent any person, except a registered pharmacist, supplying a medicine on a doctor's prescription. This was a matter of a very far-reaching character. The Government had consulted very closely with the medical profession on this point, and they had their whole-hearted support for the attitude they had taken up. This amendment asked for the pharmaceutical chemist an absolute monopoly and a control of prices. The analogy with the provision under the National Health Insurance Act did not hold good, because there the prices were controlled. The amendment would also rule out army dispensers, those who had certificates of the Society of Apothecaries, and any unregistered pharmacist. Whether that should be done or not he did not want to discuss now, but it was quite obvious that if such a very drastic proposal was to be adopted, and to be included in an Act of Parliament, there should be a very widespread inquiry into the whole case before legislative action was taken. He must therefore resist the amendment.

The amendment was negatived.

The Report stage of the Bill was concluded. On April 30th the Bill was read the third time and passed.

SMOKE ABATEMENT.

On April 28th in the House of Lords Viscount MERSEY asked the Government what measures were now being taken to deal with smoke abatement.

Lord PARMOOR (Lord President of the Council), in reply, said that an immense amount of work had been done, and was being done, with a view to a solution of this difficult problem. He thought that it was part of the Report of the Committee which was presided over by Lord Newton that it would be necessary to deal with the domestic coal fires in order to secure a real reform and modification of the atmospheric pollution which affected London and so many towns at the present time. But that, he was afraid, until public opinion was further educated in the right direction, was an obstacle standing in the way of true progress towards the removal of smoke pollution. An estimate in 1921 showed that in London the smoke pollution consisted of roughly two and a half parts by domestic smoke as against one part due to industrial smoke. Since that time industrial activity in London and its surroundings had increased, and unless steps were taken in time they would suffer very much more in the future than they had done in the past from smoke pollution. Great advances had been made in the direction of better combustion in industrial furnaces, but little or nothing had been done as regarded the ordinary open fireplace.

ADMINISTRATIVE ACTION.

Everything was being done, he thought, that could be done from an administrative point of view by the Ministry of Health. The scientific department of the Privy Council were engaged in important research experiments on this subject. No directly active function of smoke abatement was vested in the Ministry of Health, or any other Government Department, but the Ministry stood in general supervisory relation to the activities of the local authorities under the Act of 1926, and so on. So far as he knew there had been no direct complaints of the administrative action of the Ministry of Health under the Act of 1926. Generally speaking, there had been great coöperation and mutual assistance between the local authorities and the Ministry, and many steps had been taken in the right direction. Sunlight—an important factor in national health—was obscured to the extent of about 50 per cent. by smoke pollution of the atmosphere in some of the larger and more thickly inhabited districts of the country. According to the sixteenth report of the scientific department of the Privy Council in some places there was no ultra-violet light at all. He would like to think that there would be no further delay in further dealing with this problem, but he was bound to admit that just now, at any rate, was not a time when further work could be undertaken in these directions by the Government. At the same time the departments concerned were doing what they could to deal with the matter. What was really wanted was a careful analysis of the results obtained from experimental research, and then to use that analysis to put an end to what was not only a loss to health but also a loss in many other directions.

HOUSE OF COMMONS.

THURSDAY, APRIL 30TH.

Free Milk to Necessitous Children.

Mr. FREEMAN asked the President of the Board of Education the amount paid by the Government and the local authorities towards the cost of providing free milk to necessitous children last year; and whether, in view of the fact that all school-children would be benefited by this provision and the large surplus of fresh milk being produced in this country, he would consider the desirability of increasing the Government contribution to encourage local authorities to provide a daily supply of milk for every child.—Mr. LEES-SMITH replied: I regret that I have no material for a reliable estimate of the cost to local authorities and to the Exchequer, during last year, of the provision of free milk as distinct from free meals of other kinds provided for necessitous children. At the present time approximately 50,000 children are being supplied daily with free milk at a cost which may be estimated at £2000 to £3000 per week. I do not contemplate any increase in the percentage of this expenditure to be borne by the Exchequer.

National Health Insurance Funds.

Mr. REMER asked the Minister of Health what were the future liabilities against which the sum of £127,000,000 to the credit of the National Health Insurance Fund had been accumulated; and by what sum, approximately, annually this credit was being added to.—Mr. GREENWOOD replied: The sum to which the hon. Member refers is represented, in the main, by the funds of the approved societies. It is required to supplement the contributions as the insured grow older, and the claims for sickness and disablement benefits increase, to meet the cost of additional benefits provided wholly out of surplus capital as ascertained on valuation, and to cover the cost of medical benefit after the age of 65 when contributions have ceased. In answer to the latter part of the question no general average can be given. The position varies from society to society, but taking all societies together a decrease of £2,500,000 was sustained in 1929, followed by an increase of £1,000,000 in 1930.

MONDAY, MAY 4TH.

Ministry of Pensions Hospitals.

Sir ASSHETON POWNALL asked the Minister of Pensions how many Ministry hospitals were the property of the State; their situations; the total number of beds; and the average annual percentage of beds occupied.—Mr. F. O. ROBERTS replied: There are seven hospitals in the occupation of the Ministry which are the property of the State, apart from hospitals which are held on lease for short or longer periods. The particulars desired as regards each of these hospitals are as follows:—

Ministry of Pensions Hospital.	Total No. of beds.	Average annual percentage of beds occupied.
Maghull, near Liverpool	200	89·1
Chepstow, Monmouthshire	151	80·6
Queen Alexandra Hospital, Cosham, near Portsmouth	285	89·1
Chapel Allerton, Leeds	176	88·4
Mossley Hill, Liverpool	300	88·9
Latchmere (Officers Hospital), near Richmond	58	75·9
Fernbank, Roehampton	28	75·0

Vegetarian Diet.

Mr. FREEMAN asked the Home Secretary whether a vegetarian diet was provided for all prisoners who desired it.—Mr. CLYNES, replied: Yes, Sir.

Mr. FREEMAN asked the First Lord of the Admiralty whether a vegetarian diet was provided for all who desired it in the Navy.—Mr. ALEXANDER replied: The answer is in the negative.

Veterinary Colleges.

Sir WILLIAM JENKINS asked the Minister of Agriculture the number of veterinary colleges in this country; the number of such colleges in Germany, France, Russia, and the United States of America; what financial aid by way of grants was made to British colleges; and the number of students attending.—Dr. ADDISON replied: There are two veterinary colleges in England and Wales, five in Germany, three in France, fourteen in Russia, and eleven in the United States of America. My Department makes annual maintenance grants to the two English colleges as follows: £3,300 to the Royal Veterinary College, Camden Town, and £2850 to the School of Veterinary Science at Liverpool. These grants are fixed block grants for a period of five years and the amount in each case is now under reconsideration. There are 200 students at the Royal Veterinary College and 61 at the Liverpool School.

TUESDAY, MAY 5TH.

Vegetarian Diet.

Mr. FREEMAN asked the Secretary for War whether a vegetarian diet is provided for all who so desire it in the Army.—Mr. SHAW replied: No special vegetarian diet has been approved, but vegetables form a balanced proportion of the soldier's standard diet.

Provision of Spectacles for Insurance Patients.

Mr. GRAHAM WHITE asked the Minister of Health the total amount of national health insurance money spent on spectacles in each of the years 1928, 1929, and 1930; and the distribution of that expenditure between qualified and unqualified opticians.—Mr. GREENWOOD replied: The total amounts spent by approved societies and branches in England on ophthalmic benefit during the years mentioned were as follows: 1928, £270,600; 1929, £278,200; 1930, £353,300. These sums include payments for ophthalmic examinations and ophthalmic treatment, but the greater portion of them was spent on the provision of glasses. No information is available to show the amounts paid to particular opticians.

JOURNÉES MÉDICALES DE BRUXELLES.—The eleventh session of this society will be held at Brussels from June 20th to June 24th, under the patronage of the King and Queen of Belgium. The session will be the occasion of paying homage to the memory of Fernand Widal, and in this design the president, Prof. Auguste Ley, has received promises of support from a distinguished group of pathological workers. The meetings will be held on the invitation of the University of Brussels at the new buildings, the Solboch, and the Secretary-General, Dr. Beckers (145, Rue Belliard, Brussels), will give full information to intending visitors and adherents to the congress.

LONDON AND COUNTIES MEDICAL PROTECTION SOCIETY.—The annual general meeting of this society was held at Victory House, Leicester-square, London, on April 29th, the President, Sir John Rose Bradford, being in the chair. The adoption of the annual report, accounts, and balance-sheet was unanimous, following on the statement from the chair as to the numerical and financial position of the society, 800 new members having been enrolled during the year, while the surplus funds stood at a satisfactory and increasing figure. While expressing satisfaction at having so favourable a record to put forward, the President pointed out that there were still a large number of doctors and dentists not belonging to any defence association, thereby running risks with a temerity which he could not understand, having regard to the slight financial cost for which protection could be obtained. Sir John then called attention to the sad loss sustained by the society through the deaths of Mr. W. H. Carson, the well-known surgeon, who had recently joined the Council, Dr. J. H. Stowers, one of the most regular attendants at the business meetings, and Mr. A. G. R. Foulerton, who was associated with the society for 30 years and whose labours as financial secretary have been of the highest value.

Sir John Rose Bradford was re-elected as president, Dr. C. M. Fegen as treasurer, and Dr. Hugh Woods as general secretary. The President at the conclusion of the meeting made a statement arising out of the vacancy in the office of financial secretary caused by Mr. Foulerton's death, and said that it had been decided not to fill up this particular office, but to consider the appointment of a special committee upon office organisation. Messrs. le Brasseur and Oakley were re-elected as solicitors, and Messrs. Duncan Allwork and Co. as auditors.

OBITUARY

SIR BYROM BRAMWELL, M.D. Edin., F.R.C.P. Lond. & Edin.,

LATE PRESIDENT OF THE ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.

As was briefly announced in these columns last week, the death occurred in Edinburgh, on April 27th, of Sir Byrom Bramwell, the well-known physician and sometime President of the Royal College of Physicians of Edinburgh. He was in his eighty-fourth year.

SIR BYROM BRAMWELL.

[Photograph by A. Swan Watson.

Byrom Bramwell was born in 1847, the son of Dr. John Byrom Bramwell, a physician practising in North Shields. He received his preliminary education at Cheltenham and proceeded to the University of Edinburgh, where he graduated in medicine with honours in 1869. After filling the post of house physician at the Edinburgh Royal Infirmary he went into general practice in North Shields, and carried on a busy professional life there with extreme industry and ability. For five years he held numerous appointments in the poor-law and public health services, as surgeon to the police, and as a visiting medical officer at large charitable institutions. But in 1877, the year when he obtained the M.D. degree, with gold medal, at Edinburgh, he was appointed lecturer on medical jurisprudence at the Durham College of Medicine, and gave up his general practice and the numerous appointments directly associated with it to enter on a successful career as a teacher. He was appointed physician and pathologist to the Royal Infirmary, Newcastle-on-Tyne and lecturer on clinical medicine and pathology in the University of Durham College of Medicine; and held this post until his appointment in 1879 as lecturer on practical medicine in the Extra-Academical School at Edinburgh in which city the rest of his professional life was spent.

Thus, when after strenuous work at Newcastle, Byrom Bramwell decided to return to Edinburgh he was but 32 years of age, and young to aspire to the position of a consultant physician in a city like Edinburgh. But he had an unusual background, and his youth stood him in good stead. He had been appointed physician to a large infirmary some five years previously, and had used the interval in storing experience and adding to knowledge which he had already acquired in smaller institutions, in several walks of official medicine, and also in general practice. His seniors in Edinburgh may have regarded him as precocious, but his contemporaries remembered him as a brilliant student and also as a successful athlete, the proficiency in games which marked his school life at Cheltenham having been displayed in the University playing fields.

At the Extra-Academical School his teaching was an unqualified success. He attracted a large number of students and he taught them in a fundamental manner the things that it would be useful for them to know. He had the gift not only of teaching but of sensing what are the things that it was essential for a professor to teach, and his lectures on the practice of medicine and the science of diagnosis marked him out as the kind of instructor whose aid his pupils would want to obtain later in case of doubt or difficulty. Elected in 1880 to the Fellowship of his College he continued his discourses on the principles and practice of medicine in the Extra-Academical School until in 1882 he was appointed pathologist to the Royal Infirmary, a post which gave him a most valuable background for observation and research and which led soon to his election as assistant physician to the Royal Infirmary. Here again his range of knowledge and his ability to bring practical experience to bear in such varied directions made him a tower of strength as a teacher. He was soon elected full physician to the infirmary, and the success which attended his regular discourses here was as marked as it had been at the Extra-Academical School. Especially valued were his clinical demonstrations which were concise, clear, and if dogmatic were always accompanied by reasons for the view taken, deduced from personal experience. He established a large reputation as a consultant as the outcome of this work, and thenceforward, until his retirement, his advice was sought all over Scotland and the north of England.

Sir Byrom Bramwell from the beginning of his career was prompt to record what he knew, and what he surmised, in literary form, and alike as general physician, as cardiologist, and as neurologist he was the author of valuable instruction. He wrote an atlas of clinical medicine, and his studies along the same lines, published over 20 years ago, comprised eight useful volumes. He wrote on disease of the spinal cord, on the pathology of the heart and the thoracic aorta, on intracranial tumours, on the ductless glands—where he was early in associating endocrinology with certain skin diseases, and on phthisis especially from the public point of view on the question of notification. He also made early in his career interesting contributions to the subject of aphasia, and published in THE LANCET, as far back as 1897, a series of articles on this and on disorders of the speech, when his detailed accounts impressed all who read them by the extreme care displayed in the clinical observations and the importance laid throughout on the necessity of careful records of pathological conditions. These papers formed a preliminary contribution to further discussions from his pen on the subject, which always remained one of great interest to him.

As was natural, such a man received many academic honours. He was an honorary LL.D. of the universities of Edinburgh, St. Andrews, and Birmingham, and an honorary D.C.L. of the universities of Edinburgh and Durham. He was elected, not before the honour was due, President of the Royal College of Physicians of Edinburgh. He was at different times president of the Medico-Chirurgical Society of Edinburgh, and of the Association of Physicians of Great Britain and Ireland. He was a Corresponding Member of numerous foreign societies and academies, and he was the first honorary president of the Royal Medical Society of Edinburgh. The election to this post, which was particularly gratifying to him, was followed by the presentation to him of his portrait by his friends and his old pupils. In 1924 he received the honour of knighthood.

Sir Byrom Bramwell married in 1872 Martha Crighton, daughter of Mr. Edwin Crighton of North Shields, who predeceased him, and is survived by a daughter and three sons, two of whom are distinguished members of the medical profession.

MEDICINE AND THE LAW.

Sale of Poison from Automatic Machine.

A DULY registered chemist and druggist had an automatic machine outside his shop from which, amongst other drugs, a bottle of lysol could be obtained by putting sixpence in the slot. To test the legality of this transaction the Council of the Pharmaceutical Society brought an action claiming a penalty of £5 under Section 3 (1) of the Poisons and Pharmacy Act, 1908. The judge at the Wood Green County Court imposed the fine but the High Court has allowed the chemist's appeal. Thus at the moment, although Parliament must have intended to restrict the sale of poisons without supervision, it seems to be lawful to sell bottles or packets of dangerous poison to any child of sufficient stature to reach up and put in its sixpence. The material provision of the 1908 Act makes it an offence (within Section 15 of the Pharmacy Act of 1868 which imposes the £5 penalty) for any duly registered pharmaceutical chemist or chemist and druggist to carry on the business of pharmaceutical chemist or chemist and druggist "unless, in every premises where the business is carried on, the business is *bonâ fide* conducted by himself or some other duly registered pharmaceutical chemist or chemist and druggist."

The county court judge found that the automatic machine was so closely attached to the premises as to form part of them, that lysol was a dangerous poison, that its sale from the machine was not supervised, and that the chemist carried on the business of chemist and druggist at the automatic machine. The King's Bench Division says that "*bonâ fide* conducted," in the 1908 Act quoted above, means that the chemist himself must be conducting the business and not delegating the task to somebody else. The words refer to the person carrying the business on, not to the method. The machine business was conducted by the defendant chemist with regard to the placing of the machine, the contents of the machine, and the periods during which sale through the machine was possible. The words "in every premises" do not mean "in every part of the premises," or still less "at all times or hours"; in any business of any size the person conducting it must necessarily from time to time leave the actual conduct to a subordinate. The Pharmaceutical Society was seeking, says the High Court, to apply the section to something at which it was not aimed.

The result seems ludicrous. What is the use of the Society proceeding (as in the well-known Wheeldon case in 1890) against the unqualified person who sells poisons if a machine may sell them automatically? The High Court invites the Society to press for a change in the law. The Bill which is now proceeding through the House of Lords offered an opportunity, but Lord Ponsonby resisted Lord Bertie's proposed amendment on April 28th on the ground that manuscript amendments ought not to be accepted on the report stage, although the procedure of the upper House is generally elastic enough. Members of the House of Commons should be pressed to deal with the difficulty when the Bill reaches them.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED APRIL 25TH, 1931.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 212; scarlet-fever, 1499; diphtheria, 888; enteric fever, 31; pneumonia, 933; puerperal fever, 48; puerperal pyrexia, 104; cerebro-spinal fever, 76; acute poliomyelitis, 1; acute polio-encephalitis, 1; encephalitis lethargica, 15; dysentery, 6; ophthalmia neonatorum, 96. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on April 28th–29th was as follows:—Small-pox, 222 under treatment, 6 under observation (last week 208 and 8 respectively); scarlet fever, 1254; diphtheria, 1542; enteric fever, 12; measles, 143; whooping-cough, 436; puerperal fever, 28 (plus 14 babies); encephalitis lethargica, 142; poliomyelitis, 2; "other diseases," 183. At St. Margaret's Hospital there were 22 babies (plus 10 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was 1 death from small-pox, 3 (0) from enteric fever, 42 (3) from measles, 5 (2) from scarlet fever, 30 (5) from whooping-cough, 21 (4) from diphtheria, 34 (7) from diarrhœa and enteritis under two years, and 96 (20) from influenza. The figures in parentheses are those for London itself.

The death provisionally classified to small-pox was assigned to Lambeth Metropolitan Borough. There was also 1 death from small-pox reported for the month of March and provisionally assigned to Guildford Rural District. The deaths from enteric fever occurred in Blackburn, York, and Sunderland. Five deaths from meningococcal meningitis occurred in London, 2 under one year, 1 each from 2–5, 15–25, and 55–65 years. Six fatal cases of measles were reported from Birmingham, 5 from Liverpool, and 4 from Sunderland. Liverpool reported 5 deaths from whooping-cough. The 76 fatal cases of influenza outside London are scattered over 47 great towns: 7 were reported from Birmingham and 4 from Leeds.

The number of stillbirths notified during the week was 270 (corresponding to a rate of 38 per 1000 births), including 31 in London.

DEATHS CLASSIFIED TO SMALL-POX.

THE death in Lambeth was that of a girl, aged 7, who fell ill on April 13th, the rash appearing on April 16th, when her condition became much better. Dr. A. G. G. Thompson, medical officer of health, saw the girl on April 19th, when the rash was about three days old. She felt shivery but was not apparently ill. Temp. 99° F. at noon. She was removed to hospital in the evening and on arrival there had a very high temperature with considerable lethargy. She died early on April 21st. The post-mortem findings pointed definitely to an encephalomyelitis. There is not much doubt, Dr. Thompson adds, that this was in some way connected with the small-pox. The cause of death was certified as 1 (*a*) encephalitis myelitis, (*b*) small-pox. The child had not been vaccinated.

The second death was that of a male, aged 55, who was a patient in Croydon Hospital suffering from broncho-pneumonia when he contracted mild small-pox and was transferred to Clandon Isolation Hospital, where he died on March 17th. Dr. J. Ferguson, county medical officer for Surrey, tells us that the cause of death was certified: (*a*) cardiac failure, (*b*) broncho-pneumonia, (*c*) mild small-pox. There was no post-mortem examination.

MEDICAL NEWS

Royal College of Physicians of London.

A quarterly meeting of the College was held on April 30th with Lord Dawson, the President, in the chair. The following Members were elected to the Fellowship:—

Haldinstein David Haldin-Davis, M.D.Oxf.; Gustave Jean Philippe Monod, M.D. Paris; John Rupert Collins, M.D. Dublin; Alexander Greig Anderson, M.D. Aberd.; Gilbert Innes Strachan, M.D. Glasg.; Hugh James Orr-Ewing, M.D. Lond.; George Robinson Pirie, M.B. Toronto; Thomas Forrest Cotton, M.D. McGill; Hugh Stannus Stannus, M.D. Lond.; Thomas Herbert Oliver, M.D. Manch.; Frederick John Nattrass, M.D. Durh.; Alfred Alexander Webster Petrie, M.D. Lond.; Norman Brandon Capon, M.D. Liverp.; Reginald Hilton, M.D. Camb.; Adam Patrick, M.D. Glasg.; Sir Bernard Spilsbury, M.D. Oxf.; Walter Russell Brain, M.D. Oxf.; Davis Evan Bedford, M.D. Lond.; John Forest Smith, M.R.C.S.; John Davy Rolleston, M.D. Oxf.; Edgar Hartley Kettle, M.D. Lond.; Leslie John Witts, M.D. Manch.; James Andrew Gunn, M.D. Edin.

The following candidates were elected Members of the College:—

Melville Hula Aiken, M.B. New Zeal.; Mohammed Ali Arafa, M.B. Cairo; Eric Tom Bates, M.B. Liverp.; Frank Howard Beare, M.D. Adelaide; Wilfred Venn Bowman, L.R.C.P.; Edward Francis Brooks, M.D. Toronto; Thomas Benjamin Davie, M.D. Liverp.; Thomas Anwyl Davies, M.D. Lond.; Claude Ernest Dolman, M.B. Lond.; Archibald Gilpin M.B. Lond.; John Malise Graham, M.B. Camb.; Cecil John Hackett, M.B. Adelaide; Donald Frederick Kanaar, M.B. Lond.; Walter Montague Levitt, M.B., N.U.I.; Chisholm McDowell, M.B. New Zeal.; Eric Gordon Oastler, M.B. Glasg.; Catherine Jane Ormerod, L.R.C.P.; David Preiskel, M.B. Lond.; Seeniyappah Ramanathan, L.R.C.P.; William Gordon Sears, M.D. Lond.; Athelstan da Costa Stonte, L.R.C.P.; Oliver Frank Thomas, L.R.C.P.; Alexander Clive Rees Walton, M.B. Birm.; Theodore Henry Whittington, M.D. Lond.; Ernest Alan Wood, M.B. Lond.; Dorothy Evelyn Wright, M.D. Lond.

The President was appointed representative of the College on the Governing Body of the British Post-Graduate Hospital and Medical School; also representative of the College to the forthcoming centenary celebrations of the Harveian Society of London.

Licences to practise were conferred upon 106 candidates (95 men and 11 women) who have passed the Final Examination of the Conjoint Board and have complied with the by-laws of the College. The following are the names and medical schools of the successful candidates, viz.:—

R. C. Abel, Univ. Coll.; H. Allan, Middlesex; P. R. Allison, M.B., Leeds; Inez E. Banner, M.B., Punjab and Royal Free; S. Barigrasser, St. Bart.'s; J. S. Barker, *Camb. and St. Thomas's*; A. J. W. Beard, St. Bart.'s; N. J. Bee, London; D. R. Bharucha, M.B., Bombay and St. Bart.'s; N. Bissada, Cairo and Charing Cross; H. Bloom, Guy's; A. D. Bourne, St. Mary's; S. A. Bower, Birmingham; G. D. S. Briggs, St. Bart.'s; W. A. O. K. N. Bruce, Camb. and St. Thomas's; H. G. H. Butcher, Camb. and Manchester; G. N. Carrell, Guy's; P. H. Charlton, Middlesex; C. N. Chitnis, Bombay and St. George's; H. L. Cleave, Bristol; I. Culank, Middlesex; H. L. N. Davies, Birmingham; J. O. F. Davies, Middlesex; E. C. Dayus, St. Mary's; Yolande M. de la Pasture, M.B., Bristol; J. Dobson, Manchester; W. Dodd, M.B., Liverpool; G. A. Emmerson, Camb. and St. Mary's; D. Erskine, Guy's; L. P. J. Evans, Camb. and St. Bart.'s; S. H. Ferguson, Sheffield; B. Fine, London; J. Finner, Middlesex; Lena Kinkelstein, Penn. and Charing Cross; A. C. Fraser, Camb. and St. Bart.'s; J. W. O. Freeth, St. Bart.'s; L. T. Furnivall, St. Mary's; K. H. Gaskell, Camb. and King's Coll.; S. E. Godwin, St. Bart.'s; I. Gold, London; J. T. Griffiths, Cardiff and Univ. College; Constance A. Grove, Camb. and Charing Cross; E. A. Gudgeon, St. George's; K. Harris, Guy's; K. Hazell, Bristol and King's Coll.; C. B. Hinkley, St. Thomas's; G. Hyman, Leeds; F. J. V. Jaensch, St. Bart.'s; S. S. Jaikaran, Camb. and St. Thomas's; I. O. Jones, Guy's; A. Kahan, St. Thomas's; G. D. Kersley, Camb. and St. Bart.'s; D. H. Klugman, Guy's; L. E. D. Knights, Middlesex; J. S. Knox, St. Bart.'s; Nancy Laughton, Birmingham; C. H. Levick, Sheffield; D. L. Lewis, Camb. and St. George's; A. Liberis, L.M.S.S.A., St. Bart.'s; J. W. S. H. Lindahl, Camb. and St. Thomas's; A. B. MacEwan, Camb. and London; R. W. McNabb, Guy's; J. M. Matthew, Camb. and King's Coll.; R. H. Moore, Bristol; Ian More, Univ. Coll.; G. G. Mowat, Camb. and St. Thomas's; D. H. Murphy, Sheffield; W. H. Mylechreest, Camb. and St. Thomas's; W. M. Niblock, Camb. and King's Coll.; J. E. A. O'Connell, St. Bart.'s; Elizabeth G. S. Owen, Bristol; R. Palmer, Camb. and King's Coll.; W. R. Parkes, Camb. and St. Thomas's; R. M. Paton, St. Thomas's; H. A. Phillips, M.D., Melbourne; D. R. Prem, Bombay and King's Coll.; W. M. Priest, Univ. Coll.; R. V. C. Richards, Cardiff and Bristol; H. J. Riley, Birmingham; S. Rosenbloom, M.B., Leeds; A. G. Sanders, St. Thomas's; E. M. Sastry, M.B., Andhra; Ida B. Saxby, D.Sc. Lond., Bristol; J. Scholefield, M.B., Leeds; P. G. Scott, Camb. and St. Bart.'s; A. Segil, Witwatersrand and Guy's; J. H. Shakespeare, Camb. and St. George's; D. A. Smith, St. Bart.'s; R. B. F.-A. Usher Somers, Birmingham; K. S. Southam, Guy's; T. C. Stamp, Camb. and St. Bart.'s; H. W. G. Staunton, St. Bart.'s; A. B. Stokes, Oxford and King's Coll.; N. S. Taggart, Manchester; H. S. Tibbits, Camb. and Birmingham; Marion E. Townsend, Royal Free; D. S. Valentine, St. Thomas's; E. D. Ward, Camb. and St. Thomas's; Evelyn A. M. White, Univ. Coll.; Margaret M. White, Royal Free; G. A. W. Whitfield, Camb. and Univ. Coll.; R. G. Wilbond, Bristol; J. L. Wild, Camb. and St. Thomas's; I. G. Williams, Middlesex; Mary Wills, Royal Free; C. Wilson, Oxford and London.

University of London.

At recent examinations the following candidates were successful:—

D.P.H.

R. J. Muzumdar.

Part I.—R. E. Barrett, Edgar Cochrane, May P. Cowell, H. A. Crouch, N. J. England, D. W. G. Faris, Marguerite M. Fenn, H. S. Gear, J. E. Howard, I. J. Jones, G. C. Kelly, Hazel Machado, Hilta I. C. Pfister, John Portelly, L. E. J. Poulier, Dorothy M. Rees, Florence M. Rhodes, J. T. N. Roo, A. P. Ross, B. M. Roy, A. T. Till, W. J. Webster, and H. B. Wilson.

Society of Apothecaries of London.

At recent examinations the following candidates passed in the undermentioned subjects:—

Surgery.—H. R. Giblin, St. Mary's Hosp.; and H. A. T. Wells, Guy's Hosp.

Medicine.—L. Banszky, Middlesex Hosp.; G. C. Brown, Univ. of Cambridge and St. Mary's Hosp.; H. R. Fosbery and W. G. Kingston, Middlesex Hosp.; A. E. Mathews and L. Sachs, St. Mary's Hosp.; Grantley Smith, Univ. of Bristol and Guy's Hosp.; L. C. H. Sykes, Univ. of Leeds; H. W. Toussaint, St. Mary's Hosp.; C. D. Trimble, Univ. of Birmingham and St. Mary's Hosp.; and P. Wade, Univ. of Liverpool.

Forensic Medicine.—H. M. El Magidi, Univ. of Birmingham; W. Hertzog and J. S. Lane, Guy's Hosp.; F. G. Leckam, St. Mary's Hosp.; C. D. Trimble, Univ. of Birmingham and St. Mary's Hosp.; and C. F. Vieyra, St. Mary's Hosp.

Midwifery.—G. Handelsman, Univ. of Witwatersrand and London Hosp.; S. Lokecz, St. Bart.'s Hosp.; C. Morgan, Charing Cross Hosp.; R. Pakenham-Walsh, Univ. of Oxford and St. Mary's Hospital; and S. Ramarao, London Hosp.

The following candidates having completed the Final Examination, have been granted the Diploma of the Society entitling them to practise Medicine, Surgery, and Midwifery:—G. C. Brown, H. R. Fosbery, W. G. Kingston, J. S. Lane, L. Sachs, L. C. H. Sykes, C. D. Trimble, and P. Wade.

London Inter-Collegiate Scholarships Board.

This board announces that an examination for six medical scholarships and exhibitions, and one dental scholarship, of an aggregate value of £538, will begin on June 16th. They are tenable at University College and University College Hospital Medical School, the London (Royal Free Hospital) School of Medicine for Women, and the London Hospital Medical College. Full particulars and entry form may be obtained from the secretary of the board, Mr. S. C. Ranner, the Medical School, King's College Hospital, Denmark Hill, S.E. 5.

British College of Obstetricians and Gynæcologists.

A meeting of the Council was held in Glasgow on April 21st, with Prof. W. Blair Bell, the President, in the chair. The following Members were admitted to the Fellowship:—Ernest Farquhar Murray, William Henry Francis Oxley, and Gilbert Innes Strachan. The following were admitted to Membership:—Gerald Fitzmaurice Keatinge, Percy Malpas, Edward Lawton Moss, and Frank Neon Reynolds.

At the second annual general meeting, held in the Lister Memorial Hall, Glasgow, on April 22nd, it was reported that vacancies on the Council due to retirement had been filled by the re-election of Dr. Russell Andrews, Prof. H. Leith Murray, Dr. Bethel Solomons, and Prof. Beckwith Whitehouse. Dr. J. E. Stacey had been elected by vote as a representative of the provincial members.

Reviewing the work of the College during the past year the President spoke of the provision of a central home in London, which would not only be a centre for the business of the College but would be a place where Fellows and Members could meet each other and where a commencement could be made with what he hoped would become the finest obstetrical and gynæcological library in the country. The realisation of this aim had been brought nearer by a gift from Lord Riddell, who had previously given a donation of £1000 when the College received incorporation. Lord Riddell had now made a further gift of £600 per annum for seven years. Mr. Eardley Holland, the hon. treasurer, said it would be necessary to establish an endowment and a building fund. The present time did not seem propitious for launching a big appeal, but when the trade of the country improved he proposed to open an appeal for contributions.

A meeting of the new Council was held immediately after the annual general meeting, when the following officers were unanimously elected:—President: Prof. Blair Bell (Liverpool). Hon. treasurer: Mr. Eardley Holland (London). Hon. secretary: Prof. W. Fletcher Shaw (Manchester).

Aberdeen University Club, London.

The eighty-fifth half-yearly dinner of this club will be held at the Trocadero Restaurant on Thursday, May 21st, with Sir John Marnoch in the chair, and Sir Lenthal Cheatle as chief guest. The secretary's address is 9, Addison-gardens, W. 14.

Medical Prayer Union.

The annual medical missionary breakfast of this union will be held at 8 A.M. on Wednesday, May 20th, at the Refectory, University College, Gower-street, W.C.1. An address will be given by Dr. Edward A. Hunter, of Ilesha, Nigeria. An intimation of intention to be present will be welcomed by the honorary secretary, Dr. Tom Jays, Livingstone College, Leyton, E.10.

The Cancer Hospital.

The annual report states that the estimated cost of the new radiological department now being erected will be approximately £150,000. The University of London's chair in radiology, the first in the United Kingdom, is tenable at the hospital, and provision is being made for the teaching and practical training of pupils who, it is expected, will be attracted from all over the world.

Inter-State Post-graduate Assembly of North America.

In connexion with the forthcoming visit of this organisation to Europe a number of lectures have been arranged to be given in the Barnes Hall of the Royal Society of Medicine, Wimpole-street, W., on May 26th. Sir Thomas Horder will give an opening address, and Mr. Donald Armour will speak on the Treatment of Head Injuries, and Dr. Strickland Goodall on the Myocardium. On the 27th Mr. Lawrence Abel will give a cinema demonstration on the Treatment of Cancer of the Rectum, and Mr. Victor Bonney will give a gynæcological talk. Visits will be paid to the Middlesex Hospital, the Chelsea Hospital for Women, the Infants Hospital, the Temperance Hospital, the National Heart Hospital, and the Physical Therapy Institute in Park-crescent.

Medical Diary

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Tuesday, May 12th.—8.30 P.M., Psychiatry. *Election of Officers and Council.* Paper: Dr. Emanuel Miller: Eidetic Image as an Undertone of Psychosis.

Wednesday.—5 P.M., Surgery: Sub-section of Proctology. Election of Officers and Council. Discussion: The Injection Treatment of Piles.

Thursday.—8.30 P.M., Neurology. Election of Officers and Council. Specimens will be shown.

Friday.—8 P.M., Obstetrics and Gynæcology. Election of Officers and Council. Discussion: *The Relative* Value of the Induction of Premature Labour, Test Labour, and Cæsarean Section in the Treatment of *Minor Degrees of Contracted* Pelvis. Openers: Mr. R. Alan Brews, Mr. G. F. Gibberd, Dr. J. W. A. Hunter, Dr. A. Morris-Jones, Dr. Margaret Salmond, Dr. J. Gardener Wigley, and Dr. A. J. Wrigley.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

Monday, May 11th.—8 P.M., Annual General Meeting. 9 P.M., Sir John Rose Bradford: Annual Oration on Medicine as a Science and an Art, followed by a Conversazione.

HARVEIAN SOCIETY OF LONDON.

Thursday, May, 14th.—8.30 P.M. (at Town Hall, Paddington Green, W.): *Discussion* on Calcium Therapy (Opener: Dr. Donald Hunter).

PADDINGTON MEDICAL SOCIETY.

Tuesday, May 12th.—9 P.M. (at the Great Western Royal Hotel, Paddington), Dr. Egbert Morland: Medical Journalism.

MEDICAL SOCIETY OF INDIVIDUAL PSYCHOLOGY, 11, Chandos-street, Cavendish-square, W.

Thursday, May 14th.—8.30 P.M., Dr. Luff: A Case of Obsessional Neurosis. Dr. Matthew Ray: The Psychological Factor in Fibrositis and Arthritis.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn-fields, W.C.

Monday, May 11th, and following Wednesday and Friday.—5 P.M., Sir Arthur Keith: Human Monsters and Malformations—illustrated by specimens.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

Monday, May 11th, to Saturday, May 16th.—Medical Society of London, 11, Chandos-street, Cavendish-square. M.R.C.P. *Special* evening lectures at 8.30 P.M. Tues., Dr. Donald Hunter: *Bone Growth* and Metabolism. Medical Aspects of Diseases of Bones. *Fri.*, Dr. L. J. Witts: Achlorhydria and Anæmia.—British Red Cross Rheumatism Clinic, Peto-place, Regent's Park. Mon., 2 P.M., Dr. B. S. Nisse: *Demonstration* in Women's Out-patient Department. (*No tickets necessary.*)—St. Mark's Hospital, City-road, E.C. Tues., 5 P.M., demonstration in Out-patient Department by Mr. W. B. Gabriel. (No tickets required.)—Prince of Wales's Hospital, Tottenham, N. Special all-day post-graduate course in general medicine, surgery, and the special departments. Demonstrations, operations, lectures.—City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, E. All-day post-graduate Course in Diseases of the Chest. *Lectures and Demonstrations.*—Royal Eye Hospital, Southwark, S.E. *Afternoon Course in ophthalmology.* Demonstrations daily at 3 P.M.—St. John's Hospital, Leicester-square, W.C. Afternoon and evening demonstrations in skin diseases.—Further particulars from the Fellowship of Medicine.

NATIONAL HOSPITAL, Queen-square, W.C.

Monday, May 11th.—12 noon, Dr. *Greenfield: The* Cerebro-spinal Fluid. 2 P.M., Dr. Riddoch: Out-*patient Clinic.* 3.30 P.M., Mr. Williamson Noble: *Defects in the Visual Fields.*

Tuesday.—2 P.M., Dr. Walshe: *Out-patient Clinic.* 3.30 P.M., Mr. Armour: *Head Injuries.*

Wednesday.—2 P.M., Dr. Martin: Out-patient Clinic.

Thursday.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Dr. Critchley: Cerebral Vascular Disease (1).

Friday.—2 P.M., Dr. Adie: Out-patient Clinic. Mr. Elmquist: Demonstration of Re-educative Exercises (in Exercise Room).

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION, St. James's Hospital, Ouseley-road, Balham, S.W.

Wednesday, May 13th.—4 P.M., Dr. H. Crichton Miller: Functional Neurosis in General Practice.

ST. THOMAS'S HOSPITAL, Albert Embankment, S.E.

Wednesday, May 13th, and following Friday.—5.30 P.M. *(in the Governors' Hall)*: Prof. G. Grey Turner: Resection of the Rectum.

KING'S COLLEGE, *Strand*, W.C.

Monday, May 11th.—5.30 P.M., Prof. W. J. Dilling: The Pharmacology and Therapeutics of Lead Colloids. (Last lecture.)

UNIVERSITY COLLEGE, Gower-street, W.C.

Thursday, May 14th.—5 P.M., Dr. R. J. Lythgoe: Special Sense *Physiology.* (Second of six lectures.)

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE, Keppel-street, Gower-street, W.C.

Monday, May 11th.—5 P.M., Dr. C. F. White: Port Work.

Wednesday.—Dr. Bernard Hart: Mental Hygiene.

Friday.—Prof. E. L. Collis: Industrial Hygiene: Respiratory Diseases.

CITY OF LONDON MATERNITY HOSPITAL, City-road E.C.

Thursday, May 14th.—5 P.M., Mr. H. Burt-White: *Diagnosis* and Treatment of Uterine Infarction.

BRITISH INSTITUTE OF RADIOLOGY, 32, Welbeck-street, W.

Thursday, May 14th.—8.30 P.M., Annual general meeting. Mr. H. S. Souttar: Ideal Distribution of Radon Seeds.

Friday.—11 A.M. Visit to Royal Chest Hospital, City-road, E.C.

INSTITUTE OF PATHOLOGY AND RESEARCH, St. Mary's Hospital, W.

Tuesday, May 12th.—5 P.M., Prof. C. A. Ariens Kappers: The Function of the Various Layers of the Cortex.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital for Diseases of the Skin, Leicester-square, W.C.

Monday, May 11th.—5 P.M., Dr. H. MacCormac: Treatment of Syphilis.

Tuesday.—5 P.M., Dr. W. N. Goldsmith: The Nervous System in Relation to Skin Diseases.

Thursday.—5 P.M., Dr. J. M. H. MacLeod: Infections of the Skin with Yeast-like Organisms.

Friday.—5 P.M., Dr. W. Knowsley Sibley: Alopecia.

CHADWICK PUBLIC LECTURES.

Friday, May 15th.—8 P.M. (in the Institute of Mechanical Engineers, Storey's Gate, Westminster), Prof. E. L. Collis: The Coal Miner: His Health and Occupational Diseases.

UNIVERSITY OF BIRMINGHAM.

Tuesday, May 12th.—3.30 P.M. (at the General Hospital), *Mr. B.* T. Rose: Common Disorder of the Rectum.

Wednesday.—4 P.M. (in the Large Theatre of the Medical *Faculty* Buildings, Edmund-street), Sir Hubert Bond: Some Correlations between General and Psychological Medicine. (First of five William Withering Memorial Lectures.)

Friday (at the Queen's Hospital).—3.30 P.M., Dr. Philip *Cloake: Demonstration* of Medical Cases.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSE.

Tuesday, May 12th.—4.15 P.M., Dr. T. H. Oliver: Rheumatoid Arthritis.

Friday.—4.15 P.M., Mr. A. H. Burgess: Demonstration of Surgical Cases.

MANCHESTER VICTORIA MEMORIAL JEWISH HOSPITAL, Elizabeth-street, Manchester.

Wednesday, May 13th.—4.30 P.M., Dr. H. Morris: Demonstration of cases in the X ray department.

In an advertisement in our last issue the title of Prof. Samson Wright's Oliver-Sharpey Lectures at the Royal College of Physicians of London should have read: "Certain Aspects of the Reflex Control of the *Circulation.*"

Appointments

GAMMIE, A. E., M.B., Ch.B. Aberd., has been appointed Medical Superintendent, Richmond and Heston-Isleworth Joint Isolation Hospital.

HOPKINS, E. L., L.R.C.P. Lond., M.R.C.S., D.P.H., Superintendent of the Derby County Mental Hospital.

MUMFORD, P. B., M.D., Ch.B. Manch., Hon. Dermatologist, Royal Infirmary, Manchester.

REID, J. R., M.B., Ch.B. Edin., D.P.H., Chief Asst. Medical Officer to the Education Committee, West Ham Town Council.

Vacancies

For further information refer to the advertisement columns.

Aberdeen Royal Infirmary.—Hon. M.O. for Diseases of the Skin Dept.

Barnet, Herts, Wellhouse Hospital.—Asst. M.O. At rate of £200.

Barrow-in-Furness, County Borough.—Asst. M.O. £500.

Bath, Royal United Hospital.—Asst. H.S. £150.

Battersea Borough Council, Maternity Hospital, Bolingbroke-grove, Wandsworth Common, S.W.—Res. M.O. £150.

Belgrave Hospital for Children, 1, Clapham-road, S.W.—H.S. At rate of £100.

Birmingham City Babies Hospital, Maternity and Child Welfare Dept.—Jun. Res. M.O. At rate of £100.

Birmingham Queen's Hospital.—Hon. Ophth. S.

Birmingham University, Faculty of Medicine.—Chair of Anatomy. £1100.

Blackburn Royal Infirmary.—Fourth H.S. £150.

Bootle General Hospital, Lancs.—2 H.S.'s Each at rate of £150.

Cancer Hospital, Fulham-road, S.W.—Director of Research Inst.

Cheadle, Royal Mental Hospital, Cheshire.—Locum Tenens. 7 gns. per week.

Chesterfield and North Derbyshire Royal Hospital.—Cas. O. and H.S. At rate of £200 and £150, respectively.

Connaught Hospital, Orford-road, E.—Res. Cas. O. At rate of £100.

Derby, Derbyshire Royal Infirmary.—Cas. O. £150.

Doncaster Royal Infirmary.—H.S. At rate of £175.

East London Hospital for Children and Dispensary for Women, Shadwell, E.—Res. Cas. O. £125.

Elizabeth Garrett Anderson Hospital, Euston-road.—H.P., Obstet. Asst. Also 3 H.S.'s. All at rate of £50.

Gloucester, Gloucestershire Royal Infirmary, &c.—2nd H.S. At rate of £120.

Hastings, East Sussex Hospital.—Jun. H.S. At rate of £100.

Hellingly, East Sussex County Mental Hospital.—Two Jun. Asst. Res. M.O.'s. Each £350.

Hong-Kong University, Faculty of Medicine.—Professor of Pathology. £1000.

Hospital for Epilepsy and Paralysis, Maida Vale, W.—Two Med. Regs. Each £100.

Hospital for Sick Children, Great Ormond-street, W.C.—Ophth. Surgeon.

Hospital of St. John and St. Elizabeth, 60, Grove End-road, N.W.—Temp. Anæsthetist. At rate of £50.

Hove, Brighton, Hove and Preston Dispensary.—Hon. Physician for Ditchling-road Dispensary.

Hove, Lady Chichester Hospital.—H.P. At rate of £100. Also Jun. H.S. £50.

Huddersfield Royal Infirmary.—H.S. At rate of £150.

Hull Municipal Maternity Home and Infants Hospital.—Jun. Res. M.O. £100.

Hull Royal Infirmary.—H.S. to Ophthal. and Ear, Nose and Throat Depts. At rate of £150.

Ilford Borough.—Asst. M.O.H. £600.

Ilford, King George Hospital.—2 H.S.'s. Each at rate of £100.

Institute of Ray Therapy, 152-154, Camden-road, N.W.—Res. M.O. At rate of £150.

Inverness Royal Northern Infirmary.—H.P. At rate of £100.

Kettering U.D.C.—Part-time M.O. for Antenatal Clinic. £1 11s. 6d. per session.

King Edward Memorial Hospital, Ealing, W.—Consulting P., Consulting Dental S., Asst. Consulting S., and Consulting Anæsthetist. All honorary.

Leeds, Herzl Moser Hospital, Leopold-street.—R.M.O. £100.

Leicestershire and Rutland Mental Hospital, Narborough, near Leicester.—Asst. M.O. £350.

Liverpool Hahnemann Hospital, Hope-street.—Res. M.O. At rate of £100. Also Clin. Asst.

L.C.C. Hospital Laboratory Service.—Pathologist. £1100.

London Homœopathic Hospital, Great Ormond-street and Queen-square, W.C.—Asst. Surgeon for Diseases of the Throat, Nose and Ear.

London Hospital, E.—Asst. Phys. to Children's Dept.

London Jewish Hospital, Stepney Green, E.—Med. Reg. £100. Surg. Reg. and Ear, Nose and Throat Reg. Each 60 guineas. Res. M.O. and Cas. O. Each at rate of £150. Also Jun. Res. M.O. At rate of £100.

Macclesfield General Infirmary.—2nd H.S. At rate of £150.

Manchester, Ancoats Hospital.—Orthopædic H.S. At rate of £100.

Manchester Babies' Hospital, Burnage-lane, Levenshulme.—Hon. Anæsthetist.

Manchester Ear Hospital, Grosvenor-square, All Saints.—H.S. At rate of £150.

Manchester Royal Infirmary.—H.S. for Central Branch, Roby-street. At rate of £100.

Middlesex Hospital, W.—Whole-time Asst. for Radium Therapy and Research Dept. £300.

Newcastle-upon-Tyne, Hospital for Sick Children.—H.S. At rate of £100.

Norwich, Norfolk and Norwich Hospital.—Cas. O. and H.S. £120.

Oldham Royal Infirmary.—H.P. and Cas. O. Each at rate of £175.

Oxford Eye Hospital.—H.S. £150.

Plymouth Central Hospital.—H.S. £130.

Pontefract General Infirmary.—R.M.O. £200-£300.

Poplar Hospital for Accidents, East India Dock-road, E.—Sen. Res. O. £200.

Queen's Hospital for Children, Hackney-road, E.—H.P., H.S., and Cas. O. All at rate of £100.

Reading, Royal Berkshire Hospital.—Cas. O. and Res. Anæsthetist. Each at rate of £150.

Redhill, Surrey Royal Earlswood Institution.—Jun. Asst. M.O. At rate of £250.

Rotherham Hospital.—H.P. £180. Cas. H.S. £150.

Royal College of Surgeons of England.—Election to Court of Examiners and Professors and Lecturers.

Royal Free Hospital, Gray's Inn-road, W.C.—Asst. M.O. for V.D. Dept. £350. Also Sen. Clin. Assts. for Children's Dept.

St. Mary's Hospital, W.—2nd. Obstet. Surgeon for Out-Patients Dept. Also Res. Anæsthetist. At rate of £101–£150.

St. Thomas's Hospital, S.E.—Visiting Anæsthetist.

Salford City Infectious Diseases Hospital.—Jun. Asst. Res. M.O. £200.

Salvation Army Mothers' Hospital, Lower Clapton-road, Clapton, E.—Asst. Res. M.O. £80.

Samaritan Free Hospital for Women, Marylebone-road, N.W.—Hon. Surg. to Out Patients.

Southampton, Royal South Hants and Southampton Hospital.—Hon. Asst. Phys., Surg. and Anæsthetist to Special Depts.

Stoke-on-Trent, North Staffordshire Royal Infirmary.—H.S. £200.

Taunton, Taunton and Somerset Hospital.—Jun. H.P. and H.S. Each at rate of £100.

Truro, Royal Cornwall Infirmary.—H.S. £170.

University College, W.C.—Bucknill Scholarship 160 guineas. Also 2 Exhibitions each 55 guineas.

Walsall General Hospital.—H.S. At rate of £150.

Warwick County Mental Hospital, Hatton.—3rd. Asst. M.O. £400.

Western Ophthalmic Hospital, Marylebone-road, N.W.—Jun. H.S. At rate of £100.

Worcester General Infirmary.—Jun. H.S. At rate of £120.

The Chief Inspector of Factories announces vacancies for Certifying Factory Surgeons at Tooting (London) and at Cromarty (Ross and Cromarty).

The Home Secretary gives notice of a vacancy for a Medical Referee under the Workmen's Compensation Act for the districts of the Bedford (Circuit 20), Hitchin, and Luton (Circuit 35) County Courts, and the districts of the Biggleswade, Huntingdon, Peterborough, Thrapston, and Oundle (Circuit 35) County Courts. Applications should reach the Private Secretary, Home Office, Whitehall, London, S.W. 1, not later than May 27th.

Births, Marriages, and Deaths

BIRTHS.

GOVER.—On April 28th, at London-road, St. Leonards-on-Sea the wife of Dr. W. Gover, of a son.

WHITBY.—On April 29th, at Bentinck-street, the wife of Lionel Whitby, C.V.O., M.D., of a son.

MARRIAGES.

GLASGOW—WILSON.—On April 28th, at Park Church, Uddingston, Dr. William Glasgow, Annesbrooke, Swindon, to Agnes Barr Wilson, daughter of the late Sir Thomas Fleming Wilson, K.B.E., and Lady Wilson, Flemington House, Uddingston.

READ—CAMPBELL.—On May 2nd, at the Cathedral, Manchester, John Hodgson, to Mary Caldwell Campbell, M.B., Ch.B., D.P.H., Edinburgh.

SHACKEL—SWANN.—On April 29th, at All Saints' Church, Waldron, Edward Meredyth Shackel, M.B., B.Chir. Camb., to Jessie Elizabeth Gordon, only daughter of Mr. and Mrs. O. H. Swann, of Old Common, Cross-in-Hand, Sussex.

DEATHS.

LAMB.—On April 30th, at Sunnymount, Beechen Cliff-road, Bath, Jessie Lamb, M.B., B.S. Lond., Medical Missionary of the C.E.Z.M.S. at St. Catherine's Hospital, Amritsar, India.

MARSH.—On May 3rd, suddenly, at the Cottage on the Cliff, Sandown, Isle of Wight, the residence of his sister, John James Marsh, M.D., late of Sloane-street, S.W.

NORMAN.—On April 29th, at Wiltshire-road, Brixton, Frederick Norman, J.P., F.R.C.S. Eng., aged 67.

RUSHER.—On April 28th, at the Paddock, Pershore, John Golby Rusher, M.R.C.S.

WEIR.—On May 4th, at Park-road, N.W., Henry Bright Weir, M.A., M.B., B.Chir. Camb.

WILLIAMS.—On April 30th, at "Carisbrooke," Bromley Common, Mary Frances, the beloved wife of John Williams and only child of the late Matthew Henry Hodder, aged 75.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

AN OPHTHALMIC DEPARTMENT AT NORTHAMPTON.—An ophthalmic department for in-patients was last week opened at Northampton General Hospital. It comprises two wards of five beds each for men and women, two private wards of two beds, a small isolation ward, and a theatre.

NOTES, COMMENTS, AND ABSTRACTS

THE MANCHESTER CANCER COMMITTEE.

THE Christie Cancer Hospital in Manchester is the only institution outside London entirely devoted to the treatment of cancer and the study of its cause and prevention. It has joined forces with the Holt Radium Institute and the combined institutions, which both require more space, are building a new department, where the work carried out in coöperation with the Manchester Committee on Cancer and the University of Manchester can be continued. The Manchester committee continues to pay special attention to mulespinner's cancer and the carcinogenic properties of mineral oils. The Anglo-Persian, Anglo-American, and Shell-Mex oil companies have joined in contributing £1000 for two years, in providing crude oils from their wells all over the world, and in preparing in their own research laboratories samples of oils purified in ways suggested by the Manchester staff. The committee has also carried out, at the instigation of the Ministry of Health, an inquiry into the causes of 482 cases of cancer of the skin and an inquiry into the occurrence of intrathoracic cancer. The report for the year 1930 records the results of the researches up to date. The active carcinogenic principle in synthetic tar has now been concentrated to a high degree, but only one definitely active pure compound has been isolated. Its cancer-producing ability is very largely increased by oleic acid, and the effect of heat on this acid is being investigated. It has been found that a very large quantity of acid must be used to detoxicate mineral oils, but the potency can be reduced by as much as 75 per cent. by the use of smaller amounts. Filtration, oxidation, reduction, and exposure to ultra-violet light and radon markedly decrease the cancer-producing potency of oils, but the practical utility of these methods—except filtration—seems doubtful. Mineral oils from petroleum wells vary considerably in their activity, the lighter grades being on the whole somewhat more potent than the heavier engine and cylinder oils.

A MONSTER DIAGNOSTIC CHART.

WE have received from the publisher a copy of a wall chart [1] embodying Dr. Altenhaus's scheme for the complete clinical examination of a patient. The top of the chart is divided into two parts. On the left are full details of the patient's address, occupation, and birth-place; below these, previous illnesses, occupational risks and vices, in the shape of alcohol and tobacco. The right half of this part of the sheet is largely occupied by a diagram for noting the family history in full detail from grandparents to children. The lower part of the chart records the investigation of the present state. On the right side is portrayed diagrammatically the profile of the head, with a full face view of the neck and chest. In and around this diagram are placed particulars of everything to be noticed in the examination of these parts, together with anatomical charts of the front and back of the chest on which are shown the normal limits of the lung resonance. On the left of this lower there are particulars of personal peculiarities, height, colour, shape, and size of head, and every other conceivable detail. Below this the peripheral circulation and the blood are dealt with and the chart is completed by sections for the abdomen with its contained viscera, the urine, and the central nervous system. Every point receives detailed attention; for instance, the blood examination includes a Schilling differential count and a determination of the blood group, while all six of the external ocular muscles are given separate compartments. In relation to these the investigation of the symptoms receives rather scant attention. The chart measures 40 by 28 in. and it is not quite clear exactly for whom it has been designed. From its title and general format it appears to be intended to serve as a guide to the physician or student examining a patient, so that no observation shall be overlooked. If the practitioner is meant to have a stock of the charts and to fill one in for every examination he makes, however laudable the ambition may be it is scarcely practicable since to fill up even one completely would require more than a hard day's work. The chart has been worked out with the utmost care and ingenuity and is a good example of teutonic thoroughness. Let us leave it at that.

BLINDNESS IN PALESTINE.

THE amount of blindness in Palestine is appalling, and there is little evidence of improvement during the last few years. The report of the Ophthalmic Hospital of the Order of St. John of Jerusalem for 1930 makes depressing reading. Of 2396 patients seen in 1930 who were blind in one or both eyes the cause could be traced directly or indirectly to acute conjunctivitis in 79 per cent. The opening of an annexe specially devoted to the treatment of these cases is recorded. During the first six months after its opening 5320 cases of acute conjunctivitis were dealt with, 1497 complicated with corneal ulceration, and 279 of these had already or soon thereafter perforated. The infection was mainly Koch-Weeks, in a certain number it was gonococcal. The great majority attending the annexe were infants and children. In addition to the usual methods of treatment, all the severer cases were given parenteral milk injections, the preparation used being "abijon," the total intramuscular injections given being nearly 500. The benefit was usually marked and it undoubtedly shortened the duration of treatment if given at an early stage. The epidemic season lasts during the five hottest months of the year and during the peak the pressure of work on the staff is severe—ten hours a day actual seeing of patients. Not until the problem of acute ophthalmia is dealt with satisfactorily can the trachoma problem assume manageable proportions, for the one is usually spread by the acute infection of the other. At present the incidence of trachoma is practically stationary, including 91 per cent. of the patients.

FIRST-AID OUTFITS FOR MOTORISTS.

IN anticipation of Safety Week, May 11th to 16th, the British Red Cross Society is putting on the market a number of first-aid outfits for motorists. These are to be available in three sizes at 10*s*. 6*d*., 28*s*. 6*d*., and 42*s*. The first is intended for private cars; the other two are designed to meet the needs of motor-coaches. In addition, a "field dressing" has been prepared at 1*s*. The Red Cross outfits, which are made up in black tin boxes, are intended to contain everything required for dealing with the ordinary road accident, and their contents are all of British manufacture. Specifications are available to manufacturing chemists.

"AFFECTIONS OF THE EYE DUE TO VIRUSES."

IN our report of the annual congress of the Ophthalmological Congress last week Dr. L. H. Savin was said to have described a case of cavernous sinus thrombosis following injection of a vaccine for rheumatism. It should have been stated that the thrombosis followed nine days after vaccination against *small-pox* in a patient who had been suffering from rheumatism. Dr. Savin did not imply that there was necessarily any connexion between the vaccination and the cavernous sinus thrombosis.

BRISTOL INFIRMARY EXTENSION.—The Dowager Duchess of Beaufort recently opened a maids' hostel containing 73 bedrooms. It is intended to double the accommodation for out-patients and to erect a separate building for the resident medical staff.

[1] Die ärztliche Untersuchung. By Dr. George Altenhaus, formerly Sekundararzt in the Vienna General Hospital. Vienna: Moritz Perles. 1931. Mk.2.50.

ADDRESSES AND ORIGINAL ARTICLES

THE SPLEEN: ITS STRUCTURE, FUNCTIONS, AND DISEASES.*

By J. W. McNee, D.S.O., M.D., D.Sc. Glasg.,
F.R.C.P. Lond.,
ASSOCIATE PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL, LONDON.

LECTURE III.

We may now consider definite diseases involving the essential structures of the spleen, following the classification which I have suggested.

Infections, Acute, Granulomatous, and Parasitic.

These require no more than mention to bring them into line with other groups in the classification. Acute splenic tumour has already been referred to, while the chief granulomas affecting the spleen are tubercle and syphilis. Echinococcus (hydatid) is the only important parasitic infection, unless aspergillus infection, subsequently discussed, should be included.

Diseases Affecting the Myeloid and Lymphatic Structures.

Myeloid metaplasia is, I believe, a throw-back to the original function of the fœtal spleen as a blood-forming organ. It occurs in a variety of diseases, such as pernicious (Addisonian) anæmia and von Jaksch anæmia, and splenic enlargement, sometimes considerable, ensues. The leukæmias, acute and chronic, myeloid and lymphatic, also involve these structures, but need no more than mention here. In the chronic varieties the splenomegaly may be enormous. There is one case in my experience, which I have already referred to elsewhere, but in which the results of splenectomy were so remarkable that I should like to record it again.

The patient was a woman, aged 66 years, first seen by me in May, 1926, when she was emaciated and obviously dying from a disease classified by the blood picture as chronic aleukæmic leukæmia. The blood count numbered 5400 to 6500 leucocytes, of which 78–82 per cent. were lymphocytes. Splenectomy was successfully carried out at the Royal Northern Hospital by Mr. L. E. Barrington-Ward on July 2nd, 1926. The spleen was enormous, weighing nearly 3000 g., and sections of it, which have been shown to several very prominent pathologists, have always been described as showing the characteristic changes of leukæmia. Following the operation, the woman made a remarkable recovery, has put on several stones in weight, and is still alive and in good health four and a half years after the operation.

It may at first sight seem curious that I do not include the cases of chronic hæmolytic (acholuric) jaundice in this group, but I am satisfied that, so far as the spleen is concerned, it is the reticulo-endothelial phagocytic cells which are active in this disease. It is more difficult to know where to include the spleens from cases of thrombocytopenic purpura, a disease which, as is now well known, may only be curable in desperate cases by splenectomy. I have examined the spleens removed by operation from four cases of this kind, but in none of them could the histological structure of the spleen be described as in any way abnormal. A further point of some clinical interest, and one not always remembered, is that in none of these four cases was the organ enlarged above the normal.

Apart from the lymphatic leukæmias, there would appear to be no special disease in which the lymphatic structures (Malpighian bodies) of the spleen are essentially involved. A possible exception is one of the types of primary sarcoma of the spleen, but this is referred to subsequently.

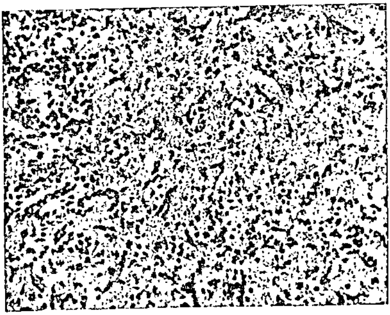
Diseases Affecting the Endothelial Elements (Reticulo-Endothelial System).

This is a most important group, which includes a considerable proportion of the splenomegalies of unknown and uncertain origin. In my previous tentative grouping I included these cases as "reticulo-endotheliosis" of the spleen, and divided them as follows:—

(1) Slight (? chronic infections), and marked.
(2) Lipoidal group—diabetes, &c.
(3) Gaucher-Pick-Niemann group.
(4) Tumours.

I now wish to modify and amplify this early conception, so as to bring it into line with the new classification. Tumours may be excluded, but simply for clearness, since the so-called endotheliomas could still be rightly considered as belonging to this group.

Fig. 10.



Section of spleen from a typical case of hereditary hæmolytic (acholuric) jaundice (low power).

There are three types of splenic disease which may be classified as belonging to this group:—

(1) Chronic hæmolytic (acholuric) jaundice.

(2) Disturbances in the lipoid metabolism of the reticulo-endothelial cells (Gaucher's disease; Niemann's disease; hypercholesterolæmic splenomegaly in diabetes).

(3) Chronic splenomegalies of unknown origin, showing marked proliferation of the reticulo-endothelial cells, and associated with giant cells.

1. *Chronic hæmolytic (acholuric) jaundice*, whether of the congenital or acquired variety, is such a well known disease that it seems quite unnecessary to refer to its clinical aspects. Recent very complete accounts have been given by Eppinger (1920) and Meulengracht (1922). The spleens from this group of cases are seldom enormously enlarged, and have a most characteristic histological structure quite unlike that of any other form of splenomegaly. The pulp spaces are seen to be engorged with red blood corpuscles, so numerous that the actual structure of the

---

* The Lettsomian lectures delivered before the Medical Society of London on Feb. 16th and 25th, and March 4th, 1931. Lectures I. and II. appeared on May 2nd and 9th respectively.

organ can only be made out satisfactorily when the spleen has been removed by operation and allowed to empty itself of as much blood as possible before fixation. It can then be seen that the spleen pulp is crowded with erythrocytes of normal appearance, whereas the blood sinuses are relatively empty. In sections stained for iron by the Prussian blue method the spleens can easily be separated into those removed during an inactive or active stage of this hæmolytic disease. In the first instance iron pigment is practically absent; in the second hæmosiderin is abundant, lying chiefly within reticulo-endothelial cells of the pulp and in the large endothelial phagocytic cells lining the blood sinuses.

It may be mentioned here that siderotic nodules, which are referred to in complete detail under diseases involving the vascular system, are by no means uncommon in cases of chronic acholuric jaundice. In one case of this kind, indeed, these nodules were more numerous than in any other spleen of my collection.

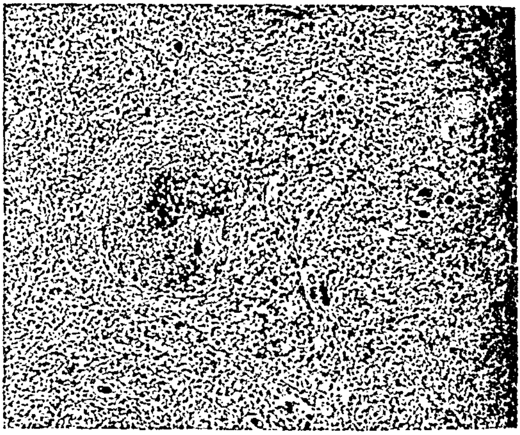
Another curious clinical point in connexion with these cases is the unusual frequency of chronic indolent ulcers of the leg. Such ulcers occur in a number of types of splenomegaly, and it is noteworthy that Stukeley (1722) has some interesting observations to make on this very point. He says (p. 68) "that even Hippocrates knew that ulcers in the legs of such—i.e., patients with splenomegaly—are difficultly healed," and Stukeley refers to a case of his own and to one observed by Mr. Becket at St. Thomas's Hospital.

In view of the histological changes seen in the spleen it is evident that, so far as this organ is concerned, the pathological process consists of a tremendous over-activity of the reticulo-endothelial cells which engulf and destroy the red blood corpuscles. In view of our knowledge of increased fragility of the red blood corpuscles in many, but by no means all, cases of this kind, it would seem probable that the disorder exists in the erythrocytes themselves, and that the splenic enlargement is simply the hypertrophic response of the overworked phagocytic reticulo-endothelial cells. On this view splenectomy may cure the disease by breaking one essential link in an abnormal chain, but the rest of the story is still unknown to us.

2. *Disturbances in the lipoid metabolism of the reticulo-endothelial cells.*—The cases in this group are particularly interesting and puzzling, and, as already stated, it is possible that new careful studies of the relations of the normal spleen to fat metabolism may help in their elucidation.

It was shown experimentally by Anitschkow (1914) that when animals are fed with excessive quantities of cholesterol the cells of the reticulo-endothelial system in the spleen and elsewhere store up immense quantities of cholesterol-ester, and the endothelial cells in ordinary paraffin sections appear large, round, and with "foamy" protoplasm. Clinical observations were ahead of this experimental result, and it was first observed by Coats of Glasgow (1889) that in some cases of diabetes, associated with lipæmia, the spleen pulp was chiefly made up of large finely granular cells, some of them fatty. Coats's work attracted little attention until Schultze (1912) and Niemann (1914) noted and described similar cases. Schultze concluded that the contents of the cells was a lipoid, but being isotropic only and not doubly refractive to light, he believed the lipoid could not be cholesterol-ester. A number of similar cases have been described since then, and two papers of fairly recent origin, from both of which a good account of the literature is obtainable, are by Oppenheimer and Fishberg (1925) and Dyke (1928). The majority of such cases have also shown definite deposits of cholesterol-ester in the skin (xanthoma), and some (e.g., Dyke's case) have been associated with hepatic cirrhosis and jaundice. It is an important point that the lipoid in the large foamy cells of the spleen may not show double refraction to light when viewed through crossed Nicol's prisms, and so confusion with the Gaucher and Niemann types of splenomegaly is possible. Great excess of cholesterol is, however, easily demonstrated by chemical analysis of the tissue, and it would seem that the cholesterol must be bound in some peculiar way to the protein molecule. Graham and Blacklock (1927) have shown that by heating frozen sections in glycerin or water the anisotropic characters of the lipoid may be revealed.

FIG. 11.



Section of a spleen showing marked reticulo-endothelial hyperplasia, with giant-cell formation.

Gaucher's disease was originally described in 1882, and excellent clinical and pathological accounts of it are given by Brill and Mandlebaum (1905), Pick (1926), and Graham and Blacklock (1927). In this disease the reticulo-endothelial cells in the enlarged spleen, in the liver and in the bone-marrow are filled to excess with a lipoid, evidently not cholesterol-ester, but the nature of which is quite unknown. In Niemann's cases the lipoid is apparently different again, but is probably a closely related compound. All of these diseases, as Graham and Blacklock conclude, are presumably the same in type, although the actual lipoids present must differ somewhat in chemical constitution. The splenic enlargement is evidently a reaction on the part of the reticulo-endothelial cells to some abnormal or unwanted product of lipoid metabolism.

In the liver the proliferation of the foamy endothelial cells containing the lipoid may, in any of the cases of this group, be so extreme that necrosis of liver cells and subsequent cirrhosis may ensue. In the bone-marrow collections of these cells may invade the ivory bone (as in an unpublished case which was shown to me by A. R. Rich, of Baltimore), so that an appearance resembling tumour formation results, and pathological fractures ensue.

3. *Chronic splenomegalies of unknown origin, showing marked proliferation of the reticulo-endothelial cells, and associated with giant cells.*—Into this group fall several of the very largest spleens in my collection.

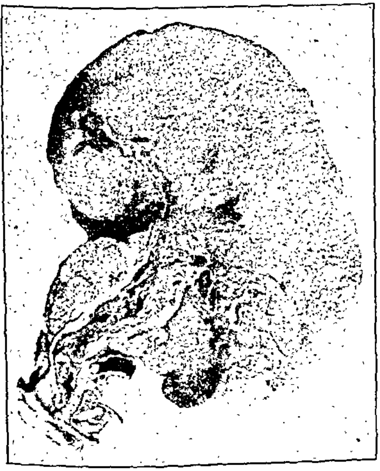
I can do little more than describe the histology, and I have no good explanation of these cases to offer. I suspect that they may be the response of the reticulo-endothelial cells to chronic inflammation of long standing. In several cases of this kind the liver was definitely cirrhotic, but in others I have no information about the liver; so this question must remain open. The histological changes consist essentially of a great proliferation of the endothelial cells, so that the spleen becomes a heavy solid organ and the pulp spaces and venous sinuses are encroached on and partly obliterated. Along with this striking histological alteration giant cells appear, and are sometimes so numerous that the sections almost resemble those from a case of myeloid sarcoma. It has been held by some that these giant cells are megakaryocytes from the bone-marrow, but I am satisfied both from their histological characters and from the results of the oxydase reaction that this view of their origin is incorrect.

Diseases Affecting the Vascular System.

This, in my opinion, forms the largest group of splenomegalies met with in Britain, and I have paid particular attention to it both for this reason and because so many difficulties present themselves for solution. I have already put forward some of my conclusions in considerable detail (1929), and McMichael (1931), working in Prof. Wilkie's laboratory in Edinburgh, has followed up the work in an important paper entitled "Local Vascular Changes in Splenic Anæmia." One section of this group has been the centre of much controversy in recent times, owing to the views, first put forward by Gibson, of Oxford, and later by Emil-Weil, Nanta, Pinoy, and others in France, that the essential splenic lesion is due to mycotic infection.

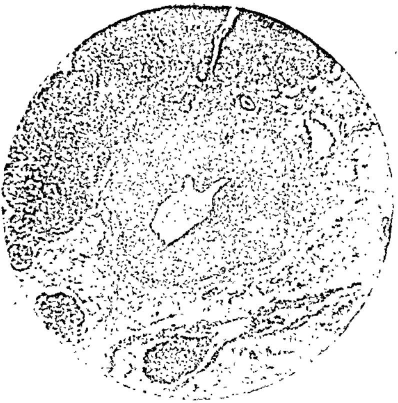
I wish to describe two types of splenomegaly in this group: 1. Thrombophlebitic splenomegaly, in which thrombosis has occurred in the splenic or in the portal vein. 2. Splenomegalies associated with peri-ellipsoidal hæmorrhages and nodular siderosis. The second of these, as I have explained before, cannot be regarded as a true and separate group, since the characteristic lesion is found in a number of quite different types of splenic disease. But the lesion is so remarkable, and discussion concerning its ætiology has been so controversial, that for clearness alone these cases must be dealt with separately.

FIG. 12.



Thrombo-phlebitic splenomegaly. The splenic vein is filled with old and partly tunnelled thrombus. The wall of the vein is irregularly thickened. (From a specimen in the museum of University College Hospital.)

FIG. 13.



Section from the hilum of a spleen removed by operation. Shows great thickening of one of the main splenic vessels (low power).

1. *Thrombophlebitic splenomegaly.*—This group includes the cases in which thrombosis is found either in the splenic vein or in the portal vein and its branches. The splenic enlargement may be enormous, and a spleen of this type is the largest I have ever seen, weighing over nine pounds. These cases have attracted attention for many years, and among the most important papers are those of Dock and Warthin (1904), Dévé (1908), and Warthin (1911). In Warthin's paper a list of nearly 80 references is given, dating back to 1857. Sometimes the thrombosis appears to be fairly recent, and completely obliterates the lumen, but generally the thrombus is old, calcified, and often "tunnelled" so that a partial blood flow has been re-established. There are nearly always calcareous plaques or other signs of degeneration in the wall of the thrombosed vein, suggesting that the clotting has been secondary to chronic phlebitis. Warthin rightly pointed out that in many cases of chronic splenomegaly reported in the literature no mention is made of the condition of the splenic or portal veins, neither of which are usually fully examined in the ordinary necropsy. He states definitely that no example of splenomegaly or "Banti's disease" can be considered seriously in any ætiological study if careful examination of these veins has been omitted. It is also important, in spleens removed by operation, to examine the stump of the splenic vein left distal to the ligature. By doing this I have several times found thickening and even calcification in the small segment of vein, and McMichael also confirms this.

Microscopically the spleens of this group show histologically nothing so characteristic as to be diagnostic, and the chief features made out are a hypertrophy of the spleen pulp associated with generalised fibrosis.

I have noticed that in these cases perisplenitis and adhesions are particularly dense, and unusual difficulties are created for the surgeon by the dense adhesions and also because of the very large size of the *vasa brevia* in the gastro-splenic omentum.

2. *Splenomegalies associated with peri-ellipsoidal hæmorrhages and nodular siderosis.*—The characteristic lesion of this group, the siderotic nodule, has been observed in a considerable variety of conditions in which the spleen is diseased. Jaffé and Hill (1928) have noted it in association with splenic anæmia, hæmolytic jaundice, portal and atrophic hepatic cirrhosis, leukæmia, Hodgkin's disease, sickle cell anæmia, and splenic tuberculosis.

It is, however, as I have stated in a previous paper, one of the commonest findings in chronic splenomegalies examined in this country, and is recognisable at once whenever the enlarged spleen is incised. Scattered over the cut-surface are a number of irregularly shaped yellowish-brown nodules, varying in size from a pin-point to several millimetres in diameter. Each yellowish-brown spot stands out prominently or even slightly projects from the cut-surface of the freshly incised spleen, and each is surrounded by a narrow chocolate-coloured rim. On scraping with the point of a scalpel the nodules are found to be firmly fixed, and can only be torn out with difficulty for bacteriological and chemical examination. On some nodules the knife makes a grating sound, evidently from the presence of lime salts. In other parts of the cut-surface of the spleen abundant small round or oval hæmorrhages occur, unassociated with any central pigmented zone, and on microscopic examination these are found to be hæmorrhages surrounding small arterioles. Diffuse hæmorrhages into the spleen-pulp are common in all forms of splenomegaly, but are readily distinguished with a lens from those surrounding the arterioles. In a few spleens I have found only the small ring hæmorrhages surrounding the arterioles, without any pigmented nodules.

The history of our knowledge of these brownish-yellow nodules is very interesting, but as I have already given it in full chronological detail (McNee, 1929) I have space here only for the briefest synopsis. The first description of them which I have found is that of Stengel (1904) who noticed them in a case of splenic anæmia associated with hepatic cirrhosis. Another very accurate account was soon given by Gandy (1905) under the heading "Lésions particulières de la rate dans un cas de cirrhose biliare." In our country the macroscopic lesion is generally known simply as the "siderotic nodule," but in France it is now often referred to as the Gandy nodule, or Gandy-Gamna nodule, although Gamna's account of two typical cases was as late as 1923. It was Gamna who compared the appearances of the pigmented nodules to "flakes of tobacco leaf."

The characteristic histological features of the fully developed siderotic nodule and of the perivas hæmorrhages have been very fully investigated b among others, Gandy, McMichael, and myself. It interesting to note, however, that some writers as Sprunt (1911) and Christeller and Puskep (1924) have taken up the same problem under headings of "calcium and iron incrustation" "perivascular iron and calcium incrustation" of spleen, unrelated to any questions of splenic or splenomegaly. The fully developed nodule has central arteriole, the wall of which commonly hyaline changes, but the endothelium is hea Surrounding the arteriole is a wide zone of hyal fibrous tissue, in which several varieties of [illegible] may be demonstrated and separated by spe histological methods.

1. Long, segmented, light yellowish green masses, somewhat resembling a jointed bamboo, and often present in sheaves.

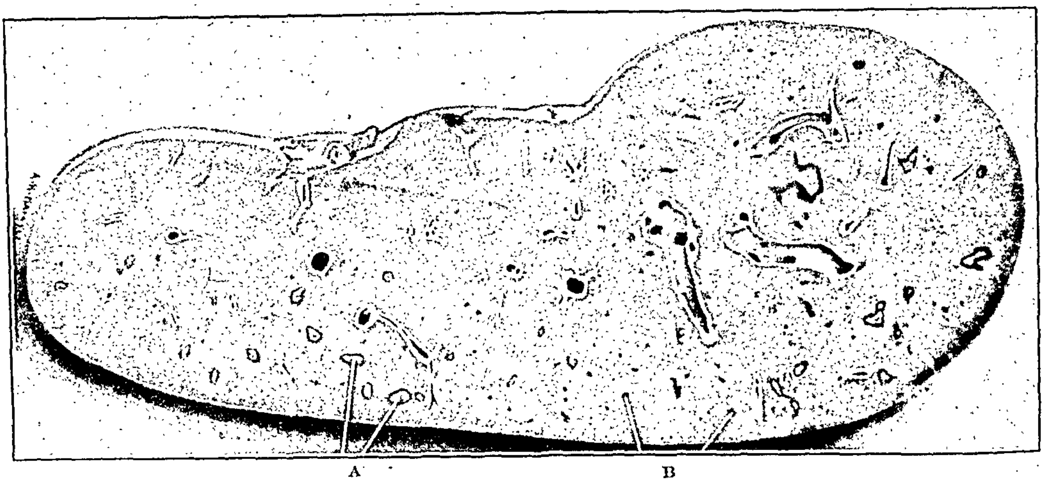
2. Golden-yellow granular pigment, either lying free in masses or contained within the fibroblasts. This pigment gives all the characteristic reactions for hæmosiderin.

3. Amorphous masses, often rounded like grains of starch, which stain blue-black with hæmotoxylin and are evidently calcium.

4. A pigment which stains dark blue with hæmotoxylin and with which the connective tissue fibres are encrusted. This pigment also gives the characteristic reactions for hæmosiderin.

The long segmented yellowish-green masses have

FIG. 14.



Spleen showing a large number of "siderotic nodules." Some very large (A) and of characteristic yellow-ochre colour; others pin-point in size (B). All are surrounded by a brownish ring of hæmorrhage.

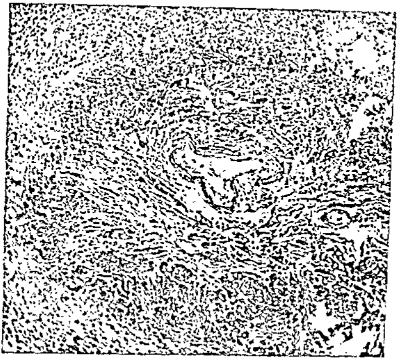
been specially investigated by Sprunt, McMichael, and others, and it now seems almost certain that they are composed of phosphate of iron. Encircling the nodule is a zone of hæmorrhage, in which the innermost layer of red cells is seen to be undergoing disintegration and organisation.

I have paid particular attention to the mode of origin of the nodules, and to their early stages of development. I am satisfied, as indeed was Gandy (1905), that the ring-like hæmorrhages surrounding an arteriole are the early stage of the lesion, and that the hæmorrhage undergoes the ordinary process of fibrosis and organisation. Both the fibrotic nodules and the perivascular hæmorrhages surround arterioles of the finest calibre, and, as has been stated, the vessel wall generally shows definite hyaline change. On attempting to trace the arterioles involved, I was at first unable to account for their apparent abrupt ending in the pulp, until I had learned the peculiar structure and functions of the ellipsoids. It is at or about the termination of a penicillar arteriole in an ellipsoid that both the fibrotic nodules and the hæmorrhages are found, although the hæmorrhage frequently runs back for some distance in the peri-arterial sheath. When the valvular function of the ellipsoid, preventing any flow back of venous blood into the arterioles, is remembered, it seems reasonable to suppose that in conditions of high portal blood pressure or of actual obstruction in the portal venous system a break or rupture is most likely to occur close to the obstructing valve.

In 1913–14, A. G. Gibson, of Oxford, first made the claim that some cases of splenomegaly are due to a streptothrix infection, and quite evidently from all that has subsequently transpired these cases are of the kind associated with siderotic nodules. In his first paper no macroscopic or microscopic descriptions of splenic histology are given, but his attention was concentrated on efforts to prove, by staining methods only, the presence of a streptothrix in the spleens. In two later papers Gibson was able to confirm, by cultural methods, the presence of a streptothrix organism in human spleens.

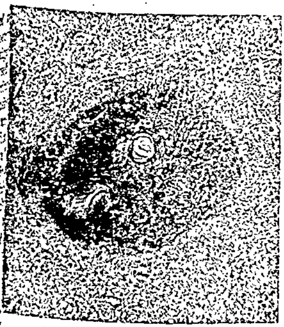
This work remained unsupported until Nanta (1926) described along with Pinoy and Gruny the presence of an aspergillus-like fungus in certain cases of splenomegaly occurring in Algeria. He claimed that the siderotic nodules are characteristic of this fungus infection, and from his cases he was able to isolate the parasite in culture. Support soon also followed from Emile-Weil, Gregoire, and Flandrin (1927) in Paris, who claimed that in 7 out of 16 cases of splenomegaly the same type of mycotic infection could be made out. In the last four years many additional papers on this mycotic hypothesis have been published, some in favour but most against the view. A full account of the matter is given by Gibson (1930) in his recent book entitled "The Mycoses of the Spleen," in which he reiterates his previous views.

FIG. 16.



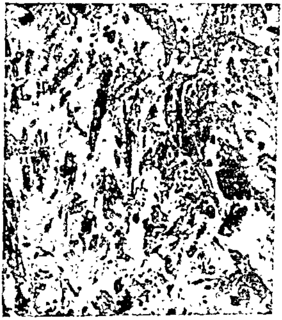
Section of a siderotic nodule (Group 1). Crystals are seen along the lower margin, just within the ring of hæmorrhage (high power).

FIG. 15.



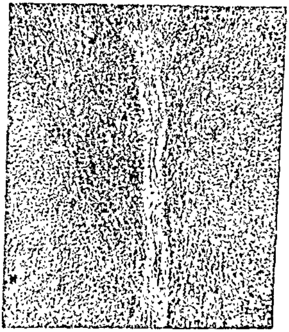
Typical siderotic nodule with central arteriole and narrow surrounding ring of hæmorrhage (low power).

FIG. 17.



Portion of a siderotic nodule, showing crystals and a few small masses of calcium (high power).

FIG. 18.



Peri-arterial hæmorrhage, without fibrosis or siderosis. From a spleen showing in addition many typical siderotic nodules (Group 1) (low power).

I have naturally been greatly interested in this question, but am convinced that all the evidence of mycotic invasion based on histological evidence and on methods of staining mycelium must be discounted, since the degenerated fibres (encrusted with iron), the branching crystals, and the rounded masses of calcium in the pigmented nodules are such obvious sources of error. It is more difficult to pass over the positive results of bacteriological cultures by different investigators, but a point strongly against the view that the organism grown stands in any causal relation to the splenomegaly is that several quite different organisms have been isolated. In my previous paper I felt compelled to leave the question of mycotic infection in this type of splenomegaly sub judice, but all that I have seen and read since then places me in complete opposition to the mycotic hypothesis. The arguments against this hypothesis have been well set forth by McMichael (1931) and I may refer you to his paper.

I have now described the histology of those types of chronic splenomegaly which fall into the old clinical categories of "splenic anæmia" or "Banti's disease." I have hitherto referred to such cases, in my own collection of spleens, simply as "splenomegalies of unknown or uncertain origin," but they now can be fitted very well into the groups of my proposed classification. Our lack of knowledge concerning their ætiology is almost complete. In Group 3 (diseases affecting the myeloid and lymphatic elements) we are faced at once with the puzzle of the leukæmias. In Group 4 (diseases affecting the reticulo-endothelial elements) we must discover much more concerning the metabolic activities of the cells of the reticulo-endothelial system in general and especially those situated in the spleen. Some of the problems for research are quite clear-cut, such as the reason for the excessive phagocytosis of red blood corpuscles in acholuric jaundice, and the explanation of the deposition of lipoid substances, either cholesterol-esters or of unknown nature, in a well-defined group of cases. As regards the splenic enlargements in which enormous proliferation of reticulo-endothelial cells is associated with giant-cell formation, we are so far without a clue. In Group 5 (diseases affecting the vascular system) we must first decide whether the mycotic hypothesis, supported by Gibson and a number of French writers, is true or false. I am opposed to this hypothesis, as I have already indicated, and believe that the solution of this problem is bound up with some other disturbances of the portal vascular system. The two characteristic lesions—phlebitis and thrombosis of the splenic or portal veins, and peri-ellipsoidal hæmorrhages with nodular siderosis—are strong evidence in favour of some form of vascular obstruction. We are still, however, very ignorant of the whole statics and dynamics of the important portal blood-supply, and although the conception of increased portal blood pressure has been mooted by French writers and by myself, there is little or no clinical or experimental evidence on this point. I hope shortly to undertake a study of the portal blood pressure under experimental conditions.

The possibility of unknown poisons, metabolic or bacterial, entering the portal circulation from the intestine must be thought of in all the groups, and particularly in those splenomegalies which are associated with hepatic cirrhosis. In the reticulo-endothelial group (Group 4) we do know that in, for example, Gaucher's disease the same lipoid substance may be deposited in the endothelial cells of both spleen and liver, and as a result the glandular cells of the liver may undergo necrosis. In the other groups, however, the cause of the hepatic damage ending in cirrhosis remains quite unknown, and at present we can only keep in mind the two possibilities of increased portal blood pressure and the entry of toxic substances from the intestine.

Tumours of the Spleen.

Simple tumours of the spleen are excessively rare. Litten describes fibromas, hæmangiomas, and lymphangiomas, but the last two might well be described as malignant. Primary malignant tumours are also rare, but when they occur are always sarcomas, and primary carcinoma of the spleen almost certainly does not exist.

The uncommon incidence even of secondary malignant growths in the spleen is well shown in a paper by Krumbhaar (1927), who summarises the results of the necropsies at the Philadelphia General Hospital. Among 17,500 necropsies 96 splenic neoplasms were found; but since the early records were unsatisfactory he confines himself especially to the last 6500 cases. In this latter group 40 splenic tumours occur, 6 being primary (4 sarcomas, 1 hæmangioma, 1 lymphangioma) and 34 secondary of all types including 21 carcinomas.

Sarcoma of the spleen is really the only important primary tumour, and both Smith and Rusk (1923), and Tasker Howard (1929) have written important papers on the subject with full bibliographies. Tasker Howard collected, up to the time of his paper, 115 cases from the literature, and added a further case of his own. Some important clinical details of his own patient are given. The spleen was large (1800 g.) and partially necrotic, but the remainder was almost entirely replaced by sarcomatous tissue. Clinically the patient closely resembled a case of pernicious anæmia, with high colour-index, leucopenia, achlorhydria, and a marked indirect van den Bergh reaction. Irregular pyrexia was present during the greater part of the illness.

The first example of sarcoma of the spleen seen by me was exhibited by Dr. Joan Ross at a meeting of the Pathological Society of Great Britain, where it attracted much attention. Since then I have had two cases in my own experience, one of them a woman of 58 (a patient of my colleague, Dr. Charles Bolton), and the other a man of 70 years. It is hoped to describe these two cases elsewhere, so I do not propose to enter into details about them now. All I need say is that there is great difficulty in determining whether these cases should be described pathologically as lymphosarcomas or endotheliomas, but this after all is a purely academic matter.

Diagnosis and Prognosis of Splenic Diseases.

It would take far too long to enter into a detailed discussion of all the points, clinical and clinico-pathological, on which an accurate clinical diagnosis of one or other type of splenic disease may be attempted. But, in actual fact, an accurate clinical diagnosis and classification is for the most part impossible at present. It will be agreed that the spleen is always enlarged when a suspicion of disease in it begins to be entertained, if we leave out the exception of thrombocytopenic purpura.

One type of splenomegaly in chronic hæmolytic (acholuric) jaundice can generally be picked out by methods now quite familiar. Spleen puncture is possible, but many of us are chary of employing it. Graham and Blacklock have, however, practised this method with success, particularly for the accurate diagnosis of Gaucher's disease, and they give a very complete and valuable account of the technique they have employed.

On the whole, however, the diagnosis during life can often only be made by the therapeutic measure of splenectomy.

Prognosis of splenic diseases.—The prognosis of most of the types of chronic splenomegaly met with in this country is, on the whole, unfavourable to prolonged life. An exception to this is chronic hæmolytic (acholuric) jaundice, but even in this disease the patient has to run the gauntlet of a number of complications such as gall-stones and biliary colic.

Cases of splenomegaly usually die from complications, and of these the most dreaded, but difficult to recognise in its early stages, is hepatic cirrhosis. I am unable to say what proportion of cases end with this complication, but obviously figures on the matter would be valuable.

Apart from hepatic cirrhosis and its well-known train of signs and symptoms, the other complications most to be feared are hæmatemesis, widespread abdominal thrombosis, and the onset of the "hæmorrhagic diathesis."

Splenectomy.

The indications for splenectomy have been already referred to indirectly in the section on diagnosis. There are only two points remaining which I wish to emphasise.

First, there are cases (such as Gaucher's disease) in which, if we knew the exact diagnosis beforehand, it would be inadvisable to remove the spleen, but on the whole the cases of splenomegaly in which removal of the organ offers the best hope of cure far outnumber the others. Secondly, splenectomy may be successful even in the most desperate and unpromising cases. I recall one patient in whom life, with good health, was prolonged for seven years, although prior to splenectomy over 100 pints of fluid had been removed from the abdomen. This patient, moreover, died of chronic interstitial nephritis and uræmia, a renal lesion being known to exist at the time of the operation. At the necropsy on this case the portal vein was found to be completely thrombosed.

Certain precautionary measures are very necessary before operation is considered. The first of these is concerned with the degree of anæmia present, and if anæmia is at all pronounced I am a confirmed believer in blood transfusion either before, during, or after operation, and sometimes even at all three times.

The second necessary precaution is one which I learned from the work of Howel Evans (1929), who brings out the great importance of blood-platelet counts in cases of splenomegaly prior to operation. Howel Evans began his observations following a paper by Rosenthal (1925), who described the results of splenectomy on 16 cases of splenic anæmia. Three patients died in the first year of widespread portal thrombosis, and three others suffered from venous thrombosis, fortunately not fatal, in different venous trunks. In the last nine cases Rosenthal carried out blood-platelet counts before and after operation, and on his results divided the nine cases into two groups.

(a) *Thrombocytopenic group*—five cases. In these patients the blood-platelet count was low before operation, rose slightly afterwards, then fell to normal. A clinical feature of all of these cases was a marked hæmorrhagic tendency.

(b) *Thrombocythæmic group*—four cases. In these the blood-platelets were normal or slightly subnormal before operation, but rose rapidly to high figures (1,000,000 or more) after splenectomy, and, moreover, the increase persisted for months or years. All of these four cases developed thrombosis; one a fatal mesenteric thrombosis, the others thrombosis of the brachial, jugular, and femoral veins respectively.

Howel Evans has confirmed these observations in a series of 19 cases, of which 9 fell into group (a), 7 into group (b), while 3 gave intermediate results.

From these observations it is obviously important to study the blood-platelet count before and after splenectomy in all cases, in reference to both prognosis and treatment. Only a lead, however, has been given, and so far we are unable to modify the conditions found; but it must be remembered that both thrombosis and a hæmorrhagic tendency are equally dangerous, and we must attempt to discover means to prevent them both.

Are there any alternatives to splenectomy? Two methods of treatment must be considered—the use of X rays in some diseases, and ligature of the main splenic artery in others.

It is difficult to discuss briefly the merits of X ray treatment of an enlarged spleen, particularly in cases in which no accurate clinical diagnosis has been made. There is, however, one group of cases in which this treatment offers the best results at present attainable—namely, the chronic leukæmias, especially of the spleno-medullary type. Our methods of treating these cases by X rays, controlled carefully by regular blood counts before and after exposure to the rays, have quite obviously improved in recent years, and I have two cases under my care at present in which the outcome, so far as prolongation of life and return to good health are concerned, can only be described as amazing. I have seen nothing like them in my past experience of leukæmia, which is considerable. Similar results must be known to most of you, but the belief that the great improvement is only for a limited time is well founded. In Hodgkin's disease temporary improvement may also ensue, but not, in my experience, so great or so prolonged as in the leukæmias. The chief danger of X rays in these cases, now that burns are avoidable, is an undue destruction of the leucocytic tissues so that marked leucopenia results and septic complications may ensue. This danger is particularly to be feared when X ray exposure of other parts of the body, such as the bones, lymphatic glands, and mediastinum has also been carried out. It must be remembered that the effects of a single exposure to X rays may be prolonged and long drawn out, so that nothing but a series of careful blood counts can avoid this error in treatment.

Ligature of the main splenic artery is a method which, with the help of my surgical colleagues, I much desire to test in suitable cases of chronic splenomegaly. So far I have no personal experiences to relate, but the operation is apparently quite safe and by no means a new suggestion. A full account of the literature is given in a recent paper by Valdoni (1929). I can think of several types of case in which this simpler operation might have been performed instead of splenectomy, and certainly this procedure should be considered seriously when dense and extensive retrosplenic adhesions greatly increase the surgical risks of removal of the spleen.

The subsequent history of patients from whom the spleen has been removed for the various types of chronic splenomegaly is of obvious interest, but my experience is not yet long enough to tell you much of importance. Most of my cases have done well, and most of them are still alive. I have alluded to the two cases in which carcinoma developed, and I have been fortunate in having no examples of thrombosis at a long interval after operation.

There is one further point to which I ought to refer. It will be remembered that, as Krumbhaar and Musser showed experimentally, removal of the normal spleen in animals is followed by a secondary anæmia, often of long standing. The same phenomenon may occur after splenectomy for a number of the splenic diseases which I have described It is not always so, and the blood count may return to normal, but in a number of patients intermittently under my observation at present the blood count remains at about two-thirds of the normal, although the patients themselves can perform all ordinary duties and feel reasonably well.

Conclusion.

In concluding these lectures I must emphasise my ignorance of the causation of the splenic diseases which I have described. The spleen still remains, in Galen's words, an organ of mystery both in its diseases and in many of its functions and metabolic activities.

The organ is not essential for life, and practically no direct gain in physiological knowledge has resulted from splenectomy in man or animals. Unlike the thyroid or pancreas in which striking clinical phenomena follow excision, there are no special facts to be noted when splenic function is arrested by excision or even by disease. It is evident that advances in our knowledge of splenic physiology must come in less direct ways.

I am convinced that, while waiting for advances in physiology, a further obstacle to progress has been a poor general knowledge of the essential structure of the organ, and I have shown how recent physiological experiments have assisted us even in the interpretation of structure as well as of function.

With accurate knowledge of structure, even when problems of function remain unsolved, it is possible to examine diseased spleens and to observe and interpret the histological changes which have taken place. In this way a *pathological classification* can be made according to the chief lesions, and this is what I have attempted to do and to describe in these lectures.

I have suggested how, from the peculiarities of some special lesion, a strong lead may be given to further study. The histological changes in Gaucher's disease, to give one example, invite us to investigate more closely the relations of the spleen to the metabolism of fats and lipoid substances.

It is only, however, when our knowledge of splenic function is increased by observation and experiment that we may expect to correlate disordered function with bodily disorders which we recognise by clinical symptoms. Then, and only then, can we attain to a *clinical classification* of splenic diseases.

I hope that after long years of inactivity and stagnation the recent physiological experiments of Barcroft, Binet, Tait, and others mark a new period of progress in the study of "The Spleen, its Structure, Functions, and Some of its Diseases."

Many friends both here and in America have helped me by sending spleens, or parts of them, and clinical histories of their patients. I wish to thank them all, and to acknowledge the special assistance I have received from my colleagues at University College Hospital.

THE SURGICAL TREATMENT OF SIMPLE ULCERS OF THE BODY OF THE STOMACH.

By A. JAMES WALTON, M.S. LOND., F.R.C.S. ENG.,
SURGEON TO THE LONDON HOSPITAL.

IN the last few years there has been a great revival in the medical methods of treatment of chronic gastric ulcers, and to-day many claim that all uncomplicated ulcers are capable of being cured by these methods. This form of treatment is by no means new. In 1902 the late Dr. F. J. Smith was strongly advocating the use of milk diet with the regular administration of alkalis, and it is remarkable how closely his technique corresponded to that advocated to-day. The majority of these cases improved and lost all their symptoms, but it was gradually realised that the apparent improvement was in a large number only the passage into one of the usual periods of remission, and that when this period had passed through its customary time the symptoms returned. So much evidence was produced that with this treatment there was still a high mortality from hæmorrhage and perforation that it was gradually abandoned and treatment by surgical measures became usual. Undoubtedly, the pendulum swung too far, and operations were performed for small ulcers in their early stages when they were still capable of being cured by medical methods. What was more serious was that the operations came to be regarded as simple procedures, and thus were often inadequately performed by those with but little experience. Gastric surgery had thus somewhat unjustly tended to fall into disrepute.

Efficacy of Medical Treatment.

There is to-day, as always, considerable difficulty in comparing the two methods of treatment—that is, in determining the indications for surgical interference.

Much has been written in favour of either method, but it is almost impossible to obtain reliable evidence from the various publications; for so often they refer to ulcers of different types in different stages of development, and I should be the first to admit that even one's own experience is fallacious, for although nearly all the cases that seek my advice have had prolonged courses of medical treatment they of necessity only represent the failures of such a method, and I have no means of determining what percentage they form of the total so treated. In the same way the surgical failures reported by physicians may and probably do represent only a very small proportion of the number that have been successfully treated. For this reason I shall make no quotation from the large number of statistics which have been published, but shall attempt to show from a consideration of my own cases (Tables I. and II.), which are in greater part medical failures, what are the indications for surgical interference. It is, however, well to remember that the late end-results of a large series of cases treated medically have never been published, whereas the percentage of cures in large series that have been operated upon for at least five years is fairly accurately known.

RELIEF OF PAIN.

As a general rule a patient with an ulcer of the body of the stomach presents a history of several years' periodic attacks of pain, often severe in nature, which arises shortly after a meal, is relieved before the next meal, and unlike that of a duodenal ulcer does not generally wake the patient at night. Examination shows, as a rule, a healthy male, perhaps with some anæmia, who has few or no physical signs beyond an area of deep tenderness localised to the site of the ulcer. A test-meal shows free HCl and a total acidity within the upper limits of normal. The stools may show occult blood, and radiography generally reveals a characteristic niche in some portion of the lesser curve or a meniscus remaining on the posterior surface after the stomach is emptied.

Without entering into a discussion of the various views as to the cause of the pain, I can say that my own experience supports the views of V. J. Kinsella, that both the pain and deep tenderness are dependent upon local tension due to an acute inflammatory change which after persisting for a certain period dies down, and the patient then enters into one of his periods of remission, during which, however, the ulcer is still present. It would be expected, therefore, that medical treatment would do much to decrease this inflammatory change, and thus to relieve the patient of his symptoms. Changes in the radiographic appearance of the meniscus must not, however, be relied upon too strongly as an indication of a cure; for, as A. E. Barclay has shown, the depth of the niche is largely dependent upon an inflammatory swelling of the mucosal margin, and as this decreases the pit or crater rapidly decreases in depth and the ulcer appears to be healing, although it is still present. My own experience has been that very severe pain, and especially pain which tends to persist and is referred to the back, is evidence of a deeply penetrating ulcer which has involved the substance of the pancreas, and thus not only is a severe and persistent pain an indication against the use of medical treatment, but such treatment often indeed fails to relieve the symptoms. A prolonged history extending over many years suggests a chronic callous ulcer with much fibrosis which is unlikely to be cured by prolonged rest and alkaline treatment, and is thus in itself an indication for surgical intervention. A very large crater as seen by examination with X rays is suggestive of similar change, but is not definite; for in some cases a thorough medical course may relieve the symptoms and lead to a rapid diminution in the size of the crater, so that even if a cure is not attained diminution of the inflammatory change may lead to much improvement, and the necessity for less severe operative measures. Definite evidence of the failure of careful treatment to relieve the symptoms, or a rapid recurrence after relief by such treatment is a positive and indeed the most common indication for surgical interference. It is true that in a certain number of cases the recurrence is due to the fact that the treatment is not followed for a sufficiently long time. Many physicians advocate a most careful dietetic and alkaline régime for many months or, indeed, for the rest of the patient's life, but the mere fact that such a course is so irksome or difficult that the patient is unable to follow it while carrying out the ordinary duties of his life's work is an indication for more radical measures. I have found within the last year that an increasing number of patients who have been relieved by a course of diet and alkalis are seeking surgical aid because they have found it impossible to maintain the irksome medical treatment, and when it is abandoned their symptoms have tended to recur. Nor is such treatment even to-day entirely free from danger. Morton, writing of a series of 139 proved chronic ulcers treated at St. Thomas's Hospital in 1929, states that 13 were verified at autopsy.

PERFORATION AND HÆMORRHAGE.

Undoubtedly the greatest dangers of a peptic ulcer are perforation and hæmorrhage. That an immediate operation should be undertaken in the event of a perforation is beyond question, but there is not so much unanimity of opinion in cases where a perforation has been operated upon and sutured without any other procedure. I have frequently laid stress upon the fact that cases treated by simple suture rarely make a complete recovery. Such a case should, therefore, always be carefully watched, and if the symptoms recur further treatment should be advocated. I have now had to operate upon 32 cases where symptoms have recurred after a simple suture for perforation, and these symptoms have not been relieved by medical treatment; but here again I have no means of determining what proportion these represent of the total number sutured. It has been, however, interesting to find that when the simple suture has been performed by my own assistant at hospital, and the case has then been watched, there has not been a single recovery from this measure. If a patient has been fortunate enough to have passed safely through the danger of a severe hæmorrhage he will rarely be willing to face the danger of a second and will seek operative treatment. Continued loss of blood while he is under medical treatment is evidence that the condition is not abating, and this is so even when the loss is very small and is only recognised as occult blood in the fæces; in fact the presence of such blood should always be regarded as an urgent danger-signal, and an operation performed without delay in order to anticipate a severe and dangerous hæmorrhage. There is still considerable difference of opinion as to the correct treatment in patients who, being evidently the subjects of chronic ulceration, are seen immediately after or during a severe hæmorrhage. Many physicians believe that the danger of operative interference is very great, and that if the patient be carefully treated by medical measures death rarely occurs. My own experience does not entirely support this view, and although there are many cases which will recover I feel that if there be any doubt, or if the hæmorrhage be repeated after a short time, an operation should certainly be performed, preferably immediately after or during a blood transfusion.

When the ulcer has led to so great an amount of fibrosis that distortion of the stomach has occurred, mechanical symptoms may arise from the distortion itself. The commonest of such changes is that of an hour-glass stomach. This only occurs in women, and generally in those who are the subjects of ptosis. It is associated with so characteristic a history that a diagnosis is rarely difficult even without radiography. In such conditions medical treatment is of no value, and an operation should be undertaken before obstruction has caused profound deterioration in the general health.

CANCER.

Beyond question the great objection to prolonged medical treatment is that it may be carried out when carcinoma of the stomach is present, and thus the one opportunity of a cure is lost. The recent fierce controversy as to the frequency of carcinomatous changes in a chronic ulcer is now abating, and it is becoming generally accepted that some 10 per cent. of chronic ulcers become carcinomatous, and that rather less than 20 per cent. of the carcinomata originate in chronic ulcers. The real danger which is so often overlooked is that cases which are carcinomatous in the beginning may be mistaken for chronic ulcer and treated by medical methods until the condition is inoperable. Even to-day, of the cases of carcinoma that come to operation, only about 33 per cent. are capable of radical treatment. The fact that one type of chronic ulcer of the lesser curve has a continuous short history of only a few months, and thus superficially resembles a carcinoma, increases this difficulty. Fortunately, a carefully taken history will nearly always give some indication that the lesion is either primarily carcinomatous or that a carcinomatous change has taken place in a chronic ulcer. The most important of such points are a short history, continuity of the symptoms, persistence of the pain from one meal to another, a gradual loss of appetite, and the failure of vomiting to give relief to the pain. If there be anything in the history to cause the merest suspicion of the presence of carcinoma, an operation should always be performed.

The indications for operative treatment are therefore:—

The presence of severe radiating pain as indicating a deep penetrating ulcer.

The failure of medical treatment to relieve the symptoms.

The presence of a very long history suggesting a fibrosed and callous ulcer.

Recurrence of symptoms shortly after an adequate course of medical treatment.

Inability of the patient, owing to the nature of his work to follow the suggested lines of treatment.

The presence of a recent or old perforation.

The onset of severe or repeated mild hæmorrhage.

Distortion and especially hour-glass deformity of the stomach from fibrosis.

The slightest suggestion of the presence of carcinoma.

Surgical Procedures.

It is often forgotten that the underlying aim of an operation upon the stomach is to bring about certain physiological and mechanical changes, and that these changes may be produced by entirely different methods; so that one surgeon by using a technique which he has perfected finds that it gives him better results than a different technique preferred by a second surgeon. Forgetfulness of this fact has often led to heated discussion as to which is the correct operation, and thus has done much to discredit surgical treatment. My advocacy of any one method must therefore in no sense be regarded as a dogmatic statement as to which is the ideal treatment, but simply an account of the method which has given the most satisfaction in my own hands.

GASTRO-ENTEROSTOMY.

It is not very many years ago that gastro-enterostomy was considered as the operation of choice for all ulcers of the body of the stomach, and there are still surgeons who prefer it to other methods and obtain satisfactory results by its use. In my own hands, and, as a study of the literature shows, in the hands of most other surgeons, it has not proved a reliable cure. It is generally stated that it cannot be depended upon to cure the patient in more than about 40 per cent. of the cases. In my own small series of 57 chronic ulcers other than perforations, there were seven in which the ulcer persisted (Table III).

TABLE III.—*Gastro-enterostomy.*

	Total.	Mortality.	Recurrence.	Carcinoma.

	57	3	7	1
Acute ulcers	17	5	—	—
Perforations	30	7	—	—
	104	15	7	1
Post G.E. for all simple ulcers	600	12	5	2

It is interesting to note that in my series of 30 cases of lesser curve perforation, where the opening was sutured and a gastro-enterostomy was performed. there has not been a single example of persistence of the ulcer. I would explain this on the assumption that the suture of the perforation acts as an autolytic stitch resection, and so destroys the ulcer. It is not in my experience due to the fact that the perforated ulcers are acute and do not require any treatment other than suture, for in my series there have been 32 cases of perforated ulcer which have persisted after simple suture as performed by other surgeons, and what is even of greater interest is that occasionally an ulcer may develop in the body of the stomach after a gastro-enterostomy has been performed for a pyloric or duodenal ulcer. In my own series there have been 14 cases where the evidence was very strong, that there was no trace of any such ulceration at the time of the gastro-enterostomy. If such a procedure, therefore, is unable to prevent the development of an ulcer it is even less likely to cure it when present. It is, however, curiously uncertain in its action. Occasionally there is found at operation a very large ulcer situated high up on the lesser curve of the stomach with acutely œdematous margins. Owing to the risk of partial gastrectomy for so extensive a lesion, often in a patient seriously debilitated by severe pain, vomiting, and hæmorrhage, it is my custom to perform a gastro-enterostomy alone, and in five such extensive cases the ulcer after this simple treatment decreased so much in size that the patient remained free from symptoms for as long as a year, after which time the ulcer was so small that a resection was a feasible and safe operation. I believe that this is a much more satisfactory form of treatment than the performance of a jejunostomy or of partial gastrectomy which will have to be so extensive that it is almost complete and is a dangerous operation in so ill a patient. In some such cases the ulcer—large as it is—has completely disappeared and no second operation has been necessary. It is cases of this type which explain the apparent cures of gastric carcinoma after a simple gastro-enterostomy.

PARTIAL GASTRECTOMY.

Undoubtedly the operation most frequently performed to-day for an ulcer of the body of the stomach is that of partial gastrectomy. It is claimed that by this method not only is the ulcer removed entirely but that the ulcer-bearing portion of the stomach is also taken away, and thus the risk of recurrence of the ulcer or of subsequent carcinoma is greatly reduced. It is to be noted that the ulcer-bearing portion is almost, if not quite, synonymous with the acid-secreting portion of the stomach, and thus by this operation the acid is reduced or completely abolished. I cannot help feeling, however, that this latter claim is based upon some confusion of thought, for ulcers of the body are not as a rule associated with a very high acid, and thus it is that gastro-jejunal ulcers following a gastro-enterostomy performed for this type of lesion are almost entirely unknown. In my own series of 59 gastro-jejunal ulcers only one occurred after an operation for a lesser curve ulcer. Moreover, a partial gastrectomy does not give an absolute immunity against a later gastro-jejunal ulcer. In my own 59 cases, four had followed a partial gastrectomy although in the one case performed by myself I had had to be content with a smaller resection than usual owing to dense perigastric adhesions. For this reason some Continental surgeons, among whom the operation is most popular, have abandoned the Polya method and returned to the Billroth I. type of operation. There is no doubt that with experience the method becomes technically easy to perform and can be carried out for relatively large ulcers high up on the lesser curve, especially if modified as in the Schoemaker and Pauchet's method. It also gives very satisfactory results, the convalescence generally being smooth and rapid, and the freedom from after-complications being very satisfactory. Although in my own hands the results have been very pleasing, I have for long been theoretically dissatisfied with it, in that so large a portion of normal stomach has so frequently to be removed. It is often necessary with a small ulcer, perhaps only half an inch in diameter but situated high up on the lesser curve, *to remove seven-eighths of the stomach.* These objections are not wholly theoretical, for it is now well recognised that pernicious anæmia is dependent upon the absence of a gastric ferment, partial gastrectomy having in several cases been followed by this form of anæmia. Morley and Roberts have shown that the Polya operation carries with it a serious liability to post-operative anæmia, 12 of the 21 cases they examined showing such a change. This liability was, however, much less with the Schoemaker method. In my own series of 388 partial gastrectomies only one has developed a serious anæmia, which Dr. J. A. Ryle informs me may turn out to be of the pernicious type, but several cases who have had profound secondary anæmia from hæmatemesis before operation have taken a very prolonged period to recover after a partial gastrectomy. The value of this method in preventing the possibility of the onset of later carcinoma has also, I believe, been exaggerated. The frequency of a carcinomatous change in an ulcer is now known to be less than was at one time believed, and as a general rule such a change will often give rise to an alteration in the symptoms sufficient to suggest the possibility of the presence of carcinoma, so that should there be the slightest suspicion of such a change either from the nature of the symptoms or from the appearances at the operation, a partial gastrectomy should be performed. That the danger of such a complication occurring late is not great is shown by the fact that in my own series of 306 cases, in which a more localised operation was alone performed, there have only been three examples of the later appearance of carcinoma (Table V.), one of which was at the pylorus and another at the cardiac orifice; only one having occurred in relation to the previous ulcer site, and in no case has carcinoma been found in one of the locally removed ulcers.

TABLE IV.—*Partial Gastrectomy.*

	cautery ..	34	1	2	—
Hour-glass ..	..	28	2	1	—
		306	12	4	3

In some cases of large adherent ulcers relatively high up, but neither so large nor so adherent as those for which a gastro-enterostomy is alone performed, a partial gastrectomy is the only possible operation. There is no doubt that in such cases this operation is easier to perform than a local resection, as it gives much better access to the ulcer and allows of a more satisfactory approach in order to free it from the pancreas. The actual method of performing the partial gastrectomy is, I believe, of but little importance provided the surgeon has practised the method he advocates. My own preference is for the original Polya method with the afferent loop attached to the lesser curve and the opening being some four to five inches from the duodeno-jejunal flexure, but the antecolic method either with the Balfour or Moynihan loop is quite satisfactory, and I frequently use it if the mesocolon is short. For a gastro-jejunal ulcer, where the opening in the jejunum is already made and is generally close to the flexure, I have no hesitation in performing the posterior method with the afferent loop going to the greater curve. The procedures of Schoemaker and Pauchet, which give very similar end-appearances, are performed by many, as they remove more of the lesser and less of the greater curve, but here, as elsewhere, I believe that surgeons will obtain the best results by the use of procedures in which they have been most practised.

LOCAL RESECTION AND GASTRO-ENTEROSTOMY.

The practical drawbacks of simple gastro-enterostomy and the theoretical objections of partial gastrectomy would seem to be best overcome by local destruction of the ulcer combined with gastro-enterostomy. There appears, however, to be a very wide diversity of opinion as to the value of this operation. On the Continent a partial gastrectomy has always been the method of choice, and in this country many others are adopting the same method, probably because of its wide applicability. In the United States local excision with gastro-enterostomy have been widely practised in the Mayo Institute, either by the method of simple excision or of late more largely by Balfour's method of cautery excision. From the theoretical consideration it has the great benefit that it removes the diseased portion and that only; that it has a low mortality and it gives a high percentage of successful results. By completely excising the ulcerated area the possibility of perforation or hæmorrhage from the eroded vessels is overcome, together with the danger of hour-glass constriction or deforming adhesions from contraction of the ulcerated area. The objection that it does not remove the whole of the acid-secreting area is of but little importance with an ulcer of the body of the stomach, for in these cases there is not the same high acidity as with a pyloric or duodenal ulcer. My own preference is to remove the ulcer widely with the knife and scissors by means of a wedge with its base on the lesser curve and to suture the resulting opening. If the wedge be made with a sufficiently wide base an early hour-glass constriction can actually be overcome. For small ulcers high up on the posterior surface this method is not easy to accomplish, and therefore Balfour's technique of destruction with a cautery is preferred, although I have always felt that this means is not quite so satisfactory in that the edges which are left to unite are formed of more injured tissues. When the resulting opening left by either method has been closed a gastro-enterostomy must be performed, for without it recurrence is common and is indeed to be expected, for the conditions which give rise to the ulceration of the normal surface are more likely, if uncorrected, to do so on a recent suture line. My own custom in this type of case is to make the gastro-enterostomy on the posterior surface parallel with and close to the greater curvature, half being proximal and half distal to the line of suture. Since this opening is often relatively high up in the stomach, it would seem preferable to temporarily occlude the pylorus, and it is my invariable rule to do this with a running silk suture. Observation of cases in my follow-up department has shown that after it the pylorus usually opens again in from six to eight weeks.

The chief objection which has been raised to this operation is that there is a risk of recurrence. It is, however, very slight. In my own series of 244 cases there has only been one recurrence. In my own hands I have found this operation the method of choice and invariably performed it where possible, chiefly on the grounds that it is associated with a low mortality and a higher percentage of complete recovery than with any other form of gastric operation. I reserve partial gastrectomy for large adherent ulcers, for those in which there is the slightest suggestion of carcinoma, and for cases of hour-glass constriction with a very narrow isthmus.

Results of Operation.

The great benefit of posterior gastro-enterostomy lies in its extreme safety. In my own series of 690 cases of posterior gastro-enterostomy the total mortality was under 2 per cent. (Table III.), while in a later series of 290 cases in this group there was no mortality, and in the small group of 41 cases of ulcer of the body of the stomach in which this step was alone performed there were also no deaths. When an anterior anastomosis has to be performed owing to the very large size and acuteness of the ulcer on the posterior wall, the mortality is naturally higher, my own 13 cases showing three deaths. Although the safety of the operation is an important factor in choosing the operative treatment for patients with very large ulcers who are seriously ill from prolonged pain and vomiting or severe hæmorrhage, it is largely offset by the risk of persistence of the ulcer, for, as I have already pointed out, this occurred in seven of the 57 of my own cases which had to be treated by this method.

The statistical comparison of the results of partial gastrectomy and local resection with gastro-enterostomy is difficult, for it will vary so greatly with the preference of the individual surgeon for the one or other method, and the choice of case for which he performs the individual operation. Thus the surgeon who uses partial gastrectomy as a routine operation for all cases will have a much lower mortality than one who performs it relatively seldom, and only for extensive ulcers in poor subject (Table IV.). There is no doubt, however, that partial gastrectomy is an operation of considerable magnitude even when carried out as a routine measure, and thus performed in easy cases with small non-adherent ulcers. Thus Louria, in analysing the cases of von Haberer, who is a strong supporter of the routine use of partial gastrectomy, found that the total mortality was 8·4 per cent., although with the use of Billroth's first method it fell to 6 per cent., but that the mortality can be even further reduced by wide experience is shown by Finsterer's series of 407 cases with a mortality of 4·4 per cent., which was again reduced in the last three years to 1·8 per cent. In the hands of surgeons without this wide experience and skill the mortality is more likely to approximate to 15-20 per cent. Recurrence after operation is very rare. When performed for pyloric or duodenal ulcers it does not give a complete immunity to the later occurrence of gastro-jejunal ulcer, and in fact some surgeons have abandoned the use of Polya's operation for these conditions owing to its danger. When performed for ulcers of the body, this complication is practically non-existent, and true recurrence is almost unknown. In my own series of 246 cases there was no single example (Table IV.). The chief objection lies in the theoretical one of the removal of so large a portion of the normal stomach and the possibility of a later occurrence of a severe pernicious anæmia, the frequency of which is very difficult to estimate.

Local resection, on the other hand, appears to be a much less severe procedure. In my series of 244 ulcers of the body treated by this method there were nine deaths, a mortality of 3·6 per cent., while in 28 hour-glass stomachs there were two deaths, a total of 272 cases with 11 deaths (Table V.). There were, however, in this series two recurrences, one after excision of a simple ulcer and one after excision for an hour-glass stomach. The end-results are good with either method. In the series of cases watched for at least five years which I have previously published, local resection with gastro-enterostomy gave 88 per cent. known cures, a figure which rose to 92·1 per cent. if the untraced cases were omitted. My own view, therefore, is that wherever possible either a local resection with a gastro-enterostomy or a partial gastrectomy should be the operation of choice. In my own hands local resection has given the lower mortality and the highest percentage of late cures and is free from the objection that it removes a large portion of the normal stomach.

TREATMENT OF TETANUS BY INTRATHECAL INJECTION OF *CARBOLIC ACID*.*

BY SYNN SUVANSA, M.R.C.S. ENG.,
SENIOR SURGEON TO THE KING CHULALONGKORN MEMORIAL HOSPITAL, BANGKOK.

THE recognised treatment of tetanus with daily intrathecal injections of 12,000–20,000 U.S.A. units of concentrated antitetanic serum is uncertain and often disappointing in its result. Bacelli's carbolic treatment (10 c.cm. of 1 per cent. solution subcutaneously every two hours) has not been successful in other hands. In 1923 I began treating a few cases of tetanus with intramuscular injections of 2 c.cm. of 5 per cent. carbolic acid twice a day. The result was far from satisfactory, but success in one mild case put the idea into my mind that carbolic acid could counteract the tetanus toxin, and if brought in close contact with it might overcome it altogether.

It is known that carbolic acid has the effect of destroying tetanus toxin in vitro. Kitasato injected toxin plus carbolic into guinea-pigs and they did not get tetanus, while the controls treated with toxin alone showed tetanic symptoms and died. There is no reason why carbolic should not be administered intrathecally, if a solution could be found that would not produce too intense a reaction or inflammation.

Fresh leucocytes were obtained by lumbar puncture from a case of tetanus which had been treated 24 hours previously with intrathecal serum (which always causes a mild aseptic meningitis). Equal amounts of the cerebro-spinal fluid and different strengths of carbolic solution in physiological saline (0·75 per cent.) were mixed and incubated at 37° C. for an hour, and then a drop was examined under the microscope. The 1 in 400 carbolic solution was found to be the strongest that did not affect the leucocytes—except that they appeared to be slightly clearer than before treatment. This solution has a specific gravity of 1006, equal to that of the cerebro-spinal fluid. It was prepared for injection by adding 400 c.cm. of physiological saline (0·75) to 1 c.cm. of liquefied carbolic acid. It was boiled before use.

Narration of Fourteen Cases.

CASE 1.—A boy of 14 was admitted at 8 P.M. on July 18th, 1924, with signs of tetanus of 24 hours' duration. He had had a nail-prick on the sole some 12 days before. General clonic spasms occurred every two or three minutes with acute pain. His teeth could open to only one fingers-breadth, his back was arched, and his legs rigid. Our serum was out of stock, and I was loth to try carbolic. However, I summoned up courage, and gave 20 c.cm. of 1 in 400 carbolic in normal saline through a lumbar puncture, after withdrawal of the same amount of cerebro-spinal fluid. The foot of the bed was raised 12 inches for two hours.

The next morning, to my surprise, the boy was walking about the ward when I went my round. The nurse reported that an hour after the injection he had had a fit and a pink rash had come out all over the body. On examination he appeared well, without rigidity anywhere, and he could open his mouth widely. The skin showed a pink but faded rash with fine scales. His pulse, temperature, and respiration were normal. Four days later he had anasarca and fever. Blood casts and albumin were found in the urine. He was therefore transferred to the medical side as a case of acute nephritis due to carbolic. He recovered in a few days.

The success in this case was so dramatic and complete that it should have been a stimulus for me to go on with the treatment, but I could not help being afraid of some unforeseen calamities, the possibilities being injury to the nerve roots and cells, aseptic meningitis which might leave adhesions in the theca, and late results, such as impairment of brain functions and weakness and paralysis due to impairment of the central nervous system. Above all these, acute nephritis might not end so happily as in the first case.

I therefore turned back to antitetanic serum, but now with larger doses intrathecally and in some cases intravenously as well. After five years of despair I gave up the serum treatment and stared ruefully at the 1 in 400 solution of carbolic once more. In the next case a smaller dose was tried and a second dose had to be given.

CASE 2.—A schoolboy of 19 had had a fall on the football field. On admission, on March 5th, 1929, it was found that he had a number of small ulcers on both knees; the jaws and back were stiff, and painful spasms occurred at hourly intervals; he also complained of headache. He was given 15 c.cm. of 1 in 400 carbolic in normal saline intrathecally, but did not appear any better. A second injection of 15 c.cm. was given the next day. Spasms then decreased and disappeared in 48 hours. Recovery was slow. The patient seemed dazed for four or five days after the second injection. The urine was found normal throughout the illness. The cerebro-spinal fluid withdrawn by the second lumbar puncture was turbid and contained numerous leucocytes.

(For nine months after this I had not a single case of tetanus, though my two colleagues had four or five cases between them.)

CASE 3.—A girl of 12 was admitted on Jan. 26th, 1930, with severe symptoms: clenched teeth, almost continuous spasms, and failing heart, within 24 hours of the onset. She was given 20 c.cm. of carbolic solution intrathecally under chloroform, but little hope for recovery was entertained, and she died 12 hours later.

Failure of the treatment in this case put much doubt in my mind as to its utility, and this accounts for the irregularity of treatment in the next case. I thought it was possible that the solution entered a vein in Case 1 and that the recovery might have been due to an intravenous instead of an intrathecal injection. As a result of my bewildered thought, 1 in 400 carbolic was tried intravenously in the next case.

---

* Read before the Eighth Congress of the Far Eastern Association of Tropical Medicine, Bangkok, Siam, Dec. 9th to 12th, 1930.

CASE 4.—A Hindu, 22 years of age, was admitted on March 21st, 1930, with four days' spasm after wounds on knee and elbow. On examination he could open his teeth one fingers-breadth, the recti were hard, and opisthotonos was present. Painful spasms occurred every five to ten minutes. I gave him 10 c.cm. of 1 in 400 carbolic in normal saline intravenously at 3 P.M., and the same amount again at 10 P.M. The next morning 15 c.cm. were again given intravenously. As he appeared worse, 9000 units of antitetanic serum were given intravenously. On the third and fourth days he seemed recovering, but he became worse on the fifth day, when the same amount of serum was again given intravenously. This was repeated on the sixth day. On the seventh day the patient appeared very ill, and 48 c.cm. of carbolic solution were given intrathecally; this was immediately followed by a rise of temperature and headache. On the eighth day the spasms disappeared, but tonic opisthotonos remained for four days afterwards. I believe the opisthotonos was produced by irritation of motor nerve roots by carbolic. He recovered fully and was discharged from hospital 15 days after admission.

CASE 5.—A girl of 15 was admitted on March 27th, 1930, with severe symptoms: clenched teeth, continuous spasms, and failing heart. The first clonic spasm had been felt 24 hours earlier. No hope of recovery was entertained, but 20 c.cm. of carbolic solution were administered intrathecally under chloroform. The patient died ten or 12 hours later.

CASE 6.—A patient of 17 was admitted on April 18th, 1930, with partial lockjaw and general spasm of five days' duration after a nail-prick on one palm which had healed. On examination, he could separate his teeth one and a half fingers-breadth; his back was rigid and he had clonic spasms at uncertain intervals. His pulse-rate was 80–90, and his temperature 38° C. He was able to pass urine naturally.

The officer on duty gave 4500 units of antitetanic serum subcutaneously and 3 c.cm. of 2 per cent. carbolic intramuscularly. On April 19th I saw the patient at 10 A.M., when clonic spasms were occurring every five to ten minutes and he could separate his teeth only one fingers-breadth. At 11 A.M. 40 c.cm. of 1 in 400 carbolic in normal saline were given intrathecally under chloroform, after withdrawal of the same amount of cerebro-spinal fluid under its own pressure. The foot of the bed was raised for two hours. The patient perspired freely, complained of heat, and was restless. The temperature rose to 38·5° C. and the pulse-rate to 100–104. He calmed down at the end of four or five hours and fell asleep. On April 20th he appeared better. He could open his mouth more, and clonic spasms were absent, though his back was slightly rigid. On the 22nd he was well. He walked about with a rigid back and neck with a certain amount of torticollis. On the 23rd the temperature was 39° C. and the pulse-rate 90–100. A scarlet rash appeared on the front of both thighs, the shins, the anterior surface of the forearms, and the lower abdomen. Examination of the urine showed granular and blood casts, red blood cells, and transitional epithelial cells—a picture of acute nephritis and pyelitis. He was put on carbohydrate diet, mainly of wet-boiled rice. On the 24th he appeared better though his back was still rigid. On the 27th the temperature, respiration, and pulse-rate came down to normal. The back was still rigid. On the 29th the urine was normal. On the 30th he was well and discharged from hospital.

He had been able to take food and pass urine and fæces naturally throughout the illness.

CASE 7.—A boy of 6 was admitted on June 2nd, 1930, for bladder stone, and operated upon on June 7th, when a stone was removed through a suprapubic incision. The notes were as follows:—

June 13th: Catheter removed from urethra. Urine contained pus and overflowed through suprapubic opening. 15th: Slight jerks of limbs noticed by father of patient in the evening but not told to the nurse on duty. 16th: Back arched, abdominal wall rigid. Distension and constipation present. Mouth opened fully. No contraction of facial muscles. Tetanus was diagnosed on the ground of the presence of tonic and clonic contractions of the back and legs. At 2.30 P.M., 8 c.cm. of 1 in 400 carbolic in normal saline were injected intrathecally under chloroform. At this moment the patient was observed to have jaundice and a pulse-rate of 112, but no rise of temperature. On June 17th the jaws were closed; the teeth opened two fingers-breadth at most. The spasms were worse. Twelve c.cm. of carbolic solution were administered intrathecally. On the 18th the patient was worse and 20 c.cm. of carbolic solution were given intrathecally. The spasms were less in frequency and severity. The legs were flaccid, the back was slightly rigid, and the teeth clenched; risus sardonicus was present but tonic in character, and the eyelids were closed tightly. The temperature was 39·5° C., and pulse-rate 120–130, and the respiration-rate 36–40. He was given 200 c.cm. of 5 per cent. glucose subcutaneously on account of acidosis. On the 20th he appeared better in the morning. Clonic spasms were slight and appeared at long intervals, but the teeth were always clenched. Coma supervened in the afternoon and death at 10 P.M. The morning urine showed pus cells but no blood or casts.

At autopsy on June 21st congestion of the brain was found but no visible change in the pons or medulla. The right kidney was congested, with scattered spots of pus. The left kidney was small and showed pyonephrosis. Microscopic sections of the medulla and pons showed no changes.

CASE 8.—A boy, 11 years of age, was admitted on July 8th, 1930, with lockjaw, stiffness in the back and abdomen, and painful spasms. He was able to open his mouth to one and a half fingers-breadth. The temperature was 36° C., the pulse-rate 74, and the respiration-rate 24. He had a wound on the shin 2 by 3 cm. due to broken wood (June 25th). The day before admission he felt stiff in the lower chest and came to the out-patient department. He was advised to stay in hospital but did not come again until the next afternoon. He was given 20 c.cm. of 1 in 400 carbolic in normal saline intrathecally under chloroform and the wound was scraped. The foot of the bed was raised for an hour and a half. Syrup of chloral, one drachm four times a day, was ordered. A few hours after the injection the temperature was 30° C., the pulse-rate 120, and the respiration-rate 30.

On July 9th, at 8.30 A.M. there were no spasms. The temperature was 38° C., the pulse-rate 120, and the respiration-rate 30. His back and legs were rigid, and he was thirsty and restless. His jaws were closed. The urine contained acetone but no albumin, sugar, or cells. At 4 P.M. the back and legs were less rigid and the jaws opened one fingers-breadth. There were no spasms and the patient felt well and said he had no more pain. On July 10th the back was arched. The jaws opened one fingers-dreadth. There were no spasms, and the limbs were relaxed. The eyelids were slightly contracted. The temperature was 36·7° C., the pulse-rate 100, and the respiration-rate 28.

The jaws and legs remained stiff and arched for many days, though the general condition showed that the patient had recovered. Stiffness disappeared slowly and not without anxiety. Electrical massage was given for 10 days, after which recovery was complete. The patient was allowed to run about but was kept in hospital for observation for three weeks. There is no doubt that the stiffness was due to irritation of motor nerve roots by the carbolic. Frequent examinations of the urine did not show any inflammation of the kidneys, and carbolic was not detected when the liquor ferri perchloridi test was employed.

CASE 9, a chauffeur of 25 was admitted on July 14th, 1930, having had a cut from a table-knife 10 days before. The wound had healed, but six days before had reopened when he was washing his car. On July 13th he had a very painful contraction of the arm. On the 14th I was called to see him at 9 P.M. He was having an attack of painful spasm in the limbs and trunk, which had begun an hour earlier. His right forearm was swollen, his wrist was flexed, and the flexor muscles of the forearm stood up hard. There was a small suppurating wound on the outer side of the wrist. The jaws were not stiff. He was shaking with violent pain. I administered an injection of morphia at once, which gave immediate relief. The general spasm disappeared but the right forearm remained contracted and painful. There was some stiffness in the left arm. The patient was taken to hospital, and at 10 P.M. 30 c.cm. of 1 in 400 carbolic were given intrathecally through a lumbar puncture without chloroform, for he could bend his back. The extrathecal portion of the path of the trocar was preliminarily anæsthetised with 1 c.cm. of 0·5 per cent. novocain.

On July 15th the patient complained of a slight headache during the night but slept fairly well. The erector spinæ stood up slightly but no stiffness was complained of. At 4 P.M. he had another painful attack of generalised spasm for an hour, which passed off after a drachm of syrup of chloral. It was lucky for the patient that I was out, otherwise I might have given him a second dose of carbolic, which would have been unnecessary and perhaps harmful. On July 16th the patient felt well and had slept well. The wrist was still flexed but without pain. Silver colloid was injected intramuscularly on account of the cellulitis of the forearm. On the 17th he felt well. The wrist was no longer flexed. The forearm was still swollen but the inflammation had receded. The wound had nearly healed. On the 18th he was discharged with a swollen but painless forearm. He reported himself well a few days later.

CASE 10.—On Sept. 13th, 1930, a patient of 20 slipped when jumping off a tramcar and his right foot was crushed by one of the wheels. He was taken to the Central Hospital, where saline and 1500 units of antitetanic serum were given subcutaneously. Amputation of the foot was advised, but the patient refused. On Sept. 17th he was admitted into the King Chulalongkorn Memorial Hospital with a foul wound and a gangrenous limb. He had been treated at home with a poultice of Chinese herbs, which generally contains many kinds of pathogenic micro-organisms. On Sept. 18th Syme's amputation was performed under stovaine. On Sept. 21st I was asked to see the patient, who had developed lockjaw. The sister of the ward had noticed the morning before that he had some difficulty in opening his mouth. When I saw him (9 A.M.) his jaws were stiff and would open only a little. The muscles of the abdomen, chest, back, and neck were contracted tonically, but there were no clonic spasms, nor had there been any. The patient said that he had no pain but felt stiff all over. His pulse was regular and strong, with a rate of 100 per minute, but on auscultation of the heart the first sound at the apex was strong, and the second sound hardly audible. Breathing was short and laboured. The wound was gangrenous, with acute cellulitis spreading to below the knee. The temperature was 37·2° C.

I here made a mistake in thinking that it was an early case, as he had no clonic spasms. It was probable that the manifestation of the disease was modified by the previous injection of serum. I put him under chloroform and made a lumbar puncture, keeping in mind the possibility of acute meningitis after an intrathecal injection (in this case, of stovaine). The cerebro-spinal fluid, however, was clear, and I injected 35 c.cm. of 1 in 400 carbolic in normal saline into the theca. At 8·30 P.M. the neck and back were less rigid, the teeth were clenched, clonic spasms were absent, the respiration was short and laboured, and the heart was failing with the second sound inaudible. He died at 4·30 A.M.

CASE 11.—A man, aged 57, was admitted on Oct. 10th, 1930, for painful spasms of the back. He had had a prick from a splinter on his finger on Sept. 20th, followed by suppuration of the whole finger, leaving a sinus. Local spasm of the finger and rigidity of the back had been present for four days. Clonic painful spasms of the back began about 5 or 6 P.M. on Oct. 9th.

On examination on Oct. 11th the back muscles were rigid, and the jaws stiff, opening to two fingers-breadth at the most. At 2.30 P.M. he was given 40 c.cm. of 1 in 400 carbolic intrathecally under chloroform, after withdrawal of 15 c.cm. of cerebro-spinal fluid. He slept for two hours afterwards. At 8 P.M. he had a severe rigor, and his temperature was 41° C., his pulse-rate 124, and his respiration-rate 30. He had headache, but his back was no longer stiff, and the jaws could open widely. On Oct. 12th he had occasional spasms from 2 A.M. to 9.30 A.M. The temperature had come down almost to normal. He could open his mouth widely and move his lower jaw freely. On Oct. 13th he was free from spasms, but somewhat drowsy, and was startled when touched. His temperature was 38° C., and his pulse-rate and respiration good. On the 14th they were all normal, and there were no spasms. The back was slightly rigid and the patient complained of stiffness all over this body. The jaws opened and moved with ease.

On Oct. 20th round scarlet macules, 1 mm. in diameter, appeared on the exposed parts of the body. On the 24th the back was no longer rigid. On the 26th the feet were œdematous. On the 28th the rash had disappeared, but there was œdema of both legs. On Nov. 4th there was œdema of both legs and ascites, and frequent painful micturition. On the 5th the patient left hospital, in spite of persuasion to remain.

Examination of the urine at frequent intervals from the day of admission showed chronic infection of the bladder. On rectal examination the prostate was not found enlarged. A stricture of the urethra was present, admitting only a small-sized catheter and that with pain. No definite impairment of the heart was detected.

CASE 12.—A married woman, aged 26, admitted for painful contraction of both arms and hands on Oct. 13th, 1930, was found to have a suppurating wound above the right heel which she had received the day before. The right calf muscle was contracted but without pain. Both arms were flexed at the elbows and wrists. The hands were closed tightly. The spasms of the upper extremities were continuous and most painful, but somewhat relieved by 0·015 g. of morphine given at once subcutaneously. Forty-five minutes after admission 35 c.cm. of 1 in 400 carbolic was given intrathecally. The temperature rose to 40° C. within four hours and then gradually declined to normal the next morning. Headache and vomiting followed the injection and passed off on the third day. The spasm of the upper extremities and the rigidity of the calf muscle disappeared a few hours after the administration of carbolic.

On Oct. 20th pink, discrete, round macules, 1–2 mm. in diameter, slightly itchy, appeared on the trunk and thighs. The patient again vomited. The temperature was 37·2° C., the pulse and respiration normal. Headache was present. Ophthalmic examination revealed no papillœdema. The rash reached its height on the third day, when the whole body, including the face, was covered with a scarlatiniform rash. On the seventh day it faded, leaving a general discoloration of the skin with slight scales on the face. The general condition of the patient was good, though she complained of a feverish and nauseated feeling and vomited occasionally. On the ninth day the whole body was covered with scales and flat vesicles. These were dressed with baby talcum. On the eleventh day all the vesicles had burst, leaving dry scales which were easily washed off. The face had suffered as much as the body. The patient was discharged well on Nov. 10th. The urine was normal throughout the illness.

CASE 13 (*Tetanus neonatorum*).—A male baby, 8 days old, was admitted on Nov. 17th, 1930, because the mother found the day before admission that it sucked with difficulty, bit the nipple, and seemed stiff in its jaws. The temperature was 38° C. The jaws opened slightly, and the back was stiff and the abdominal wall rigid and protuberant with distension of the bowels. Frequent motions containing mucus, blood, and living *Amœba hystolytica* were passed. The umbilicus was septic. He was given 1/12th of a grain of emetine intramuscularly. On Nov. 18th he passed two motions, both hard and small in volume. The jaws opened slightly, but he would not suck, and feeding was suspended for 24 hours. The back was arched and the legs and abdominal wall were rigid. General clonic spasm was present at intervals, but the baby slept between spasms. At 4 P.M. he was given carbolic 1 in 400, 3 c.cm. intrathecally under chloroform. (Some difficulty was encountered in performing the lumbar puncture.) At 12 P.M. the temperature was 40° C. with profuse perspiration. On Nov. 19th at 8 A.M. the temperature was 37·2° C., and there was dyspnœa. The baby would not suck, but was able to swallow when fed artificially. At 12 P.M. the temperature was 40° C., and at 4 P.M. it was 38°. Clonic spasms occurred at intervals, but were less in severity. He slept between spasms and his jaws opened more widely. The motions were good. The back was rigid and the legs stiff.

Scarlet macules, 1 mm. in diameter, appeared on the back of the hands and lower half of the forearms, where the skin appeared paler than elsewhere. The lips were dry, and the tongue clean. On Nov. 21st he appeared thin, but the skin was not shrunken, and there were no spasms. The back and legs were slightly rigid. He sucked his mother's breasts. The rash faded, and on the 23rd had disappeared. There were no spasms or rigidity of the back or legs, but he was constipated. He was discharged from hospital.

CASE 14.—A married woman, aged 60, was admitted on Dec. 3rd, 1930, with lockjaw and stiff back after a nail prick on the left sole 20 days before. The wound had healed. The back muscles were contracted so that a hand passed easily between the patient's loin and the bed. The left erector spinæ was more rigid than the right. Her mouth could open, but with difficulty. Risus sardonicus was present. She could not take solid food, and swallowed liquids with some pain in the back of the throat. There were slight spasm at long intervals. One drachm of syrup of chloral thrice daily was ordered. The patient seemed better in the afternoon and was able to swallow food. 10 c.cm. of antitetanic serum was given subcutaneously (to conform to the patient's wish and allay her anxiety). On Dec. 4th she was able to swallow. Spasms were more frequent—twice in an hour and on handling—and the back was stiff, and the jaws stiffer than before. She was given 30 c.cm. of 1 in 400 carbolic solution intrathecally under chloroform at 10.10 A.M. after withdrawal of 30 c.cm. of fluid. At 3.45 P.M. she was restless and hot; her head ached, and her temperature was 38·5° C. She was given one Veramon tablet (grs. 7) every three hours until the headache was relieved. On Dec. 5th the morning temperature was 37·7° C. and the pulse-rate 100. She was sleepy but her headache had gone. The back was stiff, the mouth opened widely, risus sardonicus was present, and she was startled when touched. At 9.30 P.M. clonic spasms had disappeared, and pulse and temperature were normal. On the 9th she slept well. The tongue was red and raw. On the 10th the temperature, pulse, and respiration were normal, and the patient felt well. The loin touched the bed but was still stiff. The calves and backs of the thighs were slightly stiff. The ankles were ventriflexed and the toes flexed. On the 13th she was well, and able to sit up. The left soleus muscle was slightly rigid. On the 14th she was discharged from hospital.

Urine examination was made daily and found normal.

I visited the patient at her home two weeks later and found her well and happy and able to walk upstairs unaided, though the calf muscles and erectores spinæ were still slightly stiff.

Summary.

Dosage.—30-40 c.cm. in adults; 12-20 c.cm. in children of about 12, adjusted according to the severity of individual cases. The doses in this series of 14 cases were too high, except in Case 2.

SEQUELÆ.

1. Rigidity of the back muscles is often present, due to irritation of the motor nerve roots, from the first to the seventh day of the injection. The decrease or disappearance of lockjaw is an indication of amelioration, though it is possible that carbolic may cause lockjaw through irritation of the fifth cranial nerve, when the seventh nerve will be simultaneously stimulated, as shown in Case 8 by slight tonic contraction of the facial and orbicularis oculi muscles—a tonic risus sardonicus.

2. A rash, varying in character and intensity, appears between the first and the seventh days and lasts from 4 to 14 days. It abates without treatment and should cause no anxiety. It may be due to overdose, but is probably produced by the elimination of carbolic by way of the skin.

3. Acute nephritis was present in Cases 1, 6, and 11, no doubt due to elimination of carbolic through the kidneys. This treatment should therefore not be given to patients with chronic renal disease, especially old people who have some impairment of the kidneys. However, Case 14, 60 years of age, got well without this complication.

There were no late complications of the nervous system. The older cases, 2, 5, 8, 9, were traced to their homes in November, 1930. The school-boy (Case 2) had passed his intermediate school examination. The Hindu (Case 5) was busy collecting grass for his cows and going his morning rounds in his cart with milk-bottles. The boy of 11 years in Case 8 had become an errand-boy. The chauffeur (Case 9) was driving his master prince to and from the barracks every day.

The advantages of carbolic over serum are: (1) it is more certain in action; (2) one injection suffices; (3) the cost is almost nil.

The only disadvantage is the danger in chronic kidney disease.

Conclusion.

Though the number of cases treated is as yet small, I venture to form an opinion that carbolic acid given intrathecally is a specific remedy against tetanus. Out of 14 cases treated four died, but these were severe cases, having reached the final stage of cardiac and respiratory failure, except Case 7 which, I think, died from uræmia due to the already infected kidneys rather than from tetanus. There seems to be little doubt that the ten patients that recovered owed their lives to the carbolic treatment, for they were not of the mild variety that might recover spontaneously. Any amount of serum which had been given inadvertently was not sufficient to effect a cure. Besides, in no case had it been given intrathecally. The intrathecal carbolic treatment has been given without selection to all cases of tetanus admitted into the King Chulalongkorn Memorial Hospital, since Jan. 26th, 1930 (Case 3), up to the present time (end of 1930), with the exception of two moribund cases of tetanus neonatorum. The recovery in Case 13 (tetanus neonatorum) was remarkable.

TREATMENT OF INTESTINAL OBSTRUCTION.

By Gavin Miller, M.Sc., M.D. McGill,

DEMONSTRATOR IN MCGILL UNIVERSITY AND ASSOCIATE SURGEON TO THE ROYAL VICTORIA HOSPITAL, MONTREAL.

It has been suggested that operation for the relief of small-bowel obstruction should be delayed until dehydration has been overcome, but it is necessary to review very carefully all the information available before making such a serious change. It is generally recognised that the number of hours elapsing between the onset of symptoms and the relief of small-bowel obstruction is directly proportional to the mortality percentage. Thus there will be a mortality-rate of about 30 per cent. among patients who have had symptoms of obstruction for 30 hours. While this is a rough and somewhat inaccurate basis for prognosis, a review of published mortality statistics shows that it is sufficiently correct for practical purposes. If each hour's delay increases the risk of death by 1 per cent. it is evident that operation must not be delayed on any account unless the new therapeutic procedure can guarantee a lowered mortality in spite of the delay.

As a result of the exhaustive study of small-bowel obstruction which has been carried on, mostly in America, during the past 15 years, it is now clearly recognised that such obstructions fall into two great groups: (1) simple obstruction without impairment of the blood-supply, and (2) strangulated obstruction with impairment of the blood-supply.

Most studies of small-bowel obstruction have been concerned only with the former group, and death has been definitely shown to be due in these cases to dehydration. In the strangulated type the vitality of the bowel wall is rapidly impaired, gangrene results, and death occurs through toxæmia or through perforation and peritonitis—as a rule, before there are very marked changes in the levels of the blood-chlorides, carbon dioxide combining power and total non-protein nitrogen, and before dehydration can assume a fatal proportion.

Dehydration in Simple Obstruction.

In simple obstruction, as carried out experimentally, a different picture is seen. Here the few circulatory changes in the bowel wall do not lead to the rapid onset of gangrene. Toxæmia due to these factors plays a much less important rôle. The persistent loss of gastro-intestinal secretion so deprives the body of its normal ionic content, chiefly derived from sodium chloride, that water cannot be retained in the body and death ensues owing to dehydration.

Normally, several thousand cubic centimetres of gastro-intestinal secretions, rich in sodium and chloride, are poured into the stomach and upper part of the small bowel every 24 hours. These fluids play their part in the digestion of food materials and are reabsorbed in the lower part of the bowel. As fluid in the stomach and bowel is outside the body proper it is lost to the body until it is reabsorbed. By the constant secretion and reabsorption of this great volume of fluid and salt, the normal fluid metabolism of the body is maintained. The amount of water imbibed only replaces that lost through perspiration, respiration, and excretions.

When the small bowel is obstructed this endless chain of secretion and reabsorption is broken. The secretion continues to be poured out, but it cannot pass beyond the obstruction to be reabsorbed. The bowel responds to the blockage with hyperperistalsis. The fluid is forced against the obstruction and a reverse current is formed, which carries the fluid backwards and finally into the stomach, which fills up and eventually overflows. This causes the regurgitant type of vomiting so usual in the later stages of obstruction, consisting of foul-smelling greenish or yellowish material. As these secretions collect and stagnate, aerobic and anaerobic bacteria rapidly grow, fermentation occurs, and so gas collects, increasing the distension. It is this distension by gas and fluid which makes X ray diagnosis so valuable in these cases. If a patient suspected of having intestinal obstruction is X rayed in the erect position or lying on the side, and the plate shows a distended small bowel with fluid levels, a diagnosis of intestinal obstruction can be made. The first vomiting which occurs in intestinal obstruction is reflex and empties the stomach. After this the vomitus consists of gastro-intestinal secretions rich in sodium chloride. As reabsorption of this sodium chloride is prevented, the sum total of this salt in the body progressively diminishes. Any reserve stores which may exist in the skin are soon exhausted.

It is generally accepted that the total fluid in the body is maintained by its total ionic content which, in the case of blood-plasma and interstitial fluid, consists practically wholly of ionised sodium chloride. With the loss of sodium chloride by vomiting the ability of the body to maintain its fluid is likewise lost and dehydration rapidly ensues. It is often supposed that the progressive fall of plasma chloride, so typical of intestinal obstruction, is the result of this dehydration and shows the degree of dehydration present. This is not strictly accurate. The chloride is lost, as hydrochloric acid, in the stomach secretion. This chloride radical is replaced by CO_2 radical in the blood-plasma. There is consequently a marked increase in the carbon dioxide combining power in the plasma, giving a severe alkalosis. The total ionic content of the plasma, however, is not necessarily changed. It is thus evident that both acid and base radicals must be lost from the blood-plasma before the total ionic content falls, and it is unable to retain its normal amount of fluid.

Gamble and Ross[1] suggested that dehydration is due to the loss of sodium. Sodium determinations on the blood-plasma show a slight but progressive diminution in these cases. The percentage of sodium falls, however, because the total ionic content has been increased in other directions. The total non-protein nitrogen and urea nitrogen increase greatly, and this increase may be, to some extent, ionised, thus increasing the total ionic content. If no free hydrochloric acid were lost in the stomach secretion and waste products did not accumulate in the blood, it would be quite possible to have a very marked degree of dehydration with no change in sodium and chloride blood-plasma percentage determinations. If, however, the total sodium chloride in the plasma of the body could be estimated, a very marked decrease would be shown. As I have demonstrated elsewhere,[2] the total ionic content of intracellular fluid is made up largely of potassium and phosphoric ions, which are not lost in the gastro-intestinal secretion, and thus the intracellular fluid is not disturbed in dehydration to any great degree. Dehydration affects mainly the blood-plasma and the interstitial fluid. That this dehydration is the cause of death in simple small-bowel obstruction has been definitely shown by many investigators—Hartwell and Hognet,[3] Haden and Orr,[4] Gamble and McIver,[5] Armour, Mitchell, and Stewart.[6] Animals with complete duodenal obstruction can be kept alive for six weeks or more provided that *the lost sodium chloride can be restored and starvation prevented.*

Simultaneous Treatment of Dehydration and Obstruction.

As death in simple obstruction is thus definitely caused by dehydration, it is easy to see how the suggestion has arisen that, before the patient is exposed to a serious operation, steps should be taken to overcome dehydration by the intravenous injection of sodium chloride solution. This suggestion ought to be worded differently. By all means give sodium chloride solution, either isotonic or hypertonic, but this procedure should not delay the operation by one minute. It has been shown that dehydration is the cause of death only in simple obstruction. This work has only been carried out experimentally on dogs. The great majority of cases of small-bowel obstruction found at operation are of the strangulated variety. This applies to all those cases caused by herniæ, volvulus, twisted Meckel's diverticulæ, and, as a rule, those arising from adhesions. Furthermore, except in cases where strangulated herniæ can be recognised, it is quite impossible to differentiate between the simple and the strangulated varieties before operation. It is therefore imperative to treat for the more serious possibility—namely, strangulated obstruction. Death in those cases occurs early, before any great degree of dehydration has occurred, and is due to toxæmia. Only early operation will save them.

When discussing the clinical application of experimental findings, consideration must also be given to the important question of whether the results of simple obstruction in dogs are exactly similar, in all the physiological and pathological effects, to those in man. I have found less distension and less marked changes in the bowel walls after obstruction in dogs than is usually present at operation on clinical cases. At operation the human bowel is often greatly distended, very dark purple in colour from prolonged congestion, and very thin. It has been shown that great distension impairs the circulation in the bowel wall by obstructing the venous return. If this be so, it follows that even in simple obstruction in man the factor of toxæmia due to impaired blood-supply of the bowel wall cannot altogether be eliminated. Personally, I do not believe that human beings could be kept alive for a month solely by means of the intravenous injection of salt solution, though dogs can.

A danger which must be recognised in the operative release of a mechanical obstruction is that, with the relief of distension, the venous return is permitted. After several hours of venous stasis there must be a great collection of histamine-like end-products from metabolism and from damaged bowel which are suddenly returned into the circulation. This event must accentuate any symptoms of shock which are already present. I believe this to be the cause of death in those cases of late obstruction which die a few hours after operative interference, although the operation has been relatively simple.

It seems, therefore, self-evident that to delay operation until dehydration can be overcome by means of intravenous saline therapy, checked by observation of the blood chemistry values, would be very unwise. It could only be of use in a very small percentage of cases of simple small-bowel obstruction, and these cases cannot be differentiated from the strangulated variety before operation. The rule of immediate laparotomy for intestinal obstruction must be adhered to, and it must be constantly borne in mind that the mortality in these cases is directly proportional to the number of hours occurring between onset of symptoms and relief of obstruction. In cases where the diagnosis is in doubt, the surgeon should never spend time in "masterly inactivity" or in observation of the further progress. A simple antero-posterior X ray plate will confirm the diagnosis in ten minutes. The patient should proceed directly from the X ray room to the operating room, where 1000 c.cm. of normal sodium chloride solution can be injected intravenously after the anæsthetic has started, while the patient is being prepared for the operation. The injection can, of course, be continued during the operation. If desired, 15 g. of sodium chloride may be added to the normal saline solution to hasten the return of blood chlorides to normal. Such a procedure will reduce the unfortunately large and, I believe, unnecessary mortality which occurs in so many hospitals from small-bowel intestinal obstruction.

CLINICAL AND LABORATORY NOTES

BLOOD-PLATELETS IN PERNICIOUS ANÆMIA.

By S. C. Dyke, D.M. Oxf., M.R.C.P. Lond.,
CONSULTING PATHOLOGIST TO THE ROYAL HOSPITAL, WOLVERHAMPTON;
AND
W. Stewart, M.B. Glasg.,
ASSISTANT PATHOLOGIST TO THE HOSPITAL.

Observations upon the blood-platelets in pernicious anæmia are scanty and to some extent contradictory. As the result of the study of the blood in cases under treatment with liver one of us (S. C. D.) gained the impression that these elements of the blood were scanty during the relapse phase but tended to increase in numbers with improvement of the blood picture. This impression was placed upon record[1] together with the statement that the platelets may in cases of pernicious anæmia be so low as 150,000 per c.mm. This statement was not based upon careful and systematic observation, which since then has shown that during the relapse phase the platelets occur in far fewer numbers than then stated, and, furthermore, that they actually do increase to normal under liver therapy.

Case Histories.

Case 1.—Female, aged 36. Admitted Oct. 15th, 1930, with history of weakness and lassitude extending over two years; more recently tingling, numbness, and loss of power in legs, anorexia, and loss of weight. Occasional attacks of diarrhœa. On admission a pale, asthenic, and rather wasted subject, mentally very depressed; tendon reflexes present and normal in legs and arms, plantar reflex flexor; considerable disturbance of sensation in legs and to a less extent in arms; almost complete loss of power in right leg and movement of left leg very much impaired.

A fractional test-meal taken shortly after admission showed complete absence of free hydrochloric acid; this examination was repeated two weeks after the commencement of treatment having been immediately preceded by the injection of half a milligramme of histamine; free HCl remained absent. The blood-picture at the commencement of treatment was: hæmoglobin (Hb.), 38 per cent; red cells, 1,510,000 per c.mm.; white cells, 3400; colour-index, 1·26; volume-index, 1·5. The percentages of white cells were: polymorphs, 57; lymphocytes, 41; monocytes, 2. No eosinophils or basophils were seen. There was some anisocytosis and poikilocytosis of red cells, with many nucleated red cells. The mean diameter of red cells (halo method) was 8·3μ. The van den Bergh reaction was direct negative; indirect positive, and the bilirubin 14 mg. per litre.

Treatment was carried out with a commercial liver extract and whole liver on alternate days; in addition dilute HCl to the extent of 20 minims four times daily was given, before meals. The first observation on the platelets was made on Oct. 28th, five days from the commencement of liver treatment. They were found to number 91,000 per c.mm. The blood at this time showed the height of the reticulocyte crisis, the reticulocytes forming 11·6 per cent. of the red cells, a total of 211,120 per c.mm. Four days later the platelets had risen to 293,000 per c.mm. Thereafter their numbers fluctuated considerably but never again fell so low as on the first examination. The behaviour of platelets, red cells, and reticulocytes was as follows:—

	Red cells (in thousands).	Reticulocytes. Total and per cent.	Platelets.
Oct. 28th	1,820	211,120 (5·0)	91,000
„ 31st	1,820	—	293,720
Nov. 4th	2,010	274,230 (4·6)	118,590
„ 11th	2,970	None seen.	187,110
„ 18th	3,490	„ „	320,000

Case 2.—Female, aged 55. History of anorexia and constipation with pain in lumbar region for past seven years. Loss of weight last two years, vomiting last two weeks. Admitted to surgical ward as case of cholecystitis. Jaundiced, anæmic. The blood-picture on March 13th was Hb., 38 per cent.; red cells, 1,370,000 per c.mm.; white cells, 10,000 per c.mm.; and colour-index, 1·42. The percentages of white cells were polymorphs, 39; lymphocytes, 55; and monocytes, 6; no eosinophils or basophils were seen. There was considerable anisocytosis of red cells and the mean diameter of red cells was 8·5μ.

Fractional test-meal showed complete absence of free HCl from all specimens. The progress of the case was as follows:—

	Red cells (in thousands).	Reticulocytes. Total and per cent.	Platelets.
March 13th	1,370	41,000 (3·0)	124,600
„ 20th	1,920	48,000 (2·5)	132,400
„ 25th	2,410	16,000 (0·7)	175,930
	Discharged from hospital.		
Sept. 15th	4,250	Absent.	243,256

Case 3.—Female, aged 63. History of weakness and shortness of breath for three months; numbness and weakness of legs for past month. On admission skin lemon-yellow in colour; spleen palpable, no tendon reflexes obtained in any limb. Plantar reflex flexor.

The blood-picture on Feb. 4th, 1930, at the commencement of treatment was: Hb., 34 per cent; red cells, 1,260,000 per c.mm.; white cells, 2100; colour-index, 1·35; reticulocytes, 1·3 per cent. of red cells; and platelets, 22,800 per c.mm. The percentages of white cells were: polymorphs, 47; lymphocytes, 45; monocytes, 5; and eosinophils, 3. No basophils were seen. There was marked anisocytosis and poikilocytosis of red cells and the van den Bergh reaction was negative direct, indirect positive, and the bilirubin 45 mg. per litre. A fractional test-meal showed complete absence of free HCl.

The patient was treated for two weeks on a German preparation of dried stomach upon which she made no progress whatever. At the end of this time the red cells remained at their original level, there had been no increase in the reticulocytes, and the platelets had fallen to 43,000 per c.mm. On Feb. 19th the patient was put on Ventriculin (Parke Davis), 10 teaspoonfuls daily. The subsequent behaviour of the red cells, reticulocytes, and platelets was as follows:—

CASE 4.—Male, aged 67. History of weakness, breathlessness, and increasing pallor for three months; nausea but no vomiting, tingling, and numbness of fingers. On admission on Sept. 9th, 1930, he was strange in manner; the liver was palpable two fingers' breadths below the costal margin, the spleen just palpable. The blood-picture was: Hb., 14 per cent.; red cells, 660,000 per c.mm.; white cells, 3700; colour-index, 1·08; and volume-index, 1·06. The percentages of white cells were: polymorphs, 67; lymphocytes, 32; and monocytes, 1. No eosinophils or basophils were seen. There was slight anisocytosis of red cells. The mean diameter of red cells was 9 μ (approx.). The van den Bergh reaction was delayed positive direct and the bilirubin 45 mg. per litre.

Treatment was initiated with 2 oz. of a commercial liver preparation daily, together with dilute HCl by mouth. The behaviour of the red cells, reticulocytes, and platelets was as follows:—

	Red cells (in thousands).	Reticulocytes. Total and per cent.	Platelets.

,, 15th	3,090	,, ,,	174,610

CASE 5.—Female, aged 61. Admitted July 10th, 1930. One year ago begun to feel ill and weak. In January, 1930, she had taken to her bed and had been there ever since. For some months past vomiting had been frequent; there had been epigastric pain made worse by taking food and the skin had been somewhat jaundiced. The condition had been diagnosed as carcinoma of the stomach. On admission the patient appeared pale and jaundiced; spleen not palpable, pain on pressure in epigastrium; tongue smooth and glossy. There were no very definite signs of disturbance of the central nervous system; some œdema of the feet. Treatment was commenced by commercial liver extract two ounces daily together with HCl. The blood-picture at commencement of treatment was: Hb., 30; red cells, 870,000 per c.mm.; white cells, 4400; and colour-index, 1·73. The percentages of white cells were: polymorphs, 42; lymphocytes, 46; monocytes, 7; eosinophils, 3; and basophils, 2. There was slight poikilocytosis and anisocytosis of red cells. The mean diameter of red cells was 9 μ (approx.) The van den Bergh reaction was negative direct, positive indirect, and the bilirubin 34 mg. per litre.

	Red cells (in thousands).	Reticulocytes. Total and per cent.	Platelets.
July 11th	870	60,900 (7·0)	17,400
Transfusion 12 oz. citrated blood.			
,, 14th	1,150	112,700 (9·8)	34,500
,, 17th	1,540	236,400 (16·0)	67,700
,, 23rd	2,300	151,800 (6·6)	533,600
,, 29th	2,800	25,300 (0·9)	293,600

,, 12th	3,520	None seen.	207,680
,, 19th	3,740	,, ,,	250,580
Sept. 29th	5,860	Not examined.	Not examined.

On two occasions between July 19th and 22nd the patient complained of severe epigastric pain, coming on suddenly and lasting for several hours. The second attack was of considerable severity; the onset was sudden and the patient became very collapsed and short of breath; the pulse became feeble and irregular and for some hours the condition gave rise to considerable anxiety. There was no rise of temperature.

At the time the nature of the attacks was not diagnosed; the dyspnœa and collapse were consistent with a lesser degree of pulmonary embolism, and in view of the very high platelet count found on July 23rd, two days after the second attack, it seems in the highest degree probable that both these attacks were due to embolism following upon intravascular clotting due to the thrombocytosis. Several cases both of thrombosis and of pulmonary embolism following upon liver treatment in pernicious anæmia have been placed upon record, and one of us (S. C. D.) has elsewhere hazarded the suggestion that these accidents may be due to an increase in the circulating platelets. Howel Evans[2] has shown that an increase of the platelets above the numbers usually met with may be the precipitating cause of thrombosis and consequently of embolism; the present case would seem to indicate that for this reason such thrombotic accidents may occur in the course of the liver treatment of pernicious anæmia; probably they would best be prevented by not confining the patients too strictly to bed.

CASE 6.—Male, aged 57. Health good until two years ago when he accidentally fractured two ribs on left side. Since that time pain in left side and increasing weakness, for past month tingling and numbness of fingers and toes. On admission pale, not wasted, spleen not palpable, no abnormal physical signs. The blood-picture at commencement of treatment was: Hb., 37 per cent.; red cells, 1,540,000 per c.mm.; white cells, 8100; colour-index, 1·2; and volume-index, 1·6. There was no poikilocytosis or anisocytosis; nucleated red cells were present in fair numbers. The mean diameter of red cells was 8·5 μ (approx.). The van den Bergh reaction was direct negative; indirect very faintly positive. A fractional test-meal showed complete absence of free HCl. The Wassermann reaction was strongly positive.

	Red cells (in thousands).	Reticulocytes. Total and per cent.	Platelets.
Nov. 24th	1,540	13,800 (0·9)	224,840
Dec. 3rd	1,840	58,800 (3·2)	200,000
,, 16th	2,830	None seen.	445,000

No antisyphilitic treatment was adopted while the patient was under observation, it being particularly desired to ascertain whether or not a satisfactory response to liver could be brought about in the presence of a positive Wassermann reaction without such treatment. This proved to be the case.

Discussion.

The above observations serve to demonstrate that in pernicious anæmia in the stage of relapse the platelets are diminished to far below the normal number per c.mm. The lowest count recorded in the series was just over 17,000 per c.mm. in Case 5. It is noteworthy that in spite of this very considerable diminution there was neither in this nor in any other case any tendency towards hæmorrhagic manifestations. Taken into consideration along with the constant leucopenia in the relapse phase of pernicious anæmia these observations offer further proof of the fact which with growing knowledge of the condition becomes increasingly clear that the anæmia of pernicious anæmia is not due simply to destruction of red cells, but is an expression of a morbid state affecting the whole of the hæmatopoietic system.

It further demonstrates the fact that the effect of treatment by liver or desiccated stomach is not confined to the red cell-producing portion of the hæmatopoietic system, but is active on the whole of it. The exact manner in which this effect is brought about is unknown, but the result is to restore to normal the whole, not a part only of the system.

It is a noteworthy fact that the patient showing the lowest number of platelets at the commencement of treatment also showed the most rapid and striking rise. So great was the rise in this case that, as pointed out above, there is reason to believe that it led to a certain degree of intravascular clotting of the blood, with two attacks of pulmonary embolism, fortunately both very mild.

---

[2] Evans, W. Howel: Jour. Path. and Bact., 1928, xxxi., 815.

SUMMARY.

1. In the relapse phase of pernicious anæmia the blood-platelets fall to a low level. 2. With improvement of the blood-picture due to treatment by liver or dried stomach the platelets rapidly rise in numbers. 3. This rise in the platelets may give rise to thrombotic accidents.

THE BLOOD-PLATELETS AFTER FRACTURE.

By J. Forbes Galloway, M.D. Liverp.,

FORMERLY HOLT FELLOW IN PATHOLOGY IN THE UNIVERSITY OF LIVERPOOL.

It has been pointed out by Howel Evans and his co-workers[1] that thrombosis and embolism follow parturition and surgical operations at a time which corresponds to the maximum of the rise in the number of blood-platelets that succeeds these conditions. Thrombosis and embolism tend especially to follow operations which involve the anterior abdominal wall, with resulting venous stasis due to diminution of muscular activity and of diaphragmatic respiration. An increase in the number of circulating blood-platelets and venous stasis seem therefore to be important factors in the onset of thrombosis.

FIG. 1.

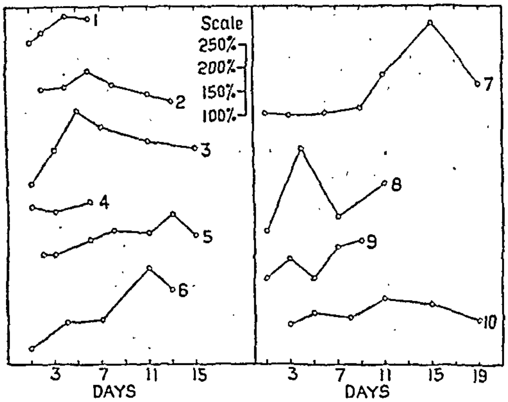

Chart showing variation in platelet counts following fracture in ten cases.

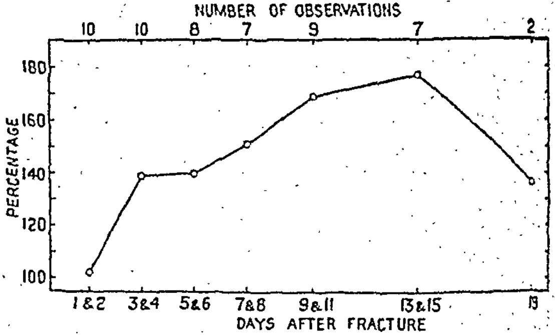
Fracture of the femur is a condition which has a high incidence of pulmonary embolism as a complication (Lister[2]). Its treatment differs from that of most other fractures in that it involves marked immobilisation of the patient, with resulting venous stasis. This suggests that another factor in post-operative thrombosis—an increase in the blood-platelets—may also occur after fracture.

Accordingly, the blood-platelets were studied in a group of ten cases of fracture, which were all simple but not in any other way selected. They consisted of :—

Case.	Age.	Fractured—
1 ..	14	Rib.
2 ..	67	Radius.
3 ..	26	Humerus, radius and ulna.
4 ..	40	Patella.
5 ..	23	Left transverse processes of 3rd and 4th lumbar vertebræ.
6 ..	77	Neck of femur.
7 ..	72	„ „
8 ..	42	Right temporal and occipital bones.
9 ..	35	Tibia and fibula.
10 ..	59	Right tibia and fibula, and left tibia.

It was obviously impossible to do platelet counts before the fractures occurred, so the first count done after fracture in each case was used as a basis for comparison and called 100 per cent., subsequent counts being expressed as a percentage of this figure. In seven cases the first count was done within 24 hours of fracture, in two cases within 48 hours, and in the remaining cases within 72 hours. The results of individual cases are shown in Fig. 1, and a composite result of all the cases has been constructed in Fig. 2.

FIG. 2.



Composite chart of the ten cases showing percentage increase of platelets following fracture.

From these figures it is seen that a definite increase in the blood-platelets occurs after fracture, reaching a maximum between the fourth and the fifteenth days.

This increase resembles so closely those which occur after parturition and surgical operations that it suggests a cause common to them all. These different conditions are all associated with damage to tissues and extravasation of blood, followed by its ultimate absorption, and in this absorption of damaged tissues lies a possible common cause.

JACKSONIAN EPILEPSY TREATED WITH TUBERCULIN.

By Walter Broadbent, M.D. Camb., F.R.C.P.,

SENIOR PHYSICIAN TO THE ROYAL SUSSEX COUNTY HOSPITAL, BRIGHTON.

In October, 1928, I was asked by Dr. W. G. Orchard to see a girl of 13, who was having right-sided fits, affecting the face and hand, several times a day, followed by a short period of unconsciousness, and affection of speech for half an hour after. She had complained of headaches since July, the fits had begun early in September, at first with a week's interval, but becoming rapidly more frequent. She was a pale, delicate-looking child. There was no apparent weakness of the right arm. Reflexes were exaggerated. The left optic disc was pinker than normal, and the vein large. The right disc was paler, but the vein looked large also. There were no abnormal physical signs in the chest or abdomen.

---

[1] Dawbarn, R. Y., Earlam, F., and Evans, W. Howel: Jour. Path. and Bact., 1928, xxxi., 833.

[2] Lister, W. A.: THE LANCET, 1927, i., 111.

Pirquet's cutaneous test was found to be positive. I concluded that the epilepsy was probably due to a tuberculous tumour in the cortex, and recommended a weekly injection of tuberculin B.E., beginning with 1/100,000 very slowly increased; also a resting life in the open air as much as possible, and cod-liver oil and malt and a two-minim capsule of creosote three times a day. In January, 1929, the fits were much less severe and less frequent. In April, 1929, the attacks were shorter, and were not followed by aphasia, and they only occurred about once a week. Headache had gone. The child had grown four inches and looked very well. The tuberculin injections were continued. A guaiacol carbonate and potassium iodide mixture was given instead of the creosote, which was causing some indigestion.

I have just seen her again. She is a well-grown, healthy looking girl, and there have been no fits for many months. The only sign left is that, if she gets overtired, she may have a twitching of the right face and tongue. In the past I have successfully treated with tuberculin two other cases of Jacksonian epilepsy, in which the Pirquet reaction was positive, but they were not so severe as this one.

MEDICAL SOCIETIES

ROYAL SOCIETY OF MEDICINE.

SECTION OF SURGERY.

At a meeting of this section held on May 6th, Mr. C. H. **Fagge** being in the chair, a discussion on the surgical treatment of

Simple Ulcers of the Body of the Stomach

was opened by Mr. A. J. **Walton**. Of late, said Mr. Walton, there had been a revival in the medical treatment of chronic gastric ulcer, advocated by Dr. F. J. Smith in 1902, and of the claim that all uncomplicated ulcers were capable of being cured by alkalis. It was no doubt true that the majority of these cases lost their symptoms, but the apparent improvement was often no more than the usual period of remission. This treatment had been gradually abandoned owing to the high mortality from hæmorrhage and perforation. The pendulum however had swung too far, operation being performed for ulcers still capable of cure by simpler methods. It should however be remembered that the late end-results of a large series of cases treated medically had never been published, whereas the percentage of cures in operated cases was fairly accurately known. Briefly, the indications for operative treatment were: (1) severe radiating pain as indicating a deep penetrating ulcer; (2) failure of medical treatment to relieve symptoms; (3) history so long as to suggest a fibrous and callous ulcer; (4) recurrence of symptoms after an adequate course of medical treatment; (5) patient's inability to follow suggested lines of treatment; (6) recent or old perforation; (7) severe or repeated mild hæmorrhage; (8) distortion and especially hour-glass deformity; (9) any suggestion of carcinoma. It was becoming generally accepted, he said, that some 10 per cent. of chronic ulcers became carcinomatous. The underlying aim of operation was to bring about certain physiological and mechanical changes which might be produced by entirely different methods. Not long ago gastro-enterostomy was the operation of choice. Its mortality was under 2 per cent., but the safety was largely offset by the risk of persistence of the ulcer. Partial gastrectomy even in expert hands still had considerable mortality and some surgeons had abandoned Polya's operation owing to its danger. Local resection was a much less severe procedure, the mortality in his own cases being 3·6 per cent. The end-results were good with either method. In a series of cases watched for at least five years local resection with gastro-enterostomy had given 88 per cent. of known cures. His own practice was to perform, wherever possible, a local resection with gastro-enterostomy or a partial gastrectomy. Local resection had given him the lower mortality and the higher percentage of late cures while it was free from the objection that it removed a large portion of the normal stomach.

Mr. G. **Gordon-Taylor** said that a survey of the immense literature on this subject had not rendered his outlook any clearer. Apart from the figures of the New Lodge Clinic and the investigations of David Smith, of Glasgow, there was little statistical evidence of an unassailable nature as to the real and permanent value of the medical treatment of gastric ulcer. A year or two ago the "alkaline treatment of ulcer" raised much hope, and many cases were dealt with on non-surgical lines for longer periods than would otherwise have been the case. Some of these, he added, had reached the surgeon at an inoperable stage. Good work had been done by Rendle Short in recording certain statistical end-results from various medical clinics. There was no doubt that medical treatment could cure ulcer of the stomach, and no ulcer should be submitted to surgery which had not received skilled medical treatment, provided that malignancy could be excluded. Short found that 75 per cent. of cases of gastric ulcer could, by medicine, be made symptom-free, but that only 40 per cent. of the patients would remain well, while 15–20 per cent. would be dead in ten years.

NO ONE OPERATION FOR THIS CONDITION.

There was, Mr. Gordon-Taylor declared, no one operation for simple ulcer of the body of the stomach. No surgeon of experience and judgment would press one type of operation for a pathological condition to the entire exclusion of all other methods. The methods of cure should be those which could be safely borne by the patient; but with carcinoma there was justification of heroic surgery to bring about cure. The great skill and experience of Hans Finsterer enabled him to resect almost any ulcer, whatever its position or condition, or at whatever age the patient had arrived; and he had the remarkably low mortality of 2·7 per cent. Mr. Walton employed wedge-resection and gastro-jejunostomy, and in some cases which others not possessing his special skill would not so approach. For more than ten years he had himself been an ardent gastrectomist, but increasing surgical knowledge had shown him that the surgeon must be an eclectic. It was personal experience, not second-hand information, upon which judgment should be based. In the case of a small ulcer on or near the lesser curvature of the stomach no experienced surgeon would perform gastrectomy; the operation of choice was an ulcer-excision or cautery combined with gastro-jejunostomy, gastro-duodenostomy, or some form of pyloroplasty. In addition a drainage or a physiological operation should be done. The value of gastro-enterostomy was greatly enhanced by local treatment of the ulcer itself. From mere gastro-jejunostomy Mr. H. J. Paterson had obtained a mortality-rate as low as 1 per cent.; that surgeon had declared that probably there was no operation which had added more to the sum of human happiness than gastro-enterostomy. For large ulcers of the body of the stomach, especially when adherent to the pancreas, liver, or diaphragm, partial gastrectomy was, Mr. Gordon-Taylor considered, the method of election.

On the relationship of ulcer to cancer opinion had changed during recent years. Hurst and Stewart had stated that 16 per cent. of cancers of the stomach started in an ulcer, and that of 180 chronic ulcers excised, over 6 per cent. had cancer in the margin. The menace of malignancy was therefore a real one. After partial gastrectomy for large ulcers of the body of the stomach, 88 per cent. of his cases had recovered normal working efficiency; no serious or metabolic upset had occurred. In 44 per cent. of the cases a certain degree of anæmia was present, not giving rise to symptoms; it was not pernicious anæmia. An increase in uric acid and blood cholesterol were the only abnormalities found on a chemical examination of the blood. In the intermediate type of case in men he advocated gastrectomy, as the end-results could scarcely be surpassed, and the mortality was low. But in women the end-results were not so good, because of the greater liability to anæmia, not of the Addisonian type. For the ulcer of intermediate size in women he practised where possible either a sleeve resection or a Billroth No. 1 operation if the duodenum was sufficiently wide to ensure a safe anastomosis. Of the extensive "letter-box" or inaccessible ulcer he had had little experience, and less success, with jejunostomy. In the male he was tempted to do gastrectomy, as the results were excellent. Finsterer considered that no ulcer was irremovable. For women having this kind of ulcer it was well to try cholecysto-gastrostomy, or even jejunostomy. In hour-glass contraction the surgical treatment should be governed by the presence or absence of pyloric stenosis, the fixity of the causative ulcer, the site of the stricture, and the sex of the patient. He preferred gastro-gastrostomy for these, with or without some form of pyloroplasty. For hæmorrhage from an ulcer, the treatment was that of the ulcer itself. For perforation he did suture and drainage only. Several times he had successfully dealt with a combination of perforation and hæmorrhage by an immediate gastrectomy. Gastric and duodenal ulcer might exist in the same patient.

DISCUSSION.

Mr. CECIL A. JOLL said that many surgeons used the term "pyloric ulcer" implying that it was a commonly occurring lesion, yet it was very rare for an ulcer to begin within an inch of the gastric aspect of the pylorus. In 916 operations for gastric and duodenal ulcer, there were only four chronic gastric ulcers which could be classed as pyloric. But he had performed duodeno-pylorectomy in 43 per cent. diagnosed as due to pyloric ulceration, in which the original site of the ulcer was the posterior surface of the duodenum. An ulcer undergoing malignant changes was not likely, he thought, to be successfully extirpated by the wedge operation. In the case of large fixed penetrating ulcers, repeated blood transfusion and the use of intravenous glucose, saline infusions and lavage of the stomach enabled partial gastrectomy to be performed without undue risks. Jejunostomy he had found disappointing.

Mr. JOHN MORLEY said it could be considered agreed among surgeons that no single operative method was suitable for all the kinds and situations of ulcer found in the stomach; there should be a readiness to postpone decision as to the kind of operation to be done until the area had actually been exposed. To obtain the best results some form of excision of the ulcer was essential. He was not driven to that view by a fear of malignant change, for malignancy occurred too seldom in a chronic gastric ulcer to influence the choice of procedure. It was often difficult, if not impossible, to determine by inspection whether an ulcer was simple or malignant. Most surgeons had a leaning to a particular operation, and his own preference was for the Schoemacher modification of Billroth No. 1 gastrectomy; this the speaker had performed 119 times for ulcer in the body of the stomach in 119 cases, with three deaths. As to the remote results of this operation, it did not—as the Polya operation did—abolish gastric digestion, nor cause the secondary anæmia which was so frequent. He urged a bolder attitude towards the surgical treatment of bleeding ulcer. Many taught that hæmatemesis should first be dealt with on medical lines, operation being deferred until strength had been restored. But he had seen patients die from a recurrence of hæmorrhage when surgery might have saved them. Until a bleeding ulcer had been excised, there was no certain means of controlling the hæmorrhage.

Mr. CECIL ROWNTREE regarded the discussion as a milestone in gastric surgery. Gastrectomy for ulcer was still on its trial, although four years ago it was coming to be regarded as the only treatment for all kinds of ulcer. The fear that ulcer might degenerate into malignancy was unfounded; he never allowed the possibility to influence his choice of treatment. Gastrectomy was admittedly the correct treatment for the penetrating ulcer which had involved the pancreas. Surgeons, it must be remembered, only treated gastric ulcer after medical treatment had had its chance. For tiny ulcers on the lesser curvature he thought the best procedure was partial gastrectomy, as it seemed to keep the patient free of symptoms afterwards. After gastrectomy he did not think a patient could be regarded, from the life-assurance standpoint, as a first-class life. He had himself adventured in the direction of jejunostomy mainly because he had been much impressed with the relief it gave in cases of inoperable cancer of the stomach. He started doing jejunostomy for ulcers which appeared to be inoperable in ordinary hands, and he had also done it for gastro-jejunal ulcer, and in one or two of the latter the patients were now well. He was now performing jejunostomy for ulcers no larger than a threepenny piece. He had long felt that hæmatemesis should be treated on the same lines as bleeding following gastro-enterostomy—namely, by immediate transfusion and a free opening of the abdomen to discover the bleeding point.

Prof. C. A. PANNETT thought an attempt should be made to apply ordinary surgical principles to hæmorrhage coming from a gastric ulcer. The loss of large quantities of blood brought the patient into a very low condition so that he was not fit for an immediate gastrectomy. The surgeon was seldom called to such a case until the hæmorrhage had been persisting for some days. It was then imperative to determine definitely whether treatment should be medical or surgical; one should not change horses in mid-stream. If surgery were to be given a chance the surgeon must be allowed to see such cases earlier. For very large ulcers he agreed that gastro-jejunostomy was the operation. Small ulcers on the lesser curvature he dealt with differently; if a sleeve resection was done, he thought a pyloroplasty should be carried out also. Where a Billroth No. 1 operation was possible he preferred that to the Polya gastrectomy.

Mr. J. **CUNNING** said he did not agree with Mr. Walton's statement that all ulcers which perforated were chronic ones; such an idea was usually based on the fact that the ulcer was indurated; but if a perforation was a slough, any ulcer could be indurated. He described a case of perforation of an acute ulcer. He did not believe in the danger of malignant degeneration of gastric ulcer; only twice had he seen malignant ulcer with a prolonged history of gastric ulcer.

REPLY.

Mr. **GORDON-TAYLOR** said his feeling now about hæmatemesis was to operate as soon as the bleeding had stopped and the blood pressure had commenced to rise. With regard to carrying out jejunostomy for some of the inoperable or inaccessible cases of ulcer, high up on the back of the stomach, he referred to a patient with perforated duodenal ulcer, which was operated upon 36 hours after the perforation. The ulcer was sewn up and nothing more done. Three days later there was a re-perforation, and a duodenal fistula developed.

Mr. **WALTON** agreed that the end-results of partial gastrectomy were good, and he believed pernicious anæmia seldom occurred. He had never seen a case of secondary anæmia become pernicious; if it occurred it must be very rare. With regard to laparotomy for perforation, at one time there existed a feeling that the abdomen should be closed almost at once. He always liked to carry out slight suprapubic drainage, and if there were a widespread infection he also drained from the stomach. He had never known trouble arise from drainage, but he had known difficulties to occur when drainage was omitted. A pyloric ulcer he conceived of as one which extended over a portion of the stomach; he had seen cases in which such an ulcer had healed as far as the duodenal side was concerned, but had developed carcinoma on the gastric side. However small that kind of ulcer might be there was the possibility of its becoming carcinomatous. He believed that 10 per cent. of carcinomas in this region originated in ulcer.

SECTION OF LARYNGOLOGY.

A MEETING of this section was held on May 1st with Mr. **FRANK ROSE**, the President, in the chair.

Upper Œsophageal Obstruction.

Dr. A. **BROWN KELLY** (Glasgow), in opening the discussion on obstruction at the upper end of the œsophagus (excluding diverticula), said that the more pronounced the stenosis the earlier the dysphagia became manifest and the greater was the menace to life. A consideration of these abnormalities should embrace their effect in the newly born, the young child, and the adult. First, in regard to atresia with œsophagotracheal fistula, he said that atresia was the most serious maldevelopment of the gullet, for the issue was always fatal. Seldom had the condition been better described than by Morell Mackenzie in 1884. In the commonest variety the atresia was associated with an œsophageal fistula. Here the upper part of the œsophagus ended blindly above the level of the bifurcation of the trachea, while the lower part passed up *from the* stomach to the posterior wall of the trachea, where it opened as a fine fistula. The signs were those of obstruction high in the œsophagus, so that from time to time the child coughed, choked, and became cyanosed because it could not swallow the accumulated saliva and mucus. A small bougie which it was attempted to pass was checked at a distance varying from 9 to 13 cm. from the gums. Usually in this condition one could find other congenital abnormalities also, imperforate anus being the commonest of these. In order to prove that a stenosis of the œsophagus was congenital it was necessary to ascertain that dysphagia and regurgitation had been present from birth, or at least from the date when the child was first given solid food; and either endoscopic examination during life or a post-mortem examination should show a smooth lining membrane, without any evidence of cicatrisation.

Referring to cases in which narrowing occurred at a lower level, Dr. Brown Kelly said these caused, in children, symptoms whose severity was intermediate between those of atresia in infants, and those of stenosis in adults. When narrowing of the lumen was not very severe no sign of œsophageal obstruction might be noted until attempts were made to give semi-solids, from which time onwards meals were constantly being brought up. At quite an early stage radiographic examination and endoscopy should be carried out. The constriction was usually found to be opposite the seventh thoracic vertebra.

Speaking next of stenoses at the upper end Dr. Brown Kelly said that the prevailing ignorance of both the normal and diseased conditions in the hypopharynx and upper end of the œsophagus was due to the difficulties encountered in the chief methods of examination—i.e., X rays and endoscopy. So quickly was the bolus of food projected into the gullet that one could not make deliberate inspection of what took place during this transit. Perhaps the cinematograph could fill this hiatus. The passage of an endoscope might be much hindered for a time by spasm of the cricopharyngeus muscle; and a further difficulty was the want of orientation landmarks, so that a delicate membrane might be ruptured even before it was seen. Narrowing of the lower part of the hypopharynx or upper part of the œsophagus could be due to a membranous diaphragm, fold, or ledge, or to a diminution in the size of the lumen.

Congenital stenoses at or near the upper end of the œsophagus were very rare. Morell Mackenzie called this condition "simple stenosis of the gullet," and said it was an abnormal narrowness of a limited part of the œsophagus without morbid changes. The speaker showed a specimen from a case of congenital stenosis at the entrance to the œsophagus, in which there was a gradual and uniform narrowing of a length of 1 cm., and beyond it the lumen of the œsophagus was normal. The lining of the funnel-shaped stenosis was quite smooth, suggesting a congenital origin. This patient was a man, aged 35, who died from cerebral hæmorrhage.

In a few of Dr. Brown Kelly's cases the narrowing was produced not merely by spasmodic muscular contraction but also by a circular membranous web with an aperture 3 or 4 mm. in diameter. A few patients who had malignant disease at or near the mouth of the œsophagus said they had had difficulty of swallowing since early childhood. Logan Turner had found in 94 cases of post-cricoid cancer that four of the patients stated they had had "a narrow throat" as long as they could remember.

Dr. Brown Kelly referred to the occasional presence, at the upper end of the gullet, of islands of gastric mucosa. To the unaided eye these appeared as sharply demarcated oval patches, yellowish-brown in colour, and they were liable to be mistaken for superficial erosions. Usually these islands were found between the lower end of the cricoid cartilage, and the level of the seventh or eighth tracheal ring on the lateral part of the posterior wall. They were commonest in adult life, but might be met with at all stages of development. Such islands were sharply demarcated from the surrounding stratified squamous epithelium of the œsophagus by the surface becoming irregular owing to the presence of a number of long papillæ, between which were deep pits.

SPASM AND STENOSIS.

Dr. D. R. **Paterson** (Cardiff) followed. He said he considered that obstruction at the upper end of the gullet could be due to two kinds of causes: spasm at the entrance, and malignant disease. His purpose was to raise some problems for discussion.

In 1919 Dr. Brown Kelly and he had drawn attention to a clinical syndrome in women chiefly characterised by a gradually increasing inability to swallow, because of spasm of the pharyngo-œsophageal sphincter, and, at a later stage, anæmia. The latter could be looked upon as a secondary manifestation of the dysphagia. A peculiar point was that he had never seen this form in a man, in which sex the obstruction was usually a malignant one. Sometimes spasm was met with in a man, but it was usually an accompaniment of malignant stricture further down. The women he referred to usually came under observation first in middle life, often giving a long history of dysphagia, which had latterly slowly restricted them to liquid food. Some of these cases were incorrectly labelled hysterical. From an early stage they might show slight changes in the mouth, possibly no more than a mild atrophy of the tongue papillæ. Only later did superficial glossitis appear, the tongue being smooth and devoid of papillæ. This atrophic change in the mucous membrane was related essentially to the food passage, and not to the air tract. Even marked atrophic pharyngitis resulting from nasal disease was rarely accompanied by dysphagia. Cases were met with of a web at the entrance of the gullet, and Mosher had pointed out that frequently the use of a tube without due observation removed a web. Anæmia was a late symptom, and was of gradual development. Munro Cameron had stated that the blood changes were essentially those of chlorosis and mild secondary anæmia, with a constant reduction in the hæmoglobin percentage.

Immediately after the passage of a tube there was an increased capacity to swallow, and if the patient was now told that she could swallow solid food she soon improved in general condition. Cures were not always permanent; in some of the patients the return to normal was not complete, and some dysphagia might persist; this was much relieved by the occasional passage of a bougie. It was the speaker's experience that malignant disease was often a late sequel of this syndrome.

With regard to malignant disease in the part concerned, Dr. Paterson drew attention to some of the salient facts which had been established by Logan Turner. One was that carcinoma at the upper end of the gullet was more common in women than in men, also it was met with at an earlier age in females than in males, 20 to 30 years of age not being uncommon in the former. A review of hundreds of cases of cancer of the œsophagus showed that at some stage each one had been diagnosed as hysterical dysphagia. Pain, which was often localised to one side, and was also felt in the ear, was almost symptomatic of grave change, and so should direct attention to that side of the hypopharynx.

The problem of the treatment of malignant disease in this region was, said Dr. Paterson, entirely bound up with its early detection. The laryngoscope, œsophagoscope, and X rays should all be brought into requisition. Only when the disease was limited did surgery give hope.

Dysphagia was only occasionally due to webs, a common site for which was behind the cricoid cartilage. Some, those which were thin and slight, could be disposed of by passing a tube, but others were thicker and might support a shallow pouch. Dr. Paterson thought that the whole subject of webs was worthy of further discussion.

ILLUSTRATIVE CASES.

Prof. Georges **Portmann** (Bordeaux) spoke of two cases of the kind under discussion. One was a woman, 20 years of age, the other a man, aged 45. Both had stenosis of the hypopharynx, not congenital, nor consequent upon trauma; no syphilis, lupus, or other disease could be incriminated. The condition was a gradual concentric stenosis by fibrous tissue. He was compelled to do first tracheotomy, then gastrostomy. He used diathermy as the treatment, and both patients were now cured. They had not a normal hypopharynx, but they were able to swallow and breathe.

Mr. Herbert **Tilley** said that in 30 years he could recall only one case which came to his personal knowledge at the hospital as a congenital atresia of the gullet. That child died in three days. As to the possibility that functional aphonia might be a precursor of malignant disease, a lady was sent to him because she had difficulty in swallowing. He passed a bougie, and a fortnight later she had no further difficulty. Five years later she was losing flesh and had great difficulty in swallowing. When he saw her again at this later date she was very thin, there was a little bright blood in the right pyriform sinus, and he was unable to pass a bougie. A post-cricoid cancer was found, and two or three months later she died. If a patient having obstruction was relieved by the passage of a bougie, and then returned after a short time, it called for a direct examination of the gullet. Youth in the patient was no guarantee that the condition was not malignant. He spoke of the case of a medical man who consulted him because of pain in the throat and difficulty in swallowing; he also had joint pains. He was found to have intense œdema of the left arytenoid and fixation of the corresponding cord. He had had acute rheumatic fever. He got well under treatment, and six months later the œdema had disappeared and the cord was moving normally. Mr. Tilley also described other cases.

Mr. V. E. **Negus** described the case of a patient (whom he showed) with an inflammatory swelling of the ary-epiglottic folds. She was aged 54, and her complaint was of a throbbing of the throat and of the formation of a "froth" there. Swallowing was not interfered with. On indirect examination one saw a regular, firm, red swelling in the posterior region of the ary-epiglottic folds; but there was no ulceration, nor was any neoplasm seen; the Wassermann reaction was negative, and there was no secondary anæmia. It might be merely an inflammatory swelling of the larynx.

Mr. A. J. M. **Wright** (Bristol) said he had been watching cases with the condition under discussion for 23 years. The condition of glossy tongue with dysphagia he thought was originally a chronic infection, which probably explained the fact that these patients when seen, though in many cases young, were almost always edentulous. It would be of great practical interest to know how often a late sequel of the condition was the formation of new growth. Hot tobacco smoke had been invoked as a possible determinant of carcinoma of the tongue, so in women the drinking of hot tea could be indicted.

Dr. **Douglas Guthrie** (Edinburgh) alluded to some cases in which various abnormalities of the gullet occurred. One was that of a child 8 months of age, which obviously had difficulty in swallowing, though it was possible for it to take nourishment. At the entrance to the œsophagus he found a soft growth, resembling a nasal polypus. He removed it under suspension laryngoscopy, passing a snare under the cyst, when it collapsed. The contents were not clear, but milky looking.

Mr. W. S. **Thacker-Neville** (Harrogate), referring to the statement that the drinking of hot fluids, such as tea, might cause cancer, said the Chinese were addicted to very hot tea-drinking, yet during the time he was in that country he did not see a case of post-cricoid carcinoma.

Dr. R. S. **Johnson** spoke of a series of cases of combined anæmia and dysphagia which were in St. Bartholomew's Hospital under Dr. George Graham, the ages of the patients ranging from 33 to 48. All showed a very low colour-index, and the anæmia was of the secondary type. In one the œsophagoscope could not be passed, owing to the spasm. The cases showed achlorhydria. He suggested that in this type of case there was a specific kind of anæmia, associated with a slightly increased fragility of the red cells, with achlorhydria and secondary changes in the mucous membrane of the tongue and the œsophagus.

MEDICAL SOCIETY OF LONDON.

THE ANNUAL ORATION.

At the general meeting of this society on May 11th, with Dr. R. A. **Young**, the President, in the chair, Sir **John Rose Bradford** delivered the Annual Oration, taking for his subject

Medicine as Science and an Art.

The last 50 years, he said, had not only been marked by numerous great discoveries in the realm of natural knowledge, but had been more especially remarkable for the rapid application of those discoveries to the practical needs of humanity. The very benefits which these discoveries had conferred led necessarily to some confusion as to the real relationship between scientific discovery on the one hand and its practical application on the other. The ever-increasing demand for practical applications and benefits was apt to dominate the situation and might even affect the mental outlook of those whose primary purpose was only to add to knowledge. The chemical or physical problems involved, for example, in the production of artificial silk, in wireless communication, or in the steam turbine, were really only fully appreciated by the experts in the particular branch of science concerned, and were often difficult of apprehension by a worker in another branch. When the practice of an art was founded on the achievements of a science, differences between the modes of thought of workers in the science and those engaged in pursuit of the art were apt to become accentuated; two camps were likely to be formed, and it was even possible for the one to doubt the value or even the very existence of the science in question, while the other asserted that all would be well if the so-called art were replaced by something which they could regard as science. Many doubted whether medicine was a science, but a practitioner could not exercise his art efficiently unless it were well grounded on scientific principles.

THE SOLDIER AND THE DOCTOR.

In many respects the profession of medicine resembled that of the soldier even more than that of the engineer, with which it was often compared. The soldier and the doctor both had to grasp a situation and determine with little or no delay a course of action; he had to have instinct or flair, military in the one case, clinical in the other; and both were useless unless their instinct was based on and regulated by sound general principles which owed their origin to the study of the science of war and of medicine respectively. A favourite definition of science was "measurement," but a wider outlook might be more satisfactory, and the orator quoted Ruskin's definition that the work of science is to substitute facts for appearances and demonstration for impressions. Such a definition was closely applicable, he said, to the science of medicine. Looked at from a particular standpoint, medicine was of course but a branch of biology, most akin to the subdivision of biology known as natural history. Many might be inclined to take a narrower view of the essential nature of medicine, and regard it as merely a deranged or abnormal physiology, for the connotation of which, for the purposes of convenience, the terms "pathology" and "pathogeny" had been applied. But the natural history of an animal or plant dealt with much more than purely physiological processes, and many of the phenomena of living organisms could not be fully investigated either in the laboratory or by the methods of the laboratory alone. To acquire a satisfactory knowledge of the life processes of an animal or plant, both the methods of study practised in the laboratory and those practised in the field were required, and it was unfortunate that both in biology and in medicine there should be a divergence of view about the relative importance of the one method and the other. What fundamentally mattered was that the pursuit of natural history in the field of clinical medicine in the wards should not suffer because supposed to be of less importance or to require a smaller degree of equipment, mental or material, for its pursuit. The two classes of workers must pursue different methods, but should both take to heart the dictum of Ruskin quoted above. The science and art of medicine or the principles of the practice of medicine were often represented pictorially by a book and the well-known caduceus, with the twined snakes, the former representing the knowledge and science of medicine, and the latter the practice of the art. That was a suitable picture, but one vital proviso must be added—namely, that the book should be regarded as the book of nature, or as Longfellow put it, "the manuscripts of God."

THE BOOK OF NATURE.

The dark ages of medicine for centuries before the advent of Harvey were in no small measure attributable to the book of nature not having been consulted, and reliance having been placed on authority, or the book of man. Harvey consulted the book of nature himself, and proceeded to ask a series of masterly questions, finding answers which established scientific medicine. In the progress of science the gift or discovery of a method of inquiry was often of more service even than the discovery of a great fact, and medicine in the person of Harvey had rendered not only great but possibly the greatest assistance to the progress of all biological sciences. The experimental method in these recent years had extended the scope of its operations to a most remarkable extent, so that at the present time much of the work of the biologist and botanist was performed with its help. In fact, the modern biologist paid an ever-increasing attention to problems capable of solution by the experimental method rather than to problems of morphology; in other words, function was being more considered than structure. Although medicine was profoundly indebted to other sciences in its own realm, the relationship was not entirely unilateral. It was natural and quite excusable for the great public to fail to recognise the value of so-called abstract research, but members of the profession of medicine, whose daily work afforded them countless instances of the priceless material benefits which had accrued to their art as a result of such work, should be chary of belittling research whose practical application was not apparent.

The science of medicine might be said to have for its field the study of the phenomena of disease as a whole and the means best suited for its prevention. The art of medicine was concerned mainly with the problems encountered in our attempts to recognise the presence of disease in individuals and to treat it. Naturally, no absolute hard-and-fast line could be drawn between the science and the art in given instances, though knowledge of the prevention of disease might reach a very high level of development from the purely scientific standpoint while failing in its application owing to imperfections in the study of the art of medicine in the clinical field. Medicine as a science was no mere appanage of anatomy or physiology or pathology. There was something else, which it was difficult to describe accurately in words, but might be conveniently summed up as the natural history of man. The natural history of diseased man was, of course, the special study of clinical medicine. Clinical medicine, like field natural history knowledge, was not easy to acquire. Both necessitated a long apprenticeship; often prolonged time was required to afford opportunity, and, further, it was exceedingly difficult to acquire habits of observation which reached the high standard of scientific accuracy.

To have a really comprehensive view of medicine it was essential not to confine the attention to human medicine. The consideration of disease in animals, at any rate domestic animals, must be included. This was important not only from the point of view of communicability of disease, but also from the far wider point of view of checking any tendency to narrowness of outlook and dogma in respect to the true causation of any disease. The comparative method had always exercised a broadening influence on the human mind, and might be applied with advantage to medicine as well as to anatomy and physiology.

CONCLUSION.

In conclusion, Sir John Rose Bradford said that his aim had been to insist that further progress must be based rather on the mental views held by the disciples of medicine than by the mere use of increased instrumental or chemical agencies now available for their service. If medicine was regarded as an appanage of physiology or even of pathology, possibly great advances might be made by individual discovery, but such discoveries would often not only be of limited scope, but still more often very difficult of application when they were removed from the relatively simple conditions of the laboratory to the complex field of operations of clinical medicine. Clinical medicine still offered plentiful scope as of old for those gifted with real powers of scientific observation, and important as the experimental method was, and valuable as the instrumental aids, these were not by any means the sole methods of advance, either for the science or for the art of medicine.

A vote of thanks to the Orator was proposed by Dr. HERBERT SPENCER, and seconded by Mr. DONALD ARMOUR, and heartily carried.

MANCHESTER MEDICAL SOCIETY AND PATHOLOGICAL SOCIETY OF MANCHESTER.

AT a joint meeting of these societies on April 15th, with Mr. J. HOWSON RAY in the chair, an address on

Epidemic Encephalitis

was given by Prof. ARTHUR HALL (Sheffield). He began by giving an account of the acute cases, which first appeared in 1916 and recurred in epidemic waves during the next seven or eight years. He called attention to their periodicity, to the variability of onset in individual cases, and to the extreme differences of reaction to infection. In some cases the acute attack presented no diagnostic features, in others quite definite stigmata showed themselves, whilst in a third group there was no recognisable illness at all, the first symptoms appearing only at a later period and in more chronic form. During the last five or six years the number of acute cases had steadily diminished. Undoubtedly, sporadic cases were still occurring but they were few in number, and in this country no epidemic outbreak of any magnitude had followed that of 1924. To-day it was the chronic progressive disease which showed itself, chiefly, though not solely, as parkinsonism. The destruction of cells in the substantia nigra found in such cases supported the view held by most clinicians, that parkinsonism is a chronic progressive encephalitis of active kind rather than a mere passive residual effect of the acute attack.

What, asked Prof. Hall, was the future of those mild and partial cases of parkinsonism which had so far remained stationary for periods varying from 7 to even 10 or 11 years?—Had the activity of the process ceased or was it only temporarily arrested? As most of the patients were young persons at an age when marriage and choice of occupation had to be considered, important decisions often depended on the answer to this question. The difficulty was great because there were no precedents. A second question was: Would the epidemic waves recur? Whilst there was evidence that since 1924 the number of new cases had been steadily diminishing, yet judging by the behaviour of other neurotropic epidemics it would be rash to prophesy that they would continue to diminish.

NOTTINGHAM CHILDREN'S HOSPITAL.—The result of the recent enlargement to 100 beds is that last year there were 920 in-patients as compared with 660 in 1929, and that at 424 the number of operations nearly doubled. The hospital is now a recognised nurses' training school.

REVIEWS AND NOTICES OF BOOKS

Principles of Epidemiology and the Process of Infection.

By C. O. STALLYBRASS, M.D., D.P.H., Chief Assistant Medical Officer of Health, City and Port of Liverpool; Lecturer on Vital Statistics and Epidemiology, Liverpool School of Tropical Medicine. London: George Routledge and Son, Ltd. 1931. Pp. 696. 30*s.*

THIS book represents a departure from the traditions of literature on public health at least in this country. It is an attempt by a medical practitioner engaged in the day to day work of a health department to bring within one compass the sum of our knowledge of epidemics, and of present-day methods of approaching the still obscure problems of epidemiology. Obviously, such a programme must cover the history of epidemics, statistical ways of studying them, their environmental, bacteriological, and immunological conditions, their cyclic and seasonal variations, and their susceptibility to practical measures of control. Moreover, if the book is intended primarily for the medical officer of health, as this is, it should be sparing in reference to the more intricate refinements of special subjects like bacteriology and statistical methods, although they have an important bearing on the main topic. On the whole, if these criteria are accepted, Dr. Stallybrass has succeeded in his purpose. Not every public health administrator, who ought to be equipped with information which has a practical bearing on the control of communicable disease, has a sufficient grounding in mathematics to understand the chapter on statistical methods, and possibly too much has been crowded into chapters which deal with micro-organisms, their invasion of the human body, and the resistance they provoke. Indeed, the impression is gathered that Dr. Stallybrass has had some difficulty in discarding from his very wide knowledge of the branches of science ancillary to epidemiology. His book is therefore not easy to read. It should be considered, however, as a book of reference, and in this respect it supplies a want which has been felt to an increasing extent in recent years as a result of the rapid progress of inquiry into the causes and behaviour of epidemics. The book is not free from defects in proof-reading, although they are not unduly prominent. There are a very few errors of a more serious character which will require correction in any future edition—e.g., the equation "Mortality-rate = morbidity-rate × fatality-rate." The index is complete and reliable. An extensive and well-selected bibliography of about 800 publications bearing on the matters discussed in the body of the book is a useful feature.

As a work of reference this book will be invaluable to medical officers of health and teachers of preventive medicine.

Physical Diagnosis.

By WARREN P. ELMER, M.D., Associate Professor of Clinical Medicine, Washington University; and W. D. ROSE, M.D., late Associate Professor of Medicine, Arkansas University. London: Henry Kimpton. 1930. Pp. 903. 42*s.*

THIS large volume is divided into two parts. The first and rather larger section concerns itself in minute detail with the time-honoured methods of physical examination—inspection, palpation, percussion, and so forth—together with an exhaustive analysis of the results obtained. Some of the detail might be spared, even by the beginner. For instance, it is noted that the intensity of vocal fremitus varies directly with the intensity of the speaking voice, and that when the voice is increased the fremitus follows suite, and vice versa. Many interesting points in the mechanism of the production of physical signs are set out. One short chapter is devoted to "Palpation of the Lower Extremities," but it is doubtful if so methodical a system in diagnosis as a complete physical examination of the human body in every case is of great value, apart from relevant symptoms. The chapter on radiographic methods by Dr. Sherwood Moore is good and excellently illustrated, and the short chapter on electrocardiography is useful.

It is disappointing, when we come to the second part of the book, where these elaborated methods should find application, to discover that it is limited to the diseases of the respiratory and circulatory systems. Thus all the detailed topography of the abdomen and the methods of its inspection and palpation, as well as the chapters on speech, gait, and station, on inspection of the head and face, and of the inguinal, genital, and perineal regions, found in Part I., do not come to any particular fulfilment as far as this work is concerned. The chapters dealing with pulmonary and circulatory disease are very full. It may be doubted whether a work only on physical signs, excluding all consideration of symptoms, may not encourage students to see the trees rather than the wood. There are 337 excellent illustrations.

Taylor's Practice of Medicine.

Fourteenth edition. By E. P. POULTON, M.A., M.D. Oxf., F.R.C.P. Lond., Physician to Guy's Hospital. With the assistance of C. PUTNAM SYMONDS, M.A., M.D. Oxf., F.R.C.P. Lond., Physician in Charge of the Neurological Department of the Hospital; and H. W. BARBER, M.A., M.B. Camb., F.R.C.P. Lond., Physician in Charge of Skin Department; and R. D. GILLESPIE, M.D. Glasg., M.R.C.P. Lond., D.P.M. Lond., Physician for Psychological Medicine to the Hospital. London: J. and A. Churchill. 1930. Pp. 1074. 25*s.*

IT is 40 years since the first review appeared of this popular treatise in our columns, and looking back at our words we think that to a great extent they forecasted what would be its happy destiny. We congratulated the author then on the comprehensiveness and the able selection of his material, on the proportion observed between the various subjects, and on the accuracy in details, closing with the statement that the book would be certain to become a welcome guide to the students of the future. We have now received a copy of the fourteenth edition of the book, which has appeared at average intervals of three years since its birth.

A quotation by Dr. E. P. Poulton from his preface to the twelfth edition indicates his ideal in dealing with a classic, so as to render the teaching practically modern while maintaining a general plan whose value has been so prominently proven. Completeness, this preface indicates, must always be aimed at, and yet the main scope of the book should remain unchanged. To reconcile these contradictories in a text-book which displays the practice of a science that itself is ever changing, by the addition of the needful and the discarding of what has been superseded, has been the work before the editor, who has felt that it could only be undertaken if the revision of the greater part remained in one hand, while assistance was freely invited to deal with certain specialties. The longest interval between the various editions has just occurred, and during this space of about five years the advance in all branches of medicine has been considerable. This has led to new articles on the streptococcal and staphylococcal infections, to the rewriting of the account of acute rheumatism so as to include chorea—with the result that the disease is now classified as one of the circulation—to new treatment of such subjects as coronary thrombosis, the acute abdomen, chronic cerebral softening and cerebral contusion, and chronic gastritis. Indeed, there is scarcely a page which has not been altered in conformity with the changes in accepted knowledge or theory. Further, the utility of the teaching has been raised in a high degree by such rearrangements of material as that which has occurred in the case of rheumatism. In previous editions many subjects, as mental diseases and the pathology of parasites, received scattered notice throughout the book, while the information concerning them has now been collated in special sections. With regard to mental diseases an article now appears by Dr. R. D. Gillespie, who remains in charge of this section of the work, on the legal relationships of these diseases, one by Dr. C. P. Symonds on the psychoneuroses finding appropriately its place in juxtaposition. Tropical diseases have been grouped in one section, and this part of the volume has been revised by Dr. Dyce Sharp and largely rewritten, while Dr. Barber has revived the dermatological sections.

Dr. Poulton makes detailed acknowledgment by name to a large group of authorities who have assisted him along the various lines into which the practice of medicine is now necessarily divided for intensive study, and by preserving the balance which has always been characteristic of "Taylor" has produced a new edition which is sure to find continued favour.

There are 64 plates (12 coloured) and 103 text-figures, including many radiograms. The increasing value of adequate illustration in clinical text-books is thus cared for.

La cryothérapie.

By Dr. LORTAT-JACOB, Physician, Hôpital St. Louis, Paris; and Dr. G. SOLENTE, Assistant Physician. Paris: Masson et Cie. 1930. Pp. 246. Fr.35.

COLD as an agent in the therapeutics of skin disease appears to have been initiated by Kaposi who applied a vessel containing ice to a few patients suffering from lupus erythematosus; but its real origin was in the attempts to utilise methyl and ethyl chloride as local anæsthetics in 1882. It was not until 1896, however, that Ullmann of Vienna published the first practical results in his treatment of angiomata by the latter substance, followed in 1901 by Dethlefsen who applied it for the cure of lupus and cutaneous cancer. The discovery of liquid air in 1884 initiated a new epoch in the history of congelation. It remained too costly and uncontrollable for general use, although A. C. White did much good work with it in the Vanderbilt clinic in New York. It was left to his countryman W. A. Pusey to devise an agent, solid CO_2, which ever since 1905 has not only proved of immense value in the treatment of localised cutaneous abnormalities, but vies with radium and other modern weapons in quite a number of departments remote from dermatology—for example, ophthalmology. Much that is collected in this volume has been known for years—the method of preparation and collection, the various sized cones for making the "pencils," the indications for treatment, and the comparative safety with which, even in inexperienced hands, good results can be obtained. The effects are the product of two factors: (1) the duration of the exposure, and (2) the pressure applied, and the latter, if the operator is a novice, can be accurately adjusted by means of the apparatus described in this book. The number of cutaneous conditions that can be treated by freezing is surprisingly large and ranges from chilblains to cancer. The authors use it for rosacea, in some forms of which localised papules and telangiectases are a pronounced feature. Even septic conditions such as indolent ulcers, and the hæmorrhagic forms of granuloma pyogenicum are amenable, while for vascular nævi it is the treatment of choice. The whole subject is methodically discussed. The histological effects are illustrated by microphotographs, and special sections are devoted to the modifications imposed by the topography of the lesions such as those in the eyelids, the alæ nasi, or the aural cartilages, in which localised disease or stigmata are relatively common.

This volume reveals a series of indications which, in view of the modern popularity of the various electrical and ray treatments, may have escaped the notice of even experienced dermatologists, while the simplicity of the technique, the relative immunity from complications, and the almost perfect cosmetic results, make their special appeal to the general practitioner.

The Charaka Club, 1931.

Proceedings of the Charaka Club. Vol. VII. New York: Paul B. Hoeber. 1931. Pp. 190. $5.00.

THIS is the seventh volume of the well-known Proceedings of the Charaka Club, and like all its predecessors provides a medley of wisdom, learning, research, and fun. The book is prefaced by a list of the members of the body, who may be congratulated on the number of names now appearing which previously appeared 20 years ago—the members live long, as witty men should. The present volume contains no exactly medical article, but the contents will appeal to all medical men who seek and find interest in the history and traditions of their profession, and its associations with literature. An essay on the education of the Barber-Surgeons in France by Dr. E. C. Streeter, is an informing history of the growth and development of surgery in mediæval France; a paper by Dr. F. R. Packard on the Journal of Jean Héroard, Physician to Louis XIII., throws an intimate light on domestic medicine in the same country in the sixteenth century. This contribution owes its origin to a manuscript preserved in the Bibliothèque Nationale at Paris, and only a certain portion of it has ever been published. It forms a minute history of the earlier bringing up of Louis XIII., starting with the accouchement of Marie de Medicis, the second wife of Henry IV., and includes an instructive list of the medical establishment attached to the court, 21 in number, with different duties assigned to them. The volume includes a selection of verses, grave and gay, by Dr. G. D. Stuart, and many illustrations, of which the best are those which accompany Dr. R. L. Dickinson's chapter on Chinese boats.

THE LANCET.

LONDON: SATURDAY, MAY 16, 1931.

SPLENIC FUNCTIONS AND DISEASES.

Readers of the Lettsomian Lectures at the Medical Society of London, reported in our columns of this and two previous weeks, have now been presented with what is really a monograph on "the spleen and its sufferings," to quote the convenient inclusive title of an address given by the late Sir Frederick Taylor before the Midland Medical Society in November, 1905. This difficult subject, long the field of hypotheses, has recently, like other branches of medicine, been extensively investigated and advanced; but, except for Lord Moynihan's volume on "The Spleen and Some of its Diseases" ten years ago, has not been exhaustively reviewed in this country, and so is in need of a scientific summary such as Dr. J. W. McNee here provides. In doing so he has returned to a subject to which he has in the past made notable contributions; in addition to work on the reticulo-endothelial system, of which the spleen is such an imporant site, he has specially investigated its normal structure and brought order into the grouping of its morbid changes. The spleen being in the portal system and containing so much lymphoid tissue may therefore naturally share in the diseases both of this system and those of the blood-forming organs, as was shown in H. Eppinger's valuable book "Die hepatolienalen Erkrankrungen" 1920, a subject which has not escaped the attention of this year's Lettsomian lecturer. In order to understand the disorders and the significance of structural changes in an organ, it is obviously essential to have an accurate knowledge of its functions and normal anatomy. The physiology of the spleen is beset with difficulties, it is not a vital organ, and its numerous functions are shared by other parts of the body and can thus be compensated when it is removed or damaged. Hence experimental excision or extensive disease does not give rise to manifestations which reveal its functional activities in the same clear and unmistakable manner as in removal of the thyroid or parathyroid glands.

It is therefore well that beginning with an attractive historical review Dr. McNee has cleared the ground by a summary of our present knowledge of the physiology and anatomy of the spleen. It is perhaps noteworthy that the contractile power of the spleen, postulated as long ago as 1722 by William Stukeley in his Goulstonian lectures at the Royal College of Physicians of London, was not fully investigated and established until 1881 by C. S. Roy, then George Henry Lewes student at Cambridge, where 40 and more years later Barcroft and his co-workers made it permanently obvious. The discussion of the relation of the spleen to the digestive processes, and especially to fat-metabolism, shows that our knowledge of the physiology of the organ is still far from finality. Some of the details of the structure of the spleen recently brought forward, such as the "ellipsoids," are really re-discoveries of what was once known, but then forgotten. The significance, otherwise uncertain, of the anatomical make-up of the organ has been elucidated by the assistance of physiological methods; thus the problem whether the intrasplenic circulation is completely closed or open, or a combination of the first two alternatives, has been brought, by Barcroft's experiments with CO and those of McNee and M. F. Cashin on other lines, to the conclusion that there is a two-fold circulation; the first is the ordinary circulation through the splenic artery, venous sinuses directly into the splenic vein; the other, intermittent, is brought about by contraction and relaxation of the whole organ, and consists of an emptying of the pulp spaces through the wide stigmata into the veins, and a filling again through the lateral channels in the ellipsoids.

As a classification for ordinary purposes of the diseases of the spleen, Dr. McNee suggests the adoption of one partly based on the histological changes in the chief constituent elements of the organ, namely: (1) the myeloid and lymphatic; (2) the endothelial (the reticulo-endothelial system); (3) the vascular system with its special peculiarities; and (4) the reticulum and supporting tissues, the trabeculæ, and the capsule. In addition to the first three of the above categories he now proposes groups headed abnormalities, tumours, infections, and combined diseases of the spleen, liver, and hæmopoietic system, making seven in all. His systematic and detailed account of the diseases met with in this country is largely derived from personal observation of clinical cases and pathological examination of many more than the 100 spleens on which he based his former classification in 1929; there is admittedly little about tropical splenomegalies or morbid changes in the spleen occurring incidentally in generalised conditions such as syphilis, tuberculosis, Hodgkin's lymphogranuloma, and leukæmia. Attention may be specially directed to the three types of disease included under the heading of those affecting the reticulo-endothelial system—namely, chronic hæmolytic jaundice, disturbances in lipoid metabolism leading to Gaucher's and Niemann's diseases, and to hypercholesterolæmic splenomegaly in diabetes mellitus, and thirdly, chronic splenomegalies of unknown origin showing well-marked proliferation of the reticulo-endothelial cells with giant cells, sometimes in such large numbers as to simulate a myeloma, but not megakaryocytes from the bone-marrow. The nature of these cases, in which the spleen may be very large, is obscure, and Dr. McNee can only suggest that they represent the response of the reticulo-endothelial cells to very chronic inflammation. The group of diseases affecting the vascular system of the organ forms the largest of British splenomegalies, and includes many cases labelled chronic splenic anæmia and those due to thrombosis of the splenic vein. Splenomegaly, associated with peri-ellipsoid hæmorrhages and nodular siderosis, is not only extremely frequent, but has excited a considerable literature not devoid of a controversial character. Scattered over the cut surface of the organ are irregularly shaped, yellowish-brown nodules, the Gandy-Gamma or Gandy nodules, which contain iron and calcium; they were regarded by A. G. **Gibson** in 1913–14, and after the war by **Nanta**, **Pinoy**, **Gruny**, **Emile-Weil**, and other French observers, as due to mycotic invasion. But **McNee** strongly opposes this view and regards them as the result of past hæmorrhages.

Though these lectures are full of personal observation, and show a critical knowledge of the vast literature of the subject, they do not profess to be a final pronouncement, and those keenly interested in this instalment of the lecturer's results and conclusions will anticipate further instruction from him in the future.

◆

THE BASIS OF PUBLIC HEALTH LAW.

The fundamentals of public health law in America have lately been analysed by an American health official[1] under the triple headings of statutes, regulations, and precedents. The same three headings would stand as the fundamentals of the law in England also, but in England they would not mean quite the same thing. By statutes in England we understand the Acts of a single supreme and sovereign Parliament. In America statutes mean the State and federal constitutions and the legislation of congress and of the various State assemblies; there is a dualism of State and federal law-making. Public health law in America reveals itself on analysis as part of the "police power"—namely, the inherent sovereignty exercised by governments for the protection of morals, safety, well being, and good order. When the Federal Government was created in America and was entrusted by the several States with certain rigidly limited powers, the States reserved to themselves the sovereign control over their own internal affairs. Public health legislation, therefore, is a power necessarily exercised by each separate State for itself; it is not a power of the Federal Government unless there is some external or inter-State aspect such as the quarantine of immigrants. The famous Fourteenth Amendment to the Federal Constitution may be invoked to challenge any arbitrary invasion by a State of an individual's rights of "life, liberty, or property" and to contest any State law which can be stigmatised as unequal or partial in its application. The Fourteenth Amendment, however, has been overworked; it was never designed to interfere with the proper exercise of police powers by a State legislature, as the American courts have frequently observed. Public health, then, is mainly a matter for State legislation. The second fundamental (regulations) means much the same to Americans as it means to us—the rules and ordinances of health boards and municipal councils. There was for a time some doubt in America whether the legislature could delegate rule-making power to an administrative body. In a Wisconsin case it seems to have been held that the State board of health was a purely administrative unit possessing no regulatory power and incapable of receiving it. But the United States Supreme Court and various States Courts have removed the doubt and have made it clear that the State legislature may delegate the regulatory authority. In England, as the Donoughmore Committee on Departmental Powers will doubtless tell us when it produces its report, the delegated legislation of departments and local bodies has long been an accepted feature of our administrative system. Finally, the third fundamental (precedents) means the same thing to America and to England—the decisions of the law courts. Here the only difference between the two countries seems to be the fact that American judges have a wider power of checking public health activities as ultra vires. Owing to the rigid written constitutions of both State and Federal Governments, the American law courts may be invoked to examine whether an Act passed for an ostensible or declared purpose is a reasonable exercise of legislative power—i.e., whether it is properly related to, and appropriate to effect, the purpose sought to be accomplished. The English observer, who knows that the Parliament at Westminster is supreme and unfettered in its sovereignty, may find it hard to understand that the public health legislation of an American State assembly can be held in check by the judiciary.

On the other hand the American observer may be surprised at one of the checks on public health administration which is presumably peculiar to England—namely, the system of disallowance and surcharge by district auditors. Section 247 of the Public Health Act of 1875 enables them to disallow any item of account which is illegal and to surcharge any deficiency or loss incurred through negligence or misconduct. This power has had a remarkable effect in restraining the ultra vires activities of local authorities and in checking corruption and illegality. The Poplar wages case, decided by the House of Lords in 1924, in effect extended the power to disallowance or surcharge where the expenditure is for a lawful purpose but is deemed by the district auditor to be excessive or unreasonable. Lord **Sumner** pictured the district auditor as a man with a duty to restrain expenditure within proper limits and with a mission to find if there is any excess over what is reasonable. Critics have remarked that the resultant situation is administratively unfortunate. Mr. W. A. **Robson**, for instance, in his recent study of "The Development of Local Government," complains that district auditors have been appointed without any practical experience of local government. Their outlook, he says, appears to be excessively narrow and lacking in vision. "The type of man who regards it as improper for a great local education authority like the London County Council to provide necessitous school-children with fruit, cod-liver oil and malt extract under the Education (Provision of Meals) Act, does not possess the mental equipment likely to produce the most satisfactory method of audit."

THE TREATMENT OF TETANUS.

In few diseases is prevention so simple and so desirable as it is in tetanus. But the comparative rarity of the infection—at least in some parts of the country—makes it all too easy to neglect the prophylactic use of antitoxin. The incidence of avoidable cases has lately been causing concern in France, and, as our Paris correspondent has related,[1] a committee has been set up to define the circumstances under which specific prophylaxis should be undertaken. The report of this committee will be welcome, but there are many cases in which the original injury does not come under medical supervision in time for preventive measures. Commonly the history is of some apparently trivial wound, such as an infected blister, which is treated by the patient himself until symptoms of tetanus begin. Sometimes, again, there has been no discovered port of entry for the infection, or mild tetanus has developed in spite of antitoxin. Taking all these together, cases are still sufficiently frequent—especially in agricultural districts—for the problem of actual treatment to be a very real one.

Such treatment may be directed along three lines: it may aim at neutralising the toxin, at preventing further absorption by dealing with the source of infection, or at stopping spasms and maintaining strength. As regards the first there has so far been no very general agreement about the dose of antitoxin to give. The fact that the toxin probably reaches the central nervous system by the perineural lymphatics and becomes fixed to the nerve-cells has led to the belief that it is not much use to inject serum once the disease has developed. Of the various possible routes, the intrathecal has seemed the most appropriate, and the number of units given in this way has been necessarily limited by the bulk of the remedy. During the past year, however, there have been several reports which suggest that very large doses of antitoxin, for the most part intravenous and intramuscular, are more effective. Administration of these doses has been facilitated by the greater concentration of antitoxin in the sera now available. C. S. Sherrington showed in 1917 that antitoxin in suitable quantity would protect monkeys in which the tetanus was artificially produced by injection of toxin, and A. E. Paterson[2] in Australia has attempted to apply these results in the treatment of human tetanus by using massive doses corresponding to those employed by Sherrington. In a series of 26 consecutive cases he has had 19 recoveries. The dosage used was considerably larger than any previously given. At the outset he injected 100,000 U.S.A. units intravenously and 40,000 intramuscularly, and he repeated the former injection every 12 hours and the latter every four hours until the clinical condition was much improved. In some of his cases the total number of units injected approached 2 million. M. H. Manson,[3] in America, agrees in attributing failure of treatment to late administration of antitoxin and inadequate dosage. While all routes may be used, he regards the intravenous as the most important. An adult, he says, should be given at least 100,000 units in the first 24 hours and not less than 300,000 altogether.

This week, at p. 1075, we publish an account of an attempt to neutralise toxin by intrathecal injection of carbolic acid. This treatment is based on the observation that carbolic acid destroys tetanus toxin in vitro, and that carbolic acid plus toxin will protect guinea-pigs. A solution of 1 in 400 was found to be the strongest which would not cause cellular damage, and solutions of this strength were used intrathecally with apparent success, 10 out of 14 cases recovering. Carbolic acid has advantages over antitoxin in that only one or two injections have to be given and it is not expensive. The only obvious disadvantage is its liability to damage the kidneys. As yet however both massive dosage and carbolic treatment are no more than on trial; the assessment of results is notably difficult in tetanus because prognosis is uncertain in any given case, and the results of treatment correspondingly doubtful. W. W. C. Topley and G. S. Wilson[4] have suggested that the apparent discrepancy between Sherrington's results and those obtained by clinicians may be due to the fact that the former was treating a disease produced by a measured dose of a toxin, while the latter are trying to neutralise toxin which is continually being given out by virulent bacteria in a wound. If this is a correct explanation the thorough cleansing of any infected wound at the earliest possible moment, even though the disease has developed, assumes a very important place in treatment. Hitherto much interference with the local lesion has been deprecated.

FLORENCE NIGHTINGALE.

Tuesday last was the birthday of Florence Nightingale, who would have been 111 years old, and whose long life extended almost to the outbreak of the Great War. It is not necessary to say more of her splendid work than to endorse the appeal, made in the *Times* by Dame Sarah Swift, to all who revere Florence Nightingale's memory, that they should rally to the support of the British Red Cross Society which has selected her birthday for an Empire celebration. The significance of what she did for humanity is so identified in all minds with her achievements—humanitarian, administrative, and scientific—in the Crimea, that it is inevitable to regard the pattern of nursing, which was the outcome of these endeavours and accomplishments, as the complete story of nursing—a story having its first chapter written in Scutari and owing its sequels to extensions and variations of an original text. It is not doing honour to one of the greatest women whom this country, or indeed the world, has seen to regard the profession of nurse from this point of view; and here FLORENCE NIGHTINGALE, with her large and liberal education, and profound religious convictions, would have been quick to agree.

[4] Principles of Bacteriology and Immunology, London, 1930.

It was the teaching of Jesus which led to the voluntary ministrations of Christian women nearly 2000 years ago among the suffering poor, and this FLORENCE NIGHTINGALE'S preparatory work at home was designed to follow. On those early deaconesses the practice of the charity that is Love was enjoined by the Great Teacher. This work of the Primitive Church, in a more organised form, fell to be discharged by the religious Orders, and when at the Reformation a great part of the civilised world repudiated the authority of the Roman Catholic Church, secular schemes to replace the work of the Orders came into being. The duties of the nurses were then divorced in Protestant countries from religious inspiration and became largely domestic. The sad position to which the service of nursing, whether definitely associated with religious practice or rendered as domestic duty, had fallen as recently as 100 years ago became obvious to all who thought on such matters when the rise of scientific knowledge made the fundamental doctrines of hygiene common property among the intelligent. The supreme merit of FLORENCE NIGHTINGALE'S work lies in the fact that she, and in the first instance she alone in the world, perceived three things and perceived them as component parts of one ideal. She realised the need for a deep vocational call as clearly as any deaconess of the early church would have done; but she saw that this spirit of charity needed for its practical expression a measure of scientific training; and, thirdly, she learnt at the outset that the nurse, thinking rightly and rightly equipped, should form a unit in an organised scheme, under which results would be produced immeasurably larger than the sum of individual efforts. And just as FLORENCE NIGHTINGALE knew that nursing as she found it, when her great call came, needed above all things the information of modern science, so to-day would she know that, while the principles which she instilled remain fundamentally sound, the actual methods of training nurses must be perpetually modified by the growth of wisdom, by the lessons of science, general and special, and, above all, by the changes in social laws and customs inevitable upon the progress of civilisation.

ANNOTATIONS

THE DRUGS OF ADDICTION.

HEROIN has acquired the evil distinction of being the worst-known drug of addiction. The general clinical opinion in this country is that its pharmacological action is distinct from that of morphine, and that therefore it is indispensable for medicinal use. This conclusion is of considerable practical importance, because the medicinal use of heroin renders its suppression as a drug of addiction very much more difficult. Few comparative studies have been made of the pharmacological actions of heroin and morphine, and for this reason a paper recently published by two members of the U.S. Public Health Service[1] is of particular interest. These authors have studied the action of morphine, heroin, and codeine on the rhesus monkey. They first measured the minimal lethal doses. All three drugs produced death from coma and respiratory failure, but heroin was found to be at least ten times as toxic as the other two drugs, the approximate minimal lethal doses in milligrammes per kilo body-weight being: morphine sulphate 100 (85); heroin hydrochloride, 7 (1·6); codeine phosphate, 80. (The figures in parentheses show the smallest dose that produced death.) These quantities are much greater than the corresponding human doses, for 1 mg. per kilo corresponds to an adult dose of gr. 1. But since the usual therapeutic dose of heroin is at least one-third that of morphine, and these results suggest that the difference between their toxicities is considerably greater, it would appear that heroin is employed with a considerably smaller margin of safety than is morphine, and for this reason has earned its reputation of being very reliable in its action in relieving pain and cough. The same authors also examined the power of morphine, heroin, and codeine to produce addiction, by giving them to the macaques in increasing doses for prolonged periods. Well-marked tolerance was produced for all three drugs, although they all caused considerable impairment of health. Addiction was measured by periodically withdrawing the drug and noting the symptoms produced. Morphine produced withdrawal symptoms after about four months, and after a year withdrawal caused collapse associated with a fall of temperature of several degrees; in one case death resulted. The charts and photographs given in the report provide clear evidence of the physical nature of the reaction produced by withdrawing morphine from an addict. Heroin produced addiction more slowly than did morphine, for withdrawal symptoms did not occur until the drug had been given for a year. This difference may have been due to the fact that the doses of heroin were only one-tenth as great as the doses of morphine. Codeine never produced any symptoms of withdrawal. Heroin, morphine, and codeine produced cross tolerance; in the case of heroin and morphine one drug relieved the symptoms produced by withdrawal of the other, but codeine produced no relief of the symptoms caused by withdrawal of morphine or heroin. The experimental evidence therefore confirms the clinical belief that codeine is not a drug of addiction.

THE EPIDERMIS AND ULTRA-VIOLET RADIATION.

The permeability of human skin to ultra-violet rays has been investigated at the Lister Institute by N. S. Lucas,[1] who has repeated some old observations of Hasselbach, using a somewhat similar method and correcting for various sources of error. Since the layers immediately under the epidermis are vascular, Lucas experimented with epidermis, which was obtained from the front of the forearm by blistering. The source of light used was a Hewettic quartz mercury-vapour lamp, which, of course, does not give the same restricted range of wave-length as the sun does. Owing to the presence of a small proportion of ozone in the earth's troposphere all rays of a shorter wave-length than 3300 A (Angstrom units) are filtered out, being cut off completely at 2850 A. Lucas studied the transmission of waves from 4370 to 2560 A and found that the longer waves were almost completely transmitted. He says, referring to what he considers his most representative experiment: It appears then that in the range of wave-lengths of the sun's light arriving at the earth's surface which are active in the cure of rickets amounts varying from 55 per cent. for wave-length 313 $\mu\mu$ (=3130 A) to 26 per cent. for wave-length 294 $\mu\mu$ (=2940 A) may be transmitted to the dermal capillaries.[2] He concludes that the apparent absorption of ultra-violet light by epidermis as determined by the usual methods of photometry is not entirely true absorption, but is in part a scattering of incident light by the epidermis which is not optically homogeneous. This scattering causes much less loss of transmission in vivo than under experimental conditions, and is dwarfed by true absorption for short waves of 3000 A or less. The curves of absorption, he remarks, are very similar to those of many proteins and amino-acids. His values are very much higher than those found by Hasselbach. It appears from this work that the clean epidermis is a fairly good transmitter of those beneficial ultra-violet rays which fall upon it and is selective against the shorter rays which are not found in the solar emission as we receive it, but are present in unscreened artificial ultra-violet light.

CAUSES OF DEATH AMONG DOCTORS.

From time to time the *Journal* of the American Medical Association analyses the records of deaths of physicians published in its columns, and the latest group is made up of 2943 which occurred in 1930.[3] Although these records may err through missing some members of the profession who died young, it is interesting to compare them with our own occupational data[4] which deal with all medical practitioners who died in this country during 1921–23 and include 1578 deaths. In the United States the average age at death was 63·7 years; in England it was just below 63 In the States 4·4 per cent. of deaths were due to accidents (half being motor-car accidents), and in England 3·7; in the States 2 per cent. were due to suicide, and in England 2·2 per cent; in the States 1·3 per cent. were due to cirrhosis of the liver, and in England 1·4 per cent. In both countries heart disease claimed most deaths. Next in order followed, for the States, cerebral hæmorrhage, pneumonia, nephritis, cancer, and arterio-sclerosis; and for England, cancer, pneumonia, cerebral hæmorrhage, arterio-sclerosis, and nephritis. It is significant that, although the order is slightly different, the same seven great causes of death for both groups claim most victims. In the absence of any census of physicians in America, no death-rates can be calculated. But our own records, which give mortality-rates comparable with the general standard, show the death-rates which are unduly high to be those of suicide, cirrhosis of the liver, accidents, digestive diseases, appendicitis, and pneumonia, in the order given. The medical profession shares several of these high rates with other professions; but pneumonia and accidents seem to present special risks for the doctor, which is easily explained by the conditions of his calling.

SALE OF PROPRIETARY MEDICINES IN U.S.A.

We have read with sympathetic interest the details of a proposed plan for the control of the sale of proprietary remedies in New York. The author of the scheme is Dr. Samuel M. Gordon, secretary of the council on dental therapeutics of the American Dental Association, who was invited by the Commissioner of Health of New York to make a survey of the present drug administration of that city and offer suggestions how to bring its activities into line with present-day notions. The sale of proprietary medicines in the United States is already subject to control; the operation of the Pure Food and Drugs Acts and the special regulations adopted in various States suffice to prevent many of the practices which are common enough in this country. Nevertheless, American legislation has not sufficed to suppress the evil, and although the heyday of the business seems to be past in the United States and the old method of advertising may have been suppressed, "it has been replaced," says Dr. Gordon "by a more subtle and more insidious exploitation of articles for various groups of ill-defined conditions, based on an evasive appeal to the health desires of the public . . . . Patent medicines are exploited by means of subtly written advertisements in such manner that the uncritical and none too careful reader is allowed to read into general, and, as a rule misleading statements, that he or she is suffering from diseases or conditions for which a patent medicine in question possesses curative properties." The cunningly worded devices do not contravene the law, although they are obviously contrary to its spirit. What has happened is that the Drugs Acts having made the "lie direct" a penal offence it has become necessary for medicine-mongers to resort to "the lie by inference." It is the desire of the New York Health Department to outwit the users of the "lawful" form of falsehood, and it is thought that this could be accomplished by putting Dr. Gordon's scheme into operation.

Most of us know the dexterous member of the family who tells us without looking at it which particular card "you hold in your hand." The trick depends upon the conjuror's ability to make us pick the card he intends us to pick. Dr. Gordon writes:—

---

[1] Biochem. Jour., 1931, xxv., 1, 56.

[2] The author here uses $\mu\mu$ as in Germany to denote a thousand millionth of a metre. In the United States of America $\mu\mu$ denotes a million millionth of a metre. The ambiguity is a strong plea for the universal adoption of the Angstrom unit or "tenth metre," the equivalents of which we have added.

[4] Occupational Mortality. Registrar-General's Decennial Supplement. England and Wales. 1921. H.M. Stationery Office. 1927.

> To-day advertising has invested itself with a psychological basis intended to make people purchase something for which there is no intrinsic need. It does not appeal to real needs, but it appeals to desires stimulated by the wording of advertising. When applied to clothing, automobiles, radio, and the like, the loss is merely an economic one. Where applied to patent medicines the aim is to make well people believe they are sick, and sick people believe they are very sick. A stimulation mentally to force the purchase of a patent medicine is thus brought about by adroitly worded advertising in newspapers . . . . Consequently this is not merely an economic waste but presents an actual menace to the physical and mental well-being of the country.

The morality of salesmanship which aims at inducing people to buy something they do not want and cannot afford to pay for has often been argued. It would, however, require a good deal of special pleading to whitewash the salesman or the copy-writer who, for the sole purpose of gain, succeeds in making some deluded person buy a cure for cancer or a pill to rejuvenate the arteries. Dr. Gordon's method would be to put such a person in gaol. The case as put by him furnishes convincing evidence of the need of further action to protect the fool from his folly. One difficulty lies in the fact that even people of culture are among the victims from the nostrum-monger and a considerable proportion of his earnings comes from the pockets of learned ignoramuses. If, then, in spite of all their enlightenment some apostles of culture are not averse from swallowing rubbish in the guise of nostrums, what is to be done to get down to the masses? Dr. Gordon believes in specialised education. He would invite the citizens of New York to write to the Health Department for information and advice on specific medicines in which they are interested. He would set up what he calls a rogues gallery. He would invite newspaper proprietors to submit advertisements of patent medicines to the Department before publication and to undertake to require advertisers to confine statements to the recommendations of the Board of Health, and his plan for dealing with those publications "which show a tendency to subvert the public health interest to financial returns" is to make them see light by a carefully planned educational campaign through the medium of other papers which are willing to follow the Department in their campaign for honesty and decency in medical advertising to the public. If the experiment is tried, as we hope it will be, the results will be examined with interest here.

A SEROLOGICAL TEST FOR CANCER.

Dr. Bendien's book,[1] which has been having much publicity in the daily press, proves on examination to be a soberly written, highly technical dissertation on the physico-chemical state of the proteins of the blood-serum. The investigations are based on a flocculation reaction which occurs when a solution containing mixtures of sodium vanadate and acetic acid in slightly varying proportions is added to the serum. Twenty different solutions of these sodium vanadate and acetic acid mixtures are placed in test-tubes containing equal amounts of normal human serum. Flocculation begins in the tube containing mixture No 6, rises to a maximum in mixtures 14 and 15, and then diminishes until the end of the series when it disappears in No. 20. The various factors which might affect this reaction have been studied in great detail—for example, viscosity, sedimentation of red corpuscles, and relation of globulin to albumin. One point to which Bendien attaches importance is the change produced in the reaction, if the serum has been inactivated previously by heating to 56° C. for half an hour. The flocculation then does not begin in mixture 6, but only in mixture 7. In a number of pathological conditions this shift of the flocculation reaction is reversed after heating the serum—that is to say, the reaction develops before mixture No. 6. From all these considerations Bendien arrives at the conclusion that in certain pathological conditions a new type of protein appears in the serum. That this is true is confirmed, he thinks, by the finding that in different diseases the flocculated material gives different and characteristic pictures on spectro-photometric examination. If the change in the reaction occurs regularly in the serum of patients suffering from cancer, especially in the early stages, it should form the basis of the long-sought serological test. On this point Bendien states that flocculation below mixture 6 indicates the presence of cancer or tuberculosis. He even believes that a disposition to these diseases finds expression in a shift of the flocculation reaction which differs for the two diseases. But the evidence he submits on this aspect of the problem is disappointing. There are now on record quite a number of serological reactions in which the serum of cancer patients shows differences from that of normal persons. But since similar differences are exhibited by serum from patients suffering from other diseases the diagnostic and even the theoretical value of these reactions is small. The material submitted by Dr. Bendien to test the diagnostic value of his reaction is, as he himself admits, not very extensive, and he is careful to point out that the subject requires further study. So far as it goes there is little evidence that the reaction is clinically specific for cancer.

FIRST-AID ON THE ROADS.

APPROPRIATELY enough for Safety Week in this country, Mr. Pierre de Bernonville, secretary of the Standing International Commission for First Aid on Highways, gives an account[1] of the rapid evolution of first-aid on the roads during the last few years. It is satisfactory to note in his international review that the first country to organise this work systematically was Great Britain. Some ten years ago the British Red Cross Society and the Order of St. John of Jerusalem set up a high-road service, using motor ambulances from their war stock. A little later, Germany, Belgium, France, and Switzerland took similar steps. Other countries to follow were South Africa, Italy, the United States, and, more recently, Denmark, Holland, Norway, Persia, Poland, Siam, and Sweden. In March, 1930, the Central International Touring Board, which is the supreme authority of the touring organisations, and comprises the Automobile Club and the Touring Club groups, pronounced in favour of a policy of coöperation between all bodies interested in the organisation of first-aid posts on highways. The Board and the Red Cross quickly established satisfactory working relations, and the matter was placed on the agenda of the Fourteenth International Red Cross Conference in Brussels. Here it was agreed to constitute a standing commission to assure uniformity of action; the first meeting of this *Commission Internationale*

[1] Review and Information Bulletin of the League of Red Cross Societies, May, 1931.

ermanente de Secours sur Route was held at the ffices of the League of Red Cross Societies in Paris st November, and at its second meeting in February ethods of establishing satisfactory collaboration etween the Red Cross and tourist bodies were tudied, as was also the problem of first-aid posts t points where roads cross frontiers. The next eeting of the Commission will be held in November. Ir. de Bernonville's paper concludes with a statistical nalysis of the mortality-rates from road accidents er 100,000 in various countries. While this rate is 9·5 for the U.S.A., it is only 8·4 in England and Vales, and as low as 2·1 in Norway.

THE DIFFICULT CHILD.

THERE always have been difficult children, but he "problem child," as the unfortunate youngster s sometimes called, has come to occupy a prominent lace in the public eye only of recent years. This nay be at least partly due to the fact that in the days f unrestricted families children very largely brought ach other up, and on the whole did not do their work oo badly. Now that families consist of ones and wos, and even the moderate-sized family is so spaced ut that every child is almost an only child, the ttention of adults is heavily focused on the young, nd their interaction is very probably bad for both. Among many recent discussions of this subject were ix lectures delivered under the auspices of the Jewish Health Organisation at Toynbee Hall last ummer. They were published in *Mother and Child* and are now reprinted as a pamphlet, in the pages of which everyone interested in the difficult child will ind food for thought.[1] Dr. Emanuel Miller deals with the general characteristics and history of the problem child and with the rôle of the psychiatrist and the coördination of social, psychological, and medical factors in his treatment. Dr. Noel Burke describes the management of a child-guidance clinic, and the physical factors in the child's make-up. Miss Beatrice Robinson discusses the functions of the social worker, and Mr. M. Fortes the intellectual endowment of the difficult child, who is by no means usually defective in brains. It is an essential feature of the child-guidance system, imported from America, that the child is studied by a team of whom only one or perhaps two members are medical. This has many advantages, not the least of which is that stressed by Dr. Miller when he says that the case conference exists psychologically in order, that those concerned in the case should understand one another; that, for instance, the psychiatrist should meet the teacher and discover whether the problem is a function of the teacher's personality, and that the teacher in turn should tell the psychiatrist frankly if she thinks that he is manufacturing a case. The system also enables the psychiatrist to deal with a very much larger number of cases than would be possible if he had to undertake the necessary research himself. It has, however, one peculiar feature which may prove of great importance and to which more attention should perhaps be directed than has been done so far. This is that the home has been made peculiarly the province of the social worker. The psychiatrist himself never sees the home and does not always see the parents. Yet it is a truism to say that the parent is the principal factor in the genesis of the difficult child. It is also a truism to say that the parent is the most difficult part of the child's environment, both for the child and for the psychotherapist. It is certainly true that in many cases some simple misunderstanding or maladjustment can be explained by a gifted social worker to an intelligent and coöperative parent. An alteration, for instance, in the child's diet or punishments or working hours may produce the desired result. There is also a large number of cases where the parents are not intelligent or coöperative, and these can be dealt with as effectively by the social worker as by anybody. It may be necessary to dismiss them as hopeless and to remove the child from them, or they may be amenable to lengthy, patient, tactful persuasion such as she, better than anyone else, knows how to apply. But all too often the child's neurosis is its reaction to a genuine psychological failure on the part of the parent, and is concerned with just that problem over which its parents have stumbled or from which they have turned away. In these cases the only genuine treatment for the child is psychological treatment of the parent; anything else is merely patching. Is the medical profession wise in tacitly allowing this type of case to be handled by the social worker? It may be argued, indeed, that only the skilled psychotherapist himself can determine which case falls into this class, and it is certainly true that no more delicate and difficult task confronts him anywhere than the task of laying bare to one or both parents the real secret of their child's misbehaviour when that secret is their own most tender spot. The problem of the parent has not been wholly solved by the child guidance scheme.

A COSMETIC QUESTIONAIRE.

THE treatment of hypertrichosis has been made the subject of continental inquiry.[1] The great majority of authorities are emphatic in their condemnation of X rays for this purpose, a notable exception being Dr. Guido Holzknecht, who holds the chair of medical radiology in Vienna, and whose unrivalled experience entitles his opinions to respect. He believes that X ray treatment has its place in selected cases, provided that the risk is realised and technique is faultless. He would base his selection on the degree and localisation of growth, the character of the skin, and the patient's age. He would not apply X rays to lanugo hairs, to sporadic single strong and coarse hairs, to symmetrical moustache hairs, or to hair on the parotid area. The skin over the extremities he regards as more sensitive to X rays than that of the face; persons with a delicate complexion are more liable to injury than those with a thick sebaceous type of integument. He would allow a period of months to elapse between each epilation, the total of which should not exceed five. The existence of a controllable endocrine factor should be borne in mind, and search made for ovarian or suprarenal dysfunction. In no case would he promise a cure, any more than in eczema or tuberculosis. F. Juliusberg thinks well of a combination of X rays with thallium acetate by the mouth, as already used with success for temporary epilation in tinea tonsurans. At present he relies chiefly on the time-honoured electrolysis or the more recent destruction of the hair follicle by instantaneous electro-coagulation. Drawbacks to these are the waste of time, the expense, and the considerable chance of recurrences. It is not a good method when the hairs are close together on account of the risk of scarring.

[1] Dermatologische Wochenschrift, April 4th.

The pumice-stone treatment demands great patience to avoid irritating the skin; it has its use over large areas, and if persisted in for years undoubtedly promotes permanent atrophy of the follicle. Chemical depilation with barium and strontium salts also brings the danger of irritation, and sufferers would be wise to prefer extraction with the epilation forceps for isolated hairs, or the safety razor. The new electric clippers, set at 1/10 mm., give safe if imperfect results. E. Langer (Berlin) condemns X rays and gives the following detailed directions for the use of pumice-stone. After a preliminary shave (the upper lip is the main indication), 5–20 per cent. pernatrol soap (H_2O_2) is applied daily for 5–10 minutes and well lathered; a smooth piece of pumice-stone is then gently rubbed over the hirsute area for about the same time. The treatment must be intermitted on the slightest occurrence of irritation. Infection is prevented by the application of eau de cologne along with a non-greasy cream and powder. G. Nobl (Vienna) prefers electrocoagulation to electrolysis, because its effect is limited to the point of the needle and does not extend along the shaft. He condemns X rays, as also does Prof. H. T. Schreus (Düsseldorf), who states that the removal of cosmetic stigmata has been sometimes more than offset by the production of hoarseness from injury to the larynx, by xerostoma from damage to the parotid, and even by epithelioma. P. Unna, jr. (Hamburg), agrees with Nobl on the advantages of electrocoagulation, but he uses X rays according to Holzknecht's technique in very pronounced cases to weaken the growth of hair when a combination of other methods is used to achieve the final result.

SURGERY IN ANIMALS.

IN his oration before the Medical Society of London, reported on another page, Sir John Rose Bradford spoke wisely of the lessons to be learnt from comparative medicine. Many of the leaders of our profession have sought such inspiration in the past and have found in the solution of problems by animals a help to similar conundrums in man. Surgeons will therefore, we think, find a perusal of the March issue of the *Veterinary Journal*, a special surgical number, of more than ordinary interest. They will meet here a group of men engaged on similar work to their own and tackling it in the same way, but with particular problems and difficulties inherent in the nature of their patients.

Man has developed a fraternal interest in the beasts which serve him, that prompts him to prevent any suffering that can be avoided, and to alleviate it when it appears. The easiest way to end animal suffering is to kill the diseased and the injured; curative treatment, which may be lengthy and in some cases expensive, is primarily undertaken not for the benefit of the patient but of its owner. Most veterinary operations are done either to overcome some disability interfering with the usefulness or earning capacity of the animal as a servant, or in the case of pedigree stock, to preserve it for stud purposes. Castration is a familiar example of the first class of operation, done in creatures ranging from cats to cattle, to render them more docile, and in birds to increase their weight. Sporting animals suffer from many common disabilities for which surgical aid is sought. Roaring, due to paralysis of one vocal cord, usually the left, renders a horse, otherwise perfectly sound, unfit for hunting or racing. Tracheotomy has been carried out for years to overcome this disability, but has the disadvantage of unsightly appearance and the need of frequent dressing; more recently the ventricle-stripping operation, advocated in this country by F. T. G. Hobday, has largely replaced the older method. Dogs have, till lately, come under the veterinary surgeon chiefly as household pets. Being bred over centuries under conditions remote from those under which their ancestors were evolved, living in circumstances of food and housing not differing greatly from those of their masters, and surviving often far beyond the physiological old age of an animal under natural surroundings, they suffer from many of the diseases to which human beings are liable. For this reason, and because of affection of their owners, canine surgery includes many of the procedures common in the hospitals of man. Dentures and spectacles have even been supplied to make good the losses of old age. Greyhound racing, moreover, has brought the dog that may win large sums for its owner, and has created the science of canine orthopædics.

Fractures are common in animals, especially in horses used for hunting and racing, and in dogs, when they are usually the result of a motor accident. In the larger quadrupeds the difficulty of reducing and splinting one of the limb bones is almost insuperable, and the animals are afterwards useless except for stud purposes. They are usually shot, though plating may be attempted in valuable horses. Fractures of the maxilla are, however, treated by wiring. Dogs are much more amenable patients and their fractures are treated by splints, of wood or plaster, with satisfactory results, a small degree of lameness detracting little from the animal's usefulness. Fractures in birds are treated with gum bandages.

The interest of surgeons in veterinary work is often of a more direct kind. Operative surgery is never taught in this country as it is in America, by instruction in operating upon animals, but surgical research in many of its branches demands animal experiments, and the research department of a modern hospital is a counterpart in miniature of a veterinary hospital. On the whole the conditions which govern animal surgery bear a striking resemblance to those under which we work. The majority of our instruments have their counterpart in the veterinary theatre, but those used on the larger animals are naturally modified greatly to obtain increased power. The theatre is similar in lighting and cleanliness; the operating table is a surgical one in miniature, for it is only used for small animals. The larger ones are operated upon either standing or lying according to the anæsthetic. Anæsthesia is produced by the recognised methods. Chloroform and ether are used for inhalation, avertin for rectal anæsthesia, and novocain or the ethyl chloride spray for local anæsthesia. Spinal anæsthetics have little application in animal surgery. Depilation is a more difficult problem in animals than in man; in some the razor is used, but it is more common to apply a depilatory paste of 25 per cent. barium sulphide, left on for five minutes. It is fortunate that dumb creatures do not suffer from pre-operative anxiety. The operation itself is conducted along lines that are familiar. The sutures and ligature materials are those used by surgeons, but, owing to the nature of the operation performed, many of the procedures may be strange. The abdomen is commonly opened by a longitudinal incision, but in experiments on cats it has been stated that transverse incisions heal with less trouble, and it would be interesting to know whether any veterinary surgeons have had a similar experience. A writer in the *Veterinary Journal* employs MacBurney's incision for ovariotomy in a mare. The commonest of our abdominal operations, for appendicitis, peptic ulceration, and gall-stones, do not appear to be in demand, but strangulated inguinal hernia occurs in dogs. Intestinal obstruction from enteroliths or swallowed foreign bodies takes proportionately a much more important place, and is treated by enterostomy, or in late cases, by resection. End-to-end suture of the intestines of dogs and cats is found to be unsatisfactory owing to the small lumen and thick walls of the gut, and lateral anastomosis is preferred. Pyometra is common in bitches, demanding hysterectomy.

It is in post-operative treatment that the difference between human and veterinary surgery becomes more apparent. Animals, with the exception of race horses and some highly bred dogs, are of hardy stock; they do not suffer from surgical shock unless the operation has been exceptionally severe, and their tissues heal well. But the patient must be returned to a kennel or stall, which, however cleanly, is far from sterile. Dressings may be applied but are never left alone, and in most cases are soon licked or bitten off; rest to the injured part is extremely imperfect. In this respect dogs and cats, when their confidence has been gained, make the best patients. But in general the veterinary surgeon has to rely on antisepsis rather than asepsis during the post-operative period, and while serious infection is rare so is primary union.

SEDIMENTATION-RATE IN TUBERCULOUS CHILDREN.

SINCE a department for tuberculous children was opened at the new St. Johannes Hospital in Budapest Dr. L. von Csöke has investigated[1] the sedimentation-rate of the red blood corpuscles for nearly every patient admitted. The method of Westergren was used throughout and the results standardised for the degree of sinking observed in an hour according to the accepted formula. Altogether 329 children were investigated with more than 1000 total sedimentation-rate determinations. A large proportion of these children suffered from tuberculosis of the bronchial lymphatic glands, a condition in which signs and symptoms are scanty and it is often difficult to establish whether the disease is active or latent. Dr. Csöke considers that the border-line value for the sedimentation-time in such cases is 12 mm. Over this value were 108 cases of active bronchial gland tuberculosis with an average rate of 18 mm., while 52 cases with latent disease showed an average rate of 10 mm. This is in accord with previous observations by Rókay, who considered rates of over 13 mm. in fever-free cases as in favour of active disease in the glands. The sedimentation-rate in six cases of what he calls "epituberculous infiltration" also gave an average of 18 mm., but the association with bronchial gland involvement with this condition made it difficult to draw deductions. The results for pulmonary tuberculosis in children followed much the same lines as those already established for adults in numerous centres. With fibrotic cases an average of 40 mm. was obtained, while for more acute exudative cases the average rate was 100 mm. Four cases of miliary tuberculosis gave rise to some difficulty because the values varied from 6 to 80 mm., and it is known that in moribund cases the sedimentation-rate may closely approach the normal. In order to obtain more help from the sedimentation-rate in distinguishing between cases with good and bad prognosis Dr. Csöke carried out a series of investigations in which the rate for each quarter of an hour was noted. The results obtained for 52 children could be divided into three groups. In the first the maximum degree of sedimentation was observed in the first half-hour and was an indication of a serious degree of disease. The second group comprised those cases where the maximum degree of sedimentation occurred in the second half hour; here the clinical features were slight and the prognosis good. In the third group sedimentation-rate was nearly regular for each 15-minute period in the hour; this occurred in the terminal stages of the disease, being also a feature of physiological sedimentation. The value of this differentiation can be made clearer by an example. If a child is found, for instance, to have a sedimentation-rate of 25 mm. it is possible from a consideration of whether the rate is maximum in the first or second half of the experimental period to say that the disease process is serious or slight respectively. Very high values for the sedimentation-rates were obtained in 18 cases of surgical tuberculosis; the highest rate of the present series was in a child with extensive spinal caries who gave a rate of 192 mm. It was observed that the sedimentation-rate in three cases of bone and joint tuberculosis was closely associated with the presence of intercurrent complications, and indeed could be taken as a very early indication of their being present, for example, weeks before clinical evidence of abscess formation. Dr. Csöke discusses, in light of his own and others' results, some of the theoretical aspects of the sedimentation-rate, but he is unable to come to any definite conclusion as to the exact mechanism. He points out however that in children the physiological values are higher than in adults, and that before the age of 10 years the sex differences, well recognised in adults, are not so pronounced.

THE next session of the General Medical Council will commence at 2 P.M. on Tuesday, June 2nd, under the Presidency of Sir Donald MacAlister.

WE regret to announce the death of Dr. Thomas Robinson Glynn, for 40 years professor of medicine in the University of Liverpool. He died on May 12th at St. Asaph at the age of 90.

LONDON HOSPITAL MEDICAL COLLEGE.—Lord Macmillan will distribute prizes and certificates to students of this College on Wednesday, June 24th.

JOINT TUBERCULOSIS COUNCIL.—A post-graduate course on tuberculosis (study tour) has been arranged by this Council to take place in Holland. Various institutions for combating tuberculosis in Holland will be visited and the methods employed will be explained. The tour will begin on June 29th and end on July 4th. There will also be a post-graduate course on tuberculosis in Lancashire from Oct. 19th to 24th.

The Council announces that Dr. Peter W. Edwards, medical superintendent of Cheshire Joint Sanatorium, near Market Drayton, Salop, has been invited to give a series of short practical courses on modern methods of treatment in tuberculosis of the respiratory system with special reference to collapse therapy. Methods of sanatorium administration will also be demonstrated. No class will exceed four members in number, and no course need last more than three days if more time cannot be spared. Arrangements for board and residence can be made within a convenient distance of the sanatorium.

Details of all these courses may be had from the hon. secretary for post-graduate courses at 8 Highway-court, Beaconsfield, Bucks.

---

SPECIAL ARTICLES

THE MECHANISM OF MICROFILARIAL PERIODICITY.

BY CLAYTON LANE, M.D. LOND.,
LIEUT.-COLONEL, I.M.S. (RETD.).

NEARLY two years ago, in writing on the difficult question of the mechanism of filarial, that is microfilarial, periodicity, I concluded as follows:—

> "If the embryos of *F. bancrofti*, when absent from the skin blood, harbour elsewhere, it is physically unthinkable that they should do so in the overwhelming current of the large blood-vessels; they accumulate in these in numbers from the lymph trunks at or after death only. Nor are they being held back from skin blood by contraction of visceral capillaries, since these can hardly close on one species and open for another circulating in the same blood at the same time. If it were their posture which maintained microfilariæ for many hours daily in deep capillaries, posturing would not be completely discarded in drawn blood. Living microfilariæ have never been found congregated by day in any deep capillaries in numbers corresponding in any way to those demanded by this hypothesis of the mechanism of periodicity; no secret retreat of theirs has been discovered. If they were long-lived, old should be distinguishable from young larvæ by visible changes induced by their activity. Periodicity, then, cannot reasonably be explained as being due to a changed distribution within the blood-vessels of long-lived microfilariæ. Moreover, such a condition holds no biological advantage for the species.
>
> "The known facts have a cumulative weight in favour of the hypothesis that microfilariæ within the body perish rapidly, at least daily, and that periodicity is the result of simultaneous cyclical parturition."[1]

Fresh work reported on filariasis seems to justify a return to the matter; but first it may be stressed that the title of the paper under reference meant exactly what it said; it considered the mechanism, that is the mechanical means, by which microfilarial periodicity in the peripheral blood is produced. It seemed so obvious that the mechanism must be brought into action "by some stimulus at present unknown," and that the stimulus and mechanism were two distinct things which should be dealt with separately, that speculation as to the former was then, and is now, deliberately avoided as not being pertinent to, but as merely complicating, the point at issue. Perhaps it was by reason of such a misunderstanding that "L. E. N."[2] has dismissed filarial periodicity in these words. "Most of the theories are dependent on isolated observations and none of them appear to fit half the known facts." If that is not the case, an enumeration of that particular half of the known facts which cyclical parturition does not mechanically explain is overdue. Another point may be expanded. Sir Patrick Manson definitely attributed microfilarial periodicity to retirement, during the day, of microfilariæ from the skin principally to the large arteries and lungs. P. H. Bahr[3] dealing with a case of the non-periodic form found in just these situations 69 per cent. of embryos made visible by blood films. It can hardly be doubted that Manson would not have suggested "retirement" as an explanation of periodicity had he first had such an experience with the non-periodic form.

TWO PHYSIOLOGICAL FORMS.

Commenting on my paper Dr. P. H. Manson-Bahr[4] expressed the opinion that there was nothing unbiological in the idea that female filariæ have certain cyclical and well-developed periods for emptying the uterus of imprisoned embryos. He further stated his belief that the two physiological forms of *F. bancrofti* had different habitats—the adults of the nocturnal form appearing to live in the main lymphatic trunks in the neighbourhood of the thoracic aorta, maintaining that is a central location; whereas those of the non-periodic form inhabit the "lymphatic glands, epididymis, tunica vaginalis, and perhaps the organs of the body. *It maintains a peripheral distribution.*" Work by F. W. O'Connor, R. Golden and H. Auchincloss, already noted in THE LANCET,[5] has since lighted up this matter. X rays, they found, could be made to throw shadows of objects in the subcutaneous tissue, and excision of parts which threw the shadows showed that these latter were due to calcified filariæ; moreover, there were in these particular instances as many living shadowless filariæ as calcified shadow-throwing ones. Fifteen subcutaneous shadows were in fact detected in one limb, and the filaria was Porto Rican with nocturnal periodicity. This paper made it clear, first that adult *F. bancrofti* swarms (the word seems fair) in habitats whose search has been greatly neglected, and second that a peripheral distribution turns out to be not specially characteristic of the non-periodic form. Dr. Manson-Bahr, who has recovered 13 live filariæ from a single epitrochlear gland of the size of a pigeon's egg, further notes that from his autopsies he would not place the number of fecund and mature *F. bancrofti* present in a filariated individual at one time as being higher than 20; he calculated on that basis that 328,000 embryos would be circulating at one time for each female filaria harboured; and he noted that, if there is daily death of a cyclical brood of microfilariæ, this prodigious number must be produced daily by each female worm. But since the Porto Rican work has subsequently shown that so many worms may lie in habitats not hitherto systematically investigated, the daily birth-rate of each female must reasonably be taken as greatly below this huge number. Time has, then, shown that these difficulties in accepting cyclical parturition as the cause of filarial periodicity have not the weight they appeared at that time to possess. On the other hand, Dr. Manson-Bahr's letter offered what seems to be very definite new evidence of the short life span of microfilariæ in the body, for he wrote:

> "In pure chyluria such few observations as I have made go to show that the filarial embryos are usually dead by the time they appear in the urine; but in hæmatochyluria where there has been outpouring of the blood into the chylous urine . . . numbers of living microfilariæ appeared in the urine passed at night time."

That single observation suggests (does it not indeed imply?) that urine is not in itself deadly to microfilariæ, and that they are usually dead when they are passed in it because their life span has been exceeded by the time they reach the bladder after a slow progress through blocked lymphatics. What is the usual finding here? The point seems unremarked in print and I have no personal records. Yet it should be readily investigated, and its importance is clear in attempting to discover whether *F. bancrofti* has in the human body a life of only a few hours.

FRESH EVIDENCE OF SIMULTANEOUS CYCLICAL PARTURITION.

The argument put forward in 1929 as to the mechanism of microfilarial periodicity was, it will have been noted, essentially inferential. It consisted in the discussion of the mechanical agents by means of which various writers have attempted to explain periodicity as a redistribution of microfilariæ within the body, their rejection one by one as being mechanically unreasonable, and the conclusion that the only reasonable explanation left was simultaneous cyclical parturition by female worms; it used that process of exclusion which has so often led medical men to right diagnostic conclusions. There was little direct evidence for cyclical parturition, for Manson's prompt and widely accepted refutation of Meyer's suggestion to this effect laid the matter at rest for half a century.

But since my reopening of the subject two years ago, more direct evidence of cyclical parturition has been sought for and has, I think, been found. F. W. O'Connor[6] has reported the result of examination of a testis and cord handed over to him. It had been removed at 5 P.M. from a Porto Rican who had died apparently from 6 to 12 hours earlier. As has been mentioned, periodicity is here nocturnal. General dilatation and hypertrophy of lymphatics suggested that there had been blockage in the abdomen. In a dilated lymphatic vessel of the parietal layer of the tunica vaginalis lay a fully developed female *F. bancrofti* containing no microfilariæ but having the posterior two-thirds or more of the uterus full of eggs. This was the only worm in which calcification had not at least begun—the only living worm. Microfilariæ were not found within half an inch of this worm nor yet in the upper part of the specimen; but about an inch and a half above the worm there was a zone in which they were present in the walls of the lymphatic vessels and in the connective tissues round them, and indeed were very numerous about the equator of that zone. O'Connor concludes: "Histological studies suggest that the hypothesis of Clayton Lane, to the effect that the phenomenon of filarial periodicity is due to simultaneous cyclical parturition of the gravid female, is correct." Further, Dr. O'Connor has generously put at my disposal his notes on a more recent and as yet unpublished case. A man was shot late at night, the right testis, cord, and hydrocele being removed next day. There were a few microfilariæ in some of the blood-vessels and enormous numbers in the right hydrocele. In the tissues were discovered four fully developed gravid females. "Every stage of development of ova and microfilariæ was found in each of the worms except the final stage . . . . In the four worms the stages of development were identically the same and [the microfilariæ] would therefore, had the patient lived, been born at the same time." There was then, as O'Connor himself points out, evidence pointing towards simultaneous cyclical parturition, and it is sufficiently satisfying to warrant further work on a considerable scale on the same lines with a view to determining whether this is a normal finding in regions in which microfilarial periodicity occurs, and an abnormal one in those in which there is non-periodicity.

DESTRUCTION OF MICROFILARIÆ.

As regards the destruction of microfilariæ there is now this to add. Lymphatic filarial obstruction has hitherto been considered as explicable in terms of damage done to main lymphatic trunks, or to lymphatic glands by adult worms or by larvæ injected by mosquitoes. But the work of O'Connor and his colleagues has shown that adults may live in numbers in the smaller lymphatics of the limbs and on the distal side of all lymphatic nodes; the conditions then are such that, so long as the lymph circulation remains reasonably normal, every microfilaria from these adults must pass through the nodes concerned, and, if the fate of hookworm larvæ be any criterion, the passage will induce considerable activity in them during the process of getting rid of the embryos. Persistent passage of embryos is then likely to be followed by fibrosis and lymphatic obstruction; so that in the destruction of microfilariæ, in the removal of their dead bodies or the dissolved products of them, and in subsequent production of lymphatic obstruction, these nodes are likely to prove to play a part—if all microfilariæ die within 24 hours a very considerable one. Even in this small corner of the filarial problem there is much that will repay intensive study.

MEDICINE AND THE LAW.

Artificial Cream.

THE Artificial Cream Act of 1929, which began life as the Reconstituted Cream Bill, has shown that hasty and unofficial legislation encounters perils in draftsmanship. Its origin is well known. The dairying industry, hard hit by restrictions on the use of preservatives, found itself fighting two new commercial competitors. One was synthetic cream, derived from vegetable fats and easily distinguishable from raw cream on analysis. The other, called "reconstituted cream" though in fact it had never been cream, was a substance made from butter-fat, milk powder, and water and thus contained elements actually derived from the cow. Agricultural interests in England would have preferred that Parliament should absolutely forbid the use of the word "cream" except in relation to genuine dairy cream. The Artificial Cream Act, however, when it emerged after copious amendment as a valid statute, was not so drastic. The Act defines "cream" and "artificial cream." Its principal provision enacts that nobody shall sell "under a description or designation including the word 'cream' any substance *purporting to be cream* or artificial cream as defined in this Act unless (*a*) the substance is cream as defined in this Act, or (*b*) where the substance is artificial cream as defined in this Act, the word 'cream' is immediately preceded by the word 'artificial.'" Commenting on the words "purporting to be cream," which we have italicised above, the editor of Bell's "Sale of Food and Drugs" observed that the enactment does not apparently apply to articles of food like cream buns which do not "purport to be" cream, though they may be thought to contain it. His observation has been proved correct by the King's Bench Division on the appeal of J. Lyons and Co. from a decision of the Swindon justices.

A county council inspector in Wiltshire bought something labelled "Lyons' Swiss Rolls, Chocolate Sponge (Cream Filled)." There was also a purchase of "Lyons' Cream Sandwich (Vanilla Filled)." The justices thought these articles of food were sold as containing cream; they held that they did not contain cream but a cream-like substance (perfectly wholesome) made of an emulsion of fat from vegetable oil and not derived from cream or milk. The justices convicted but the High Court sent the case back to them for their decision whether the articles sold were sold as "purporting to be" cream. The justices, at a further hearing, decided in the affirmative and imposed a conviction. The King's Bench Division has now allowed the appeal of the confectioners. As Lord Hewart says, the Act uses the words "purporting to be cream," not "purporting to contain cream." It may be that the statute was meant to cover composite articles of food such as cream sandwiches, but the statute does not say so. If there is a gap, the gap must be filled by the legislature not by the law courts. As it now stands, the Act applies only to cream as a separate commodity. Mr. Justice Avory, concurring, said he could find no evidence to support the justices in their decision that the articles were sold as substances purporting to be cream. Lord Hewart had expressed the opinion earlier that it might be unfortunate, and in some cases entirely misleading, that composite articles should be sold under names including the word "cream." But the judges are obliged to confine themselves to what Parliament actually says; they cannot speculate on what Parliament might have meant to say.

Coroners and Post-mortem Examinations.

There was lately mentioned in these columns an inquest upon a young soldier who died after being run over by a motor-car. A medical witness had given evidence that the consequent injuries to the head were so grave that he deemed it unnecessary to make a full post-mortem examination; the coroner took the witness to task for the omission; death, he suggested, might have been due to heart disease. A converse case has since occurred as the result of an accident to a soldier at Chichester Barracks. It appeared that he had been practising a gymnastic exercise known as the "front dive" over two forms on each side of a bed-cot with a mattress on the further side—an exercise ordinarily performed in the gymnasium under experienced supervision. As the man came down on the mattress, he landed on his head. The depôt medical officer was summoned and the patient was removed to the Royal West Sussex Hospital where X ray examination showed a fracture of the vertebræ. At the inquest the senior house physician, Dr. I. F. W. Edwards, said he was unable to state on oath the cause of death; he did not personally think the injury to the vertebræ was sufficient cause; the deceased had been able to speak, and said: "hit neck in barrack-room last night jumping over forms." The Chichester coroner said he was satisfied that, though the doctors might not agree as to the exact cause of death, the man died from the injuries he received in making the dive; death was entirely accidental; nobody was to blame, and he proposed to return a verdict accordingly. Dr. R. Brooke, honorary senior surgeon at the hospital, protested; he had had charge of the case and was prepared to say that the deceased died from natural causes. Dr. Brooke, giving evidence at his own request, was of opinion that the man had a lesion of the brain which led to dizziness and that the accident was the result of that disease. He raised a point of principle as to the desirability of closer coöperation between coroners and medical practitioners in the matter of post-mortem examinations, and the necessity of ascertaining by all possible medical means the exact cause of death. The coroner replied that he had no hesitation in ordering a post-mortem where he thought it necessary; he had often been asked to make such order where he thought it absolutely unnecessary. He had come to the conclusion that the evidence showed death to be due to the accident; he had to ascertain the cause of death sufficiently for registration purposes, and he had a duty not to throw the rate-payers' money away on post-mortem examination fees.

There, since the coroner has the last word, the matter ended. From the merely legal point of view the coroner was doubtless justified. He had to decide whether or not to issue his order authorising the burial of the body. For this purpose he had sufficient material. There was no doubt of the facts of the accident, no suspicion of foul play, and no element of crime; the relatives, presumably, were satisfied with the investigation. But it was natural that the medical practitioners who had had charge of the case should wish that the fullest medical evidence should be made available and that it should be adequately considered before a judicial decision was made. Dr. Waldo, commenting lately in his court on the qualifications of coroners, stated that the 350 coroners in England and Wales consist of 310 with solely legal qualifications, 30 with solely medical qualifications, and 10 whole-time coroners possessing both kinds of qualification. More coroners, it seems, have a legal than a medical outlook.

Pay-beds at the Miller General Hospital.

The application to the Chancery Division for a scheme providing 50 "pay-beds" at the Miller General Hospital for South-East London, mentioned in THE LANCET of May 2nd (p. 981), has been further adjourned in order that the accounts for the year 1930, which have now been prepared, may be put in evidence.

Dangerous Drugs Act: Substantial Fine.

A doctor was fined £175 in the Manchester City police-court on April 24th on charges of unlawful possession of drugs other than for professional purposes, giving false particulars in prescriptions, and failing to keep a dangerous drugs register. There was no allegation of trafficking, but it was represented that the defendant had abused the privilege conferred upon him as a member of the medical profession. On the ten summonses taken out against him he had made himself liable to fines totalling £2500.

A Question of Ambulance Practice.

In consequence of adverse criticism [1] of the method followed in the London Ambulance Service of dealing with street accident cases, Sir George Hume, on behalf of the London County Council, has conferred with the Commissioner of Police for the metropolis as to the position of the ambulance when the attendants are rendering first-aid to injured persons in the roadway. It was agreed that, when an ambulance reaches a street accident case, the position in which it stops shall be a matter for the ambulance staff to determine, and that any police officers present will give all assistance in their power. Further, it was decided to add the following instruction to the ambulance service:

> When an ambulance reaches a street accident case and the patient is found to be lying in the roadway, the ambulance shall be stopped in the position that is most favourable for dealing with the case. In a busy thoroughfare the ambulance shall, if possible, be placed between the patient and oncoming traffic. When a police officer is present he will be responsible for keeping back bystanders and for the regulation of traffic until the case is removed, and he will aid the ambulance staff in any way he can. All accident ambulances will be furnished with a portable electric red lamp which shall be placed in the roadway, so as to show a red light in the direction of oncoming traffic during lighting-up time on every occasion when an ambulance is stationary in a public thoroughfare in connexion with a casualty.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

A NEW SWEEPSTAKES BILL.

LAST week in the Dáil Mr. FitzGerald-Kenney, Minister for Justice, introduced a Bill designed to extend the operations of the Hospital Sweepstakes Act. The Bill proposes to make certain hospitals mentioned by name, which were not eligible for participation in the sweepstakes under the existing Act, eligible in the future. The *principal of these* are the Royal Victoria Eye and Ear Hospital, Dublin, and St. Mary's Open-air Hospital, Cappagh. The feature of most interest in the Bill, however, is the provision for public (i.e., rate-supported) hospitals to benefit by the sweepstakes. Section 6 lays down that of the sums available for hospitals three-fourths shall be paid to the governing bodies of the promoting hospitals in proportions to be decided on by the Minister. Section 7 provides that the remaining fourth shall be paid to the Minister for Local Government and Public Health, who is to apportion it to the several counties and county boroughs in the Irish Free State in proportion to their respective populations. The share given in this way the Minister is to allocate as he shall think fit to such one or more of the hospitals for the sick poor of such county or county borough maintainable under the enactments relating to the relief of the sick poor. The sum so allocated is to be applied as the Minister shall direct for the improvement of the hospital or for its equipment. The Government appears to have some qualms lest the ratepayers should think themselves relieved of the responsibility of the upkeep of the public hospitals, and the succeeding provisions are intended to exercise some control. The allocation by the Minister of a sum to a particular hospital may be made conditional upon the fulfilment by the local authority of such conditions as he may think fit to impose. Again, it is provided that

> "Money allocated under this Section by the Minister for Local Government and Public Health to a hospital shall be in addition to, and not in substitution for, the moneys required for the ordinary maintenance of such hospital, and shall not be taken into consideration by the local authority by whom such hospital is maintainable by law when determining the amount to be expended by them on the maintenance of such hospital."

It is difficult to see how this provision can be made operative. The legal responsibility for the maintenance and equipment of the hospital rests on the local authority: for what purpose is the Minister to give his grant? Moreover, it is impossible to prevent the members of the local authority taking anything they choose into consideration whatever laws may say. In this connexion it is worth noting that last week the Westmeath Board of Health decided to postpone the consideration of all works involving capital expenditure pending legislation to enable them to benefit from the sweepstakes. The soundest provision in the present Bill is probably the concluding clause, to the effect that the Act shall remain in force for so long as the principal Act continues in force, and no longer.

PROBLEMS OF NATIONAL HEALTH INSURANCE.

A debate of considerable interest to the medical profession lately took place in the Dáil on the vote for the National Health Insurance. Mr. Mulcahy, Minister for Local Government and Public Health, in moving the vote, mentioned that he had succeeded in effecting considerable economies in the cost of the headquarters staff. Consultations were taking place with officials of approved societies and the doctors to see how far the increase in the cost of sickness benefits was due to laxity in certification or to increase of illness, or to both. In the ensuing discussion charges were brought by various deputies against medical men of carelessness or impropriety in the issue of certificates. Statements were made in particular that certain medical men signed *certificates in blank*, leaving them to members of their families to issue. Or again it was suggested that certificates were issued without an interview on the date of the certificate between the certifier and the member in whose favour the certificate was issued. Two of the medical deputies who spoke in the debate, Sir *James Craig* and *Dr. T. Hennessy*, suggested that if there were grounds for the charge that certificates were wrongly signed or issued by medical practitioners, such practitioners should be reported to the Medical Council. The Minister, in his reply, gave his opinion that the weakness in medical certification probably was not due to the doctors. The difficulty was the hesitancy of the doctors to put a person who had been in receipt of benefit back on the working list, but their certificates for two or three days had a material effect on the total amount of benefit to be paid. The fact, as appeared from figures quoted by Mr. Mulcahy, that the number of cases of cash payment, the number of certificates issued by medical practitioners, and the number of insured persons had increased in almost identical proportions in the past four years does not seem to have elicited any comment. An interesting point made by Mr. Hugh Law, in a criticism of the National Health Insurance system in general, was that it differed from an insurance scheme run on commercial lines in that a man who enjoyed good health all his life obtained no bonus or reduction of premiums.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED MAY 2ND, 1931.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 192; scarlet fever, 1570; diphtheria, 901; enteric fever, 27; pneumonia, 905; puerperal fever, 42; puerperal pyrexia, 115; cerebro-spinal fever, 61; acute poliomyelitis, 5; encephalitis lethargica, 13; continued fever, 2; dysentery, 3; ophthalmia neonatorum, 112. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on May 5th–6th was as follows:—Small-pox, 257 under treatment, 7 under observation (last week 222 and 6 respectively); scarlet fever, 1220; diphtheria, 1519; enteric fever, 10; measles, 160; whooping-cough, 439; puerperal fever, 33 (plus 10 babies); encephalitis lethargica, 148; "other diseases," 186. At St. Margaret's Hospital there were 21 babies (plus 10 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 1 (0) from enteric fever, 46 (2) from measles, 4 (0) from scarlet fever, 24 (8) from whooping-cough, 22 (1) from diphtheria, 55 (13) from diarrhœa and enteritis under two years, and 74 (10) from influenza. The figures in parentheses are those for London itself.

Sheffield reported the only death from enteric fever. Only 2 deaths from meningococcal meningitis occurred in London. Ten deaths from measles were reported from Liverpool, 7 from Birmingham, 3 each from Leeds and South Shields. Birmingham reported 4 deaths from diphtheria, Liverpool 3. Diarrhœa accounted for 7 deaths in Manchester, 3 in Liverpool. The 64 fatal cases of influenza outside London are scattered over 37 great towns: 6 each were reported from Bradford and Leeds, 5 from Birmingham.

The number of stillbirths notified during the week was 286 (corresponding to a rate of 41 per 1000 births), including 38 in London.

CORRESPONDENCE

ORTHODOXY AND HETERODOXY IN SURGERY.

To the Editor of THE LANCET.

SIR,—I am so accustomed to read the writings of Mr. Ogilvie with profit, and with warm admiration not only for his surgical knowledge and good judgment, but for his mastery of the English language, that I too was surprised to read his statements with regard to the operation of gastro-duodenostomy. Now that another brief unhappy period of monopoly in the treatment of chronic duodenal ulcer by that ancient fetish the "triple carbonates" is nearing its timely end, and surviving cases are returning, disillusioned and disappointed, to the surgeon, it is necessary that the exact rôle, so far as we know it, of various surgical procedures relevant to their treatment should be accurately assessed.

Like Mr. Flint, I most strongly deprecate the operation of duodenectomy, which gives, with greater risk, no greater benefit to patients than do short circuiting operations combined, as they should always be, with destruction or infolding of the ulcer. Of the short-circuiting operations, gastro-duodenostomy may be difficult to perform, indeed it is not always possible. Vomiting may occur after it, and convalescence is not in every case so uneventful as after gastro-jejunostomy. With the limitations of the operation I have dealt fully in my book and need not repeat them here. I think I may sum up my attitude towards the surgical method to be practised in any case of chronic duodenal ulcer by saying that I think first of gastro-duodenostomy, and only when this seems likely to be difficult, impossible, or less desirable do I perform gastro-jejunostomy.

I have never lost a case of gastro-duodenostomy; I have never seen hæmorrhage that gave me the least anxiety; leakage from the suture line has not fallen within my experience; and I have never yet had to perform a secondary operation upon any case of my own for recurrence of ulceration. I hope Mr. Ogilvie will give the operation a further trial. In his most skilful hands it would I am sure prove satisfactory and earn his gratitude.

I am, Sir, yours faithfully,

Portland-place, W., May 11th, 1931. MOYNIHAN.

To the Editor of THE LANCET.

SIR,—I am sorry that my reference to gastro-duodenostomy has brought me into disagreement with Mr. Flint. The main grounds upon which he bases his advocacy of the method, that in his hands it has proved very successful, are unassailable, for Mr. Flint's work is well known and his results beyond question.

The gastro-intestinal junction is guarded by a sphincter under nervous control, whose functions are to prevent chyme leaving the stomach too rapidly and in too coarse a form, and to regulate the acidity of the gastric contents. The biliary and pancreatic secretions are probably directed also by a nervous mechanism, since they occur normally after gastro-jejunostomy and in persons with achlorhydria. When the pylorus is abolished, whether by excision or exclusion, emptying of the stomach becomes a mechanical process. The alkaline juices will be secreted as before, and will mix with the gastric contents at the stoma, wherever situated. It appears therefore that that opening will be most satisfactory which is made most easily, and which lies most naturally after completion. Mr. Flint rightly points out that the technical difficulties which I discussed are chiefly encountered in operations at the pylorus itself; but even in gastro-duodenostomy the parts employed for the stoma are thicker and more vascular than those concerned in posterior gastro-jejunostomy.

The chief difficulty in reaching any certain standpoint in the surgery of ulcer is that men of equal skill and experience hold entirely different views about the type of operation which is most suitable in any class of case, so that their opinions cancel each other out. It is probably fair to say that, apart from Prof. Wilkie, there are few surgeons of comparable standing to Mr. Flint who have as great an enthusiasm for the operation of gastro-duodenostomy.

I am, Sir, yours faithfully,

Harley-street, W., May 11th, 1931. W. H. OGILVIE.

DURACAINE IN SPINAL ANÆSTHESIA.

To the Editor of THE LANCET.

SIR,—It is all to the good that the excellent paper of Dr. Bernard Johnson on spinal anæsthesia, which appeared in the current issue of the *British Journal of Anæsthesia*, should be given a wider publicity in your columns. We must all feel grateful to Dr. Howard Jones for calling attention to it, especially as it is so capable of standing the fire of his criticism and coming through the ordeal not only unscathed but with enhanced reputation.

Dr. Johnson injected 100 spinal thecas with "duracaine" a solution lighter than cerebro-spinal fluid, and put the table "head up feet down" 10 degrees so that the lighter solution should rise. In 93 cases it did rise within a few minutes and a high anæsthesia was obtained. In seven cases the onset of anæsthesia was delayed, but eventually occurred. It is not clear whether these patients were in the "head down" position or not; they probably were not, Dr. Howard Jones assumes they were. Let us suppose he is right. He attributes the anæsthesia in these seven cases to the fact that the anæsthetic solution is really heavier than cerebro-spinal fluid and so flowed to the thoracic region as soon as, but not before, they were put in the Trendelenburg position. He says: "In other words the novocain will not go up hill, but waits for the Trendelenburg position, for this mixture becomes a hyperbaric [heavier] solution when diluted with cerebro-spinal fluid." How does he account for the high anæsthesia in the 93 cases when it occurred in the head-up position? Duracaine is a very remarkable liquid but it is not both lighter and heavier than cerebro-spinal fluid at the same time. It *is* lighter than cerebro-spinal fluid outside the body and 93 times out of a hundred in this series it acted as though it were lighter inside the body. It is therefore reasonable to suppose that it *is* lighter inside the body.

Secondly, the case referred to by Dr. Howard Jones of the 6-year-old child who received 200 mg. of novocain (as duracaine) is an excellent example of the safeguarding action of gliadin, for 150 mg. of novocain is considered by many authorities—*e.g.*, Prof. Forgue of Paris, Prof. Sebrechts of Bruges—as a super maximum dose for an adult. Yet this child of six received 200 mg. How is such a thing possible! The answer is that gliadin made it so. Gliadin limits the diffusion of novocain in the cerebro-spinal fluid and delays its absorption into the blood. After telling us that the respiratory centre can be paralysed by novocain, which is well known, Dr. Howard Jones says the centre was "badly *affected*," presumably with novocain. There is no evidence to that effect. All the evidence points to a very different conclusion. Here is the most relevant part of it. "Upon tilting the table more head downwards the patient's condition was *rapidly restored* to normal." What possible effect could tilting the table more head downwards have on a respiratory centre badly affected by novocain? Just none. The explanation is quite otherwise. Owing to the fall of blood pressure the venous return to the heart was inadequate, the heart was therefore failing and was not supplying the respiratory centre with blood. The centre was suffering from anæmia not novocain. An efficient Trendelenburg position immediately gave the heart its desire—namely, blood. The heart responded and gave the respiratory centre blood; the respiratory centre responded and gave the heart oxygenated blood, and the "patient's condition was rapidly restored to normal."

Dr. Johnson in the face of an alarming situation made a correct diagnosis and his treatment was as effective as his diagnosis had been prompt. Dr. Howard Jones in the quietness of his study misinterprets the situation.

I am, Sir, yours faithfully,
E. FALKNER HILL.
Manchester, May 10th, 1931.

SYPHILIS AND YAWS.

To the Editor of THE LANCET.

"The faintest streak that on a petal lies
May speak instruction to initiate eyes."
(Bryant—"The Mystery of Flowers.")

SIR,—Captain Butler of the U.S. Navy heads his letter in THE LANCET for April 25th with a quotation from William Cullen Bryant. I have followed his example; and I imply by my quotation, of course, that if Captain Butler has seen the streak on the petals of syphilis and yaws, his eye is not sufficiently initiate to appreciate the instruction available.

His communication amounts to this—that in his belief syphilis did not originate in America, and also that syphilis and yaws are one and the same disease. I am tempted to indicate briefly certain things which show that syphilis has not an European ancestry, and also that it and yaws are separate and distinct disease-entities.

Although Captain Butler says that "the ancient European ancestry of syphilis may be shown in a dozen ways, direct and indirect, and yet we find in current literature physicians subscribing to the moth-eaten fallacy that syphilis is of New World origin," nevertheless, he fails to mention one single way. If syphilis existed in the Old World prior to 1493, then all he has to do is to produce one reference to it before that date. He has only to cite one case of congenital syphilis, one case of tabes, one case of paresis, or one pre-Columbian syphilitic bone. But that, of course, he is quite unable to do.

Before the return of Columbus, all is silent upon the subject of syphilis. But shortly thereafter the new disease under divers names resounds throughout Europe, causing consternation and dismay. It behaves as a new disease, spreads as a new disease, and is recognised by contemporary physicians as a new disease. Nay more, it is immediately shown to have been introduced by the returned crews of Columbus, some of the men being infected—including the pilot, Pinzon—when they arrived in Palos on that fateful Ides of March. Las Casas and Oviedo, among others who visited the New World soon after, showed that the disease had been prevalent among the natives of America from time immemorial.

I am writing with a full knowledge of the joint paper by Captain Butler and Lieut. Harnandez in the *Southern Medical Journal* (vol. xxii., December, 1929); and here I would like to correct them upon one point. They state that there were no Spanish troops in the French army of Charles VIII. which carried out the invasion of the Kingdom of Naples. This is not correct. If they will read the first book of Ruy Diaz de Isla, they will find the following words: "And afterwards in the following year, 1494, the Most Christian King Charles of France, who then was reigning, having gathered a great army, passed into Italy. And at the time he entered the country with his host, many Spaniards infected with the disease were in it. . . ."

Of the duality of syphilis and yaws there is ample evidence. Of their unity, there is none. It is true that morphologically the parasite of yaws resembles that of syphilis; but then morphology counts for next to nothing. An ordinary brick which has been gilded may be morphologically indistinguishable from an ingot of gold. It is their different *behaviour* which matters. So with the *Treponema pallidum* and the *Treponema pertenue*. One behaves in a different way to the other. Yaws does not exist in a congenital form—i.e., the child does not acquire the infection in utero. In contrast with syphilis the primary lesion of yaws is seldom genital, and it is usually preceded by marked constitutional symptoms. Endarteritis is absent in yaws whereas it is characteristic of syphilis. In yaws there is little or no adenitis, the type of exanthem is single, there is great itching, alopecia is absent, and so likewise is iritis. From a yaws-infected mother no child is born who develops notched teeth, interstitial keratitis, eighth nerve deafness, oral fissures, or saddle nose. Yaws and syphilis often coexist in the same person. The one disease does not confer immunity against the other. Yaws does not give rise to tabes, paresis, or aortic aneurysm.

I have just read the letter of Dr. Stannus in THE LANCET for May 2nd, and I am inclined to differ from him in what he says with regard to sibbens—namely, that it is a "non-venereal epidemic syphilis." I rather regard it as being an European type of yaws. With respect to the remainder of his letter I agree.

In conclusion, I would point out that it would not be valid for Captain Butler to argue the European antiquity of syphilis by showing that yaws—framboesia, sibbens—was known in the Old World before the discovery of America, without first proving that yaws *is* syphilis. He must avoid the fallacy of *petitio principii*.

I am, Sir, yours faithfully,
E. TYTLER BURKE.
Municipal Clinic, Regent-road, Salford, May 8th, 1931.

SWEEPSTAKES AND VOLUNTARY HOSPITALS.

To the Editor of THE LANCET.

SIR,—The treasurer of St. Thomas's Hospital is very sceptical of the benefit to be derived from an English version of the Irish hospital sweepstake. But supposing the sweepstake were promoted by either the State or the local authority, in relief of the taxes and rates—what then? Germany can give us reliable data. Could we not pay off the "dole" debt, finance a specialist and clinic organisation for the National Health Insurance scheme, and perhaps get the income-tax in more quickly, if there were a gambling element in the matter? If the contribution to the National Health Insurance or income-tax carried a ticket per £1 for some lottery—the winner need not be drawn by a horse!—surely we should pay up far more readily, and have something of considerable psychological value in the way of interest. We should have something of a counter to the very disagreeable feelings aroused by the payment, or even the mention, of a compulsory tax, to such of us as still have a feeling that our money is our own, and that, being adult, we should be allowed to spend it in our own way, provided this is not directly harmful to others.

I am, Sir, yours faithfully,

H. G. P. CASTELLAIN, M.D. Cantab.

Moseley, Birmingham, May 8th, 1931.

TOXIC EFFECTS OF LUMINAL.

To the Editor of THE LANCET.

SIR,—I would like to add one important symptom of luminal poisoning to those described by Dr. R. W. L. Pearson and Dr. H. S. Pemberton in your issue of March 21st. In one of the cases I have seen, the acute symptoms appeared as a result of taking about a drachm of luminal by mistake. The patient was almost unconscious and had suppression of urine for more than 48 hours. Cupping in the kidney region was done but there was no response. On the third day the toxæmia had increased and the operation of capsulotomy of the kidneys was suggested. But before any operative measures of doubtful value were undertaken it was decided to give medical treatment a full chance. As a last resource it was decided to give 2 per cent. sodium sulphate intravenously. Accordingly, about a pint of the sterilised solution was injected and to the great relief of the patient and the attending staff a few ounces of urine were obtained on catheterisation about eight hours later. The urine continued to be secreted slowly and there was no necessity for repeating the intravenous injection. The patient made an uneventful recovery.

I am, Sir, yours faithfully,

P. L. DESHMUKH, M.B., B.S. Bombay,
Hon. Clinical Pathologist,
B.J. Medical School, Poona, India.

April 21st, 1931.

PANEL AND CONTRACT PRACTICE

Diagnostic Aid in Insurance Practice.

ALTHOUGH ample facilities exist for the provision of drugs for insured patients none has yet been made for laboratory diagnosis. It is true that when the service was established the laboratory did not occupy its present position in diagnostic medicine, while the bottle of medicine held almost undisputed sway—a domination which has been maintained, possibly even strengthened, by arrangements made under the Insurance Acts. "Treatment without diagnosis" has been suggested as a suitable slogan. Attempts to induce the Ministry of Health to include within insurance benefit some facilities for diagnosis have hitherto met with no success. A step forward has been brought about by the action of the British Medical Association in promulgating a schedule of fees for the performance of various laboratory procedures in general use in clinical medicine, and in arranging with a number of pathologists attached to general hospitals and clinical laboratories to undertake examinations for insured persons and their dependants at the rates therein laid down. This schedule, together with the names of the institutions undertaking the work, has now been circulated to panel committees. No funds are available for the working of the scheme, and the fees for the examinations must be a charge either upon the patient or upon the medical man asking for them. This fact makes it probable that the volume of work done under the scheme will not be great.

The schedule of fees was drawn up by the Consulting Pathologists' Group of the B.M.A., with the assistance of the council of the Association of Clinical Pathologists, and represents the first real attempt in this country to make the fees for this class of work approximate to the actual cost. It is the result of much actuarial work based upon the work done and the costs of maintenance of a number of laboratories throughout the country. Investigation showed that much of the pathological work at present done represents a charge on the institution performing it, a fact which has escaped notice inasmuch as most of these institutions depend for their maintenance not upon the fees received but upon the rates or charitable or educational funds. No doubt the vaccine has to some extent served to redress the balance. Insurance committees have been known to pay as much as ten guineas for an autogenous vaccine for a patient under their charge, although in the opinion of those who drew up the schedule two guineas represents a reasonable flat rate for all preparations of this kind. In view of the highly specialised nature of the work the scheme is framed to utilise the laboratories attached to general hospitals, an exception being made for certain laboratories engaged in clinical pathological work.

Hospitals, Drugs, and Panel Patients.

We learn from the *Manchester Guardian* that the board of management of the Eccles and Patricroft Hospital will persist in their effort to have the hospital placed on the list of dispensing chemists under the National Health Insurance Acts. The object is to make the hospital eligible for payment on account of drugs and dressings supplied to insured patients. The hospital was informed by the insurance committee that no application could be considered unless it complied with the terms of the Pharmacy and N.H.I. Acts. The hospital has become incorporated and is now assured by counsel that the legal provisions of these Acts have been fully complied with by incorporation. During the last 20 years the hospital, it is stated, has supplied over £10,000 worth of drugs and dressings to panel patients without recompense, and while they do not claim to participate in the drugs fund the board of management do consider they have a claim on insurance funds to cover the cost of drugs and dressings given to insured persons while in hospital.

QUEEN CHARLOTTE'S HOSPITAL.—At the annual meeting recently Sir Samuel Scott, the chairman, said that if the whole hospital could be moved to the new site in Goldhawk-road, Hammersmith, it could be made a centre of post-graduate teaching in obstetrical work and for the training of students, but to do that £200,000 was required. Meanwhile last year's expenditure exceeded the income by £6600.

OBITUARY

HENRY BRIGHT WEIR, M.B. Camb.

Dr. H. B. Weir, whose death occurred on May 4th, was the younger son of the late Dr. Archibald Weir, of Malvern. Born in 1880 he was educated at Harrow, where he played for the football eleven and was its acting captain in 1898. He was also a great runner and won many cups at the school sports, chiefly for the mile and half mile. In 1899 he entered Trinity College, Cambridge, taking honours in science, proceeding to St. Thomas's Hospital where he took the Conjoint diploma in 1907, and held a resident appointment. In 1910 he took the M.B., B.Chir. Camb., was appointed Louis Jenner research scholar in pathology for 1911 and 1912, and became assistant director of the Louis Jenner clinical laboratories and demonstrator of clinical pathology. When the war came he obtained a commission in the R.A.M.C., and became acting director of the laboratories, when much of the teaching in addition to the pathological work fell on his shoulders. To these he devoted his entire time and energy without stint, carrying on alone the work usually shared by several, and with conspicuous success. The war over, he was asked to make room for others, and thus severed a connexion of over 15 years with the hospital he had served so well.

DR. WEIR.

[Photograph by Jas. Bacon.

In 1918 Dr. Weir was appointed assistant lecturer in pathology at Charing Cross Hospital, and from there he went, in 1920, as pathologist to the National Hospital for Diseases of the Heart in Westmoreland-street, where he was working less than two hours before his death. At this hospital he became interested in causes of sudden death. He published, with others, a series of cases of death from ruptured heart, due to joy, grief, and many other causes, which he thought might be more common than was generally believed. The museum of this hospital is now, thanks to his efforts, one of the finest of this type in the country. During this period he was increasingly engaged in the scientific application of his branch of medicine to medico-legal needs. For many years he was one of the pathologists attached to the Coroner's Court for Central London. Dr. Ingleby Oddie tells us that he was a most painstaking and careful pathologist, sound and reliable in his work, an excellent witness, and a man of great personal charm. Dr. Oddie adds: He never expressed an opinion without clear grounds to support it, and was one of those quiet, modest people whose work was always characterised by signal efficiency.

One of his younger associates writes: "H. B. Weir or Goyle, as his intimates were privileged to call him, will be really missed by those who had the good fortune to count him among their friends. He was not easy to get to know, but once admitted to his confidence one had a very true friend. Having known him well for 15 years the characteristic which stands out strongly is his reliability; we could always count on his help or advice and feel certain it was the best we could get. 'Ask Goyle' was almost a bye-word with some of us. His kindness was proverbial; during the war he used to ask a few of us to dinner and then take us over to the laboratory and coach us in pathology, not officially but simply to help. Lenient where the faults of others were concerned, he was if anything over-conscious of what he considered his own shortcomings. He was a brave man; knowing so much of heart disease and fully aware of his own condition he was never heard to complain or give way to depression, but faced it cheerfully and carried on. He died at his home, as he would have wished, at the end of a day's work."

In 1926 Dr. Weir joined the Order of Crusaders whose object appealed strongly to him, being that of keeping alive the war-time spirit of "helping lame dogs over stiles." He was Master of his Conclave for this year and Member of the Grand Conclave. He leaves a widow and two young children.

JESSIE LAMB, M.B.Lond.

Dr. Jessie Lamb, who died on May 1st at Bath, after a serious operation, had been associated for many years with St. Catherine's Hospital, at Amritsar, India. She was the youngest child of the late Canon B. Lamb, and was born at Wheldrake, near York, in 1877. She was educated at the Leeds High School, at Westfield College, and at the London School of Medicine for Women, taking her medical degrees in 1903. Before going to India in 1906 she held resident appointments at Bermondsey Medical Mission and at the Elizabeth Garrett Anderson Hospital. For four years she worked under the Church of England Zenana Missionary Society at St. Mary's Hospital, Tarn Taran, in the Punjab, and in 1910 she went to Amritsar. The St. Catherine's Hospital there had been founded 30 years earlier by Miss S. S. Hewlett as a centre for training Indian midwives; to-day it has 100 beds with an annual turnover of 1700 in-patients and 15,000 out-patients. There are several Indian doctors and nurses on the staff, and when during recent troubles in India the English staff, as a precautionary measure, left the city and slept in cantonments, Dr. Lamb remarked: "It was the proudest moment of my life when I walked out of my hospital knowing that my Indian fellow workers would carry on the work just as efficiently as if we were still there." Dr. Lamb's service to India was recognised in 1920 by the bestowal of the Kaisar-i-Hind silver medal. Two of her sisters went out as missionaries under the same society; another sister who trained as a nurse at the Sussex County Hospital went out to Amritsar in 1911 and is still there.

THE LATE SIR BYROM BRAMWELL.

We have received from Prof. G. Lovell Gulland the following eloquent and just appreciation of Sir Byrom Bramwell, his chief and colleague:—

"The death of Sir Byrom Bramwell removes a great figure and a great name. Not every physician is a hero to his assistant physician, but during our long partnership in that relation I admired him more and more, and have always retained my veneration for him. When he was promoted to the physicianship in 1892 to take charge of the women students, who were then first admitted to the Infirmary, I was appointed assistant physician and assigned to him. He was full of the delight of having wards, and as he was not yet overwhelmed with practice, he spent long hours in investigating his cases, often with myself as a fascinated helper. From him I learnt the invaluable lesson of clinical thoroughness, and also of pathological thoroughness, for we used to go together to do post-mortem examinations on private cases, and on cases which had been in his wards, and which he had followed up, often for years. As time and his great reputation brought an increase of practice the hours that he was able to spend in the wards became shorter, but he regularly supplemented them by constant study of case-records at home. This made him more dependent on his resident physicians, but he was able to command the services of the best graduates, and was singularly fortunate in his selections. To them, as to me, his vast knowledge of clinical medicine was a revelation, as it was also to outsiders. An eminent London physician once said to him in my presence: 'Every time I hear of you, Bramwell, it is as an authority on some fresh subject.' While he was best known as a neurologist, his work on the heart, on anæmia, and diseases of the ductless glands and other subjects was in the first rank in its day. His monumental 'Atlas of Clinical Medicine' has never been equalled, but his 'Clinical Studies' were more widely read than any other of his publications and more appreciated by the profession at large. They were the outcome of his famous 'Wednesday Cliniques,' which were held in the 'Duck Pond' below Ward 28, and which were always crowded to the doors and windows; so much so, indeed, that some of his colleagues enjoyed a happy respite from teaching on that day. I never knew him as a systematic teacher, but as a clinical teacher he was superlatively good, clear, concise, dogmatic when it was possible to be so, cautious when it was not, bringing to the illustration and elucidation of a doubtful case the whole of his vast experience. He *was* the Edinburgh method of teaching at its best.

"We thought that his opportunity and that of the school had come, when at the death of Grainger Stewart the chair of Medicine became vacant. Bramwell presented a marvellous collection of testimonials from every part of the world, a wonderful evidence of his fame and reputation, but to our—and his—bitter disappointment he was not elected. In spite of this he carried on his work as keenly as ever. When his term as physician came to an end his colleagues and friends entertained him to dinner in the College of Physicians, an occasion of happy memory, and an honour which has not been extended to any other clinician. After his retirement from the Infirmary he long continued to be active in practice, but made few public appearances. How much this was to be regretted was evident when his colleagues chose him as President of the Association of Physicians on the visit of that body to Edinburgh in 1923. His conduct of the meeting was admirable, and his summing up of some of the discussions was in his old masterly style. Only a year or two ago, as one of the senior members of the consulting staff of the Infirmary, he presented to Mr. W. S. Caw, on behalf of the whole staff, a memento on his retirement from the post of Secretary and Treasurer to the institution. His speech was full of grace and dignity, with a touch of pathos.

"*But his fame as a teacher and investigator* were often forgotten by his friends in their love of the man himself. He was always approachable, always interested more in your doings than in his own, *glad to give advice if it was asked*, but never thrusting it upon you, kindly, even-tempered, but not sparing a rebuke in season if he thought it would do good. He was a keen sportsman. By the time I knew him well he had given up the *more* active sports, and settled down to fishing. I remember well one hot August afternoon by the Tummel when I came upon him in his shirt-sleeves wielding a big two-handed rod and getting fish when I couldn't raise them. Many a fishing story I have heard from him in his work-room in Drumsheugh Gardens, when with the inevitable cheroot in full blast he would forget work and worry in the tide of memory. He was the best of company. He had been a keen whist-player, and one day expressed a desire to learn bridge. Haultain, Norman Walker, and I taught him the game one evening at my house, and when we separated about 3 A.M. he was the winner. To the end he was keenly interested in the school and in medicine. About a year ago he asked some of his old residents to dine with him, and aged though he was, he made us all talk about our doings and was as interested and sympathetic as of old.

"All over the world his students will regret him and feel that they have lost not only a teacher and a source of inspiration, but a friend. His memory will endure long after they, too, have departed."

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE.

Surg.-Comdr. J. M. Horan is placed on the Retd. List. A. F. Davy to be Surg. Lt.

Surg. Lt.-Comdr. J. M. M. Wright to *Hood*. Surg. Lt.-Comdrs. (D.) D. H. Le Marchant to *Excellent*; F. R. P. Williams to *Malabar*, for R.N. Hospital, Bermuda; A. W. Wallace to *Greenwich*; and D. Paterson to *Pembroke*, for R.N. Barracks, Chatham. Surg. Lts. J. G. Ollerenshaw to *Vernon* and L. P. Spero to *President*, for two months' post-graduate course. Surg. Lt. (D.) H. A. Ginn to *Vivid*, for R.N. Barracks, Devonport.

ROYAL ARMY MEDICAL CORPS.

Lt. (on prob.) O. Ive resigns his commn.

ARMY RESERVE OF OFFICERS.

Lt.-Col. G. K. Maurice (Maj., ret. pay) to be Lt.-Col.

Capt. A. J. R. O'Brien, from the Gen. List, Res. of Off., to be Capt., retaining his present seniority.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Capt. E. Holmes from Active List to be Capt.

INDIAN MEDICAL SERVICE.

Capts. to be Majs.: M. K. Kelavkar and H. M. Strickland.

To be Capt. (on prob.): E. P. Carroll.

To be Lts. (on prob.): B. Temple-Raston, G. K. Graham, A. W. West, Mazhar Hussain Shah, M. K. Bryce, J. Guthrie, J. E. S. MacDonald (since deceased), H. R. Macevoy, M. M. Mansfield, J. L. O'Neill, *and* W. J. Stewart.

ROYAL AIR FORCE.

Flight Lt. P. J. Nyhan is transferred to the Reserve, Class D (ii), and is employed with the Regular Air Force for one year.

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS.

PROPRIETARY MEDICINES BILL.

On Monday, May 11th, in the House of Commons Dr. **Hastings** presented a Bill to regulate the manufacture, sale, and advertisement of certain medicines and surgical appliances; and for purposes connected therewith. A forecast of its provisions appeared in a leading article in our issue of March 28th (p. 707). The Proprietary Medicines Bill seeks to make it unlawful for any person to manufacture or prepare for sale any proprietary medicine, or any proprietary surgical appliance, unless he is duly registered under the Act as the owner of the medicine or appliance, or his authorised agent. The medicine or appliance must also be registered and particulars must be forwarded to the Registrar (who will be appointed by the Minister of Health) showing the ingredients used in the preparation of the medicine. These ingredients must be specified in the Register. The Registrar must not disclose any information concerning the formulæ to any person except the authorised owner or agent. The Bill makes it an offence to advertise any proprietary medicine or appliance for the prevention, cure, or relief of a number of diseases specified in a schedule to the Bill, including cancer, consumption, diabetes, epilepsy, paralysis, and Bright's disease. Dr. Hastings, the introducer of the measure, has the backing of medical and lay members of Parliament belonging to all the three parties. The names on the back of the Bill, in addition to that of Dr. Hastings, include Lieut.-Colonel Fremantle (Unionist), Dr. Morris Jones (Liberal), and Dr. Salter (Labour).

HOUSE OF LORDS.

WEDNESDAY, MAY 6TH.

THE TWENTY-FOUR HOUR TIME-TABLE.

Lord **Newton** moved: "That in accordance with the recommendations of the Home Office Committee appointed in 1919 to report upon the advisability of adopting for official and other purposes the 24-hour method of expressing time, the Ministry of Transport should invite the railway companies to adopt this system from a certain date, and that it should be simultaneously introduced into the Post Office." He said that the Government in 1919 appointed a Committee, which was presided over by Lord Stonehaven. They examined a large number of witnesses of all kinds, scientific, commercial, persons interested in shipping, military, and naval authorities, and railway authorities. They reported that the 24-hour system had been found completely satisfactory wherever it had been tried, and that it caused no inconvenience because the old and the new systems were quite easily worked together. They recommended that the railways should be invited to put the new system into effect and that at the same time the Post Office should give the railways the necessary lead by introducing it into their services. No legislation was required and no public expenditure, beyond the alteration of date stamps and hours on pillar boxes by the Post Office, would be involved. In view of these recommendations it seemed surprising that the change had not been made. The recommendations of the Stonehaven Committee had been completely ignored. The request he was putting forward was of a very modest character. It was insignificant compared with the much greater reform of summer time, the greatest boon, perhaps, that this generation had ever experienced. If the 24-hour system were adopted it would remove many inconveniences.

Lord **Stonehaven** said he was in favour of the change in 1919 when he presided over the Committee which examined this question, and nothing that had occurred since had led him to think that the Committee were wrong in submitting that the 24-hour system would be an advantage and an improvement.

Lord **Banbury** said he hoped the Government would adhere to their former decision. He could see no object in changing what they had been accustomed to all their lives, nor in asking the railway companies to spend money in altering their time-tables, clocks, and various other things.

Lord **Lamington** said our present system of time-keeping was distinctly artificial and the reasons given for a change to a simpler system were overwhelming. The change was bound to come. In these days when intercommunication from one part of the world to another was so rapidly developing it was impossible to conceive that the various air services could work on any other system than the 24-hour table.

Lord **Monkswell** said that for a long time something simple and convenient like the 24-hour system had been a crying necessity. He hoped that the Post Office and the railways would abandon their attitude of opposition and would accept this reasonable reform with a good grace.

Lord **Trenchard** said the 24-hour system had been found necessary in connexion with flying, and he hoped it would be adopted universally.

THE WISHES OF THE PEOPLE.

Lord **Moynihan** said he hoped that the Government would not listen to the request of Lord Newton. No greater mistake could be made than to suppose that the people of this country desired to live under good laws. They desired only to live under laws which they made themselves, and the law which divided the day into two periods of 12 hours seemed to him to be consonant with the wishes of the people. He (Lord Moynihan) might make the claim—he hoped it was not an arrogant one—that he had travelled more upon the railways than any other noble lord present. He had never confused A.M. with P.M., nor did he think it the least likely that he would ever make so grave a mistake. If they had a 24-hour day they would find great difficulty even with so large a clock as that attached to Big Ben in distinguishing exactly to what hour the hour hand pointed. It was true that very high, perhaps the highest, scientific authority in this country, the Astronomer Royal, had twice forcibly expressed himself in agreement with Lord Newton. He (Lord Moynihan) had every consideration for the opinion of his old friend Sir Frank Dyson, but he would point out that the language of the laboratory was not the language of the everyday common room. For example, they spoke of the daisy and the primrose, not of the *ranunculus*, which was qualified by some hideous epithet or another. It would be a pity if they allowed the language of science to step in and replace the everyday and much more attractive words that were in use. He did not know whether their lordships had recently been so happy as to consult their physicians. If they had they would find on the prescriptions provided, in the top left-hand corner, some sort of hieroglyph which looked as though a fly had dropped into the ink bottle, had managed to escape and deposit itself on the top left-hand corner of the prescription paper, and there had suffered many seizures of epilepsy. That hieroglyph was really an invocation to the god Jupiter that he would bless the various ingredients of the prescription which were written in Latin. He would remind their lordships, if they were not familiar with the fact, that the names of drugs were written in Latin in order that patients might not in the least understand what drugs they were taking, and that psychotherapy might be added to the benefit they received from the drugs. But there was really a very profound physiological reason why the day should be divided into two parts. All nature consisted of cycles. There was death and resurrection; there was ascent and decline; there was adolescence and the climacteric. St. Paul expressed a profound truth when he said, "I die daily." In all these matters there was a sort of rhythm in life. Whether it had to do with pulse beats, or the regularity of the heart, or the frequency of respiration, or what not, he could not say, but there was a feeling that there was a division of the day into two parts, one of increasing activity as the morning went on, reaching an altitude, and from then suffering a decline when the period of repose came on. The division of the day into two parts was not only in consonance with the wishes of the people of this country, but was a recognition of a profound biological truth that there were two periods in each 24-hour day, a period of what should be activity, and a period of what should be repose. He thought it was the common sense of the people of this country as against the lack of common sense in the people of other countries which made them wish to retain the double cycle in the 24-hour day. They were told that Britain was in isolation so far as other nations were concerned. He hoped it was. He hoped that not for the last time they would see the stubborn infrangible British common sense opposed to the freakishness and vapourishness of other nations on the Continent.

Viscount Churchill said that if the Government, the Post Office, and the country generally adopted the 24-hour system the railways would naturally fall into line. But until that was a *fait accompli* they naturally were not in a hurry to spend money and alter their time-tables, preferring to wait until the suggestion if it was adopted was in universal use.

USE IN MORE ADVANCED GOVERNMENT DEPARTMENTS.

Lord Marley (Under-Secretary for War), replying for the Government, said the discussion had produced a number of interesting speeches including the particularly brilliant speech of Lord Moynihan, which must have delighted their lordships. It was true that the more advanced Government Departments did use the 24-hour system. The War Office had used it for many years, the Air Force had come into line, and in civil aviation the system was bound to be universal. It was doubtful whether there was any real public demand for the change. Nevertheless, there had been a widespread expression of opinion in their lordships' House that some examination of this question ought to take place, and that the Government should in some way assist in the consideration of the problem. He was authorised to say on behalf of the Government that careful and sympathetic consideration would be given by them to the whole question raised by Lord Newton.

Lord Newton said that on the understanding that he was at liberty to question the Government again on the subject he would not insist on a division being taken that day. He would withdraw his motion.

The motion was by leave withdrawn.

HOUSE OF COMMONS.

WEDNESDAY, MAY 6TH.

Voluntary Milk Clubs in Schools.

Mr. R. S. Young asked the President of the Board of Education whether he was taking any action to encourage education authorities to organise voluntary milk clubs in the schools of their respective areas.—Mr. Morgan Jones replied: Yes, Sir. My Department are actively coöperating with the National Milk Publicity Council, and every opportunity is taken of bringing the Council's scheme to the attention of local education authorities and teachers.

Mr. Young: Is the right hon. gentleman aware that only 10 per cent. of the children in the country are now taking advantage of this excellent scheme, and will he therefore do his utmost to encourage this development throughout the country?

Mr. Morgan Jones: I can assure my hon. friend that every encouragement is being given. As a matter of fact the National Milk Publicity Council say that this year they provided milk for 600,000 children as compared with 350,000 last year.

The Census.

Mr. Freeman asked the Minister of Health when the information obtained at the recent Census would be available for the public.—Miss Susan Lawrence replied: It is expected that the first figures obtainable from the recent Census will be made available to the public in the form of the preliminary report within approximately two months from the present date.

Regional Town Planning.

Sir Kingsley Wood asked the Minister of Health whether the committee which was examining the reports of the regional planning committees had yet reported.—Mr. Greenwood replied: An interim report has been made by the committee and is now being considered.

THURSDAY, MAY 7TH.

Silicosis.

Mr. Rennie Smith asked the Home Secretary, arising out of the recommendations of the International Silicosis Conference of 1930, that every effort should be made to emphasise the necessity for a whole series of provisions relating to hygiene, including methods for reducing production and diffusion of dust, maintaining the purity of the air in the mines, and the provision of suitable means for ensuring personal hygiene, and what steps he proposed to take to ensure that these recommendations were put into effect.—Mr. Clynes replied: The particular recommendation mentioned in the question relates only to mines and does not, therefore, directly affect my Department. As regards, however, the protection of factory workers against exposure to dust, this question has, for many years past, received the greatest possible attention from the Home Office, and has been dealt with not only by general provisions in the Factory Acts, but also by special provisions included in various codes of regulations for industries in which dangerous dusts are produced. The need of strengthening and extending these provisions is constantly under review, and my hon. friend may be assured that every possible precaution will continue to be taken. I may add that the preventive measures recommended by the Conference were, I understand, based on the measures actually adopted and applied in this country.

Mr. Rennie Smith asked the Home Secretary what steps had been taken to carry out the recommendations of the International Silicosis Conference of 1930 that an international classification of the stages of silicosis and their radiological diagnosis be established and that research be undertaken on an international basis into the causation of silicosis and other diseases due to dust.—Mr. Clynes replied: The classification of silicosis mentioned in the report of the Conference was, I understand, unanimously adopted by the Conference, and I am advised that, having regard to the representative character of the Conference, it may be regarded as generally accepted. As regards the other recommendations referred to, the intention of the Conference was that each country should institute researches on the lines suggested and should communicate the results to the International Labour Office. So far as this country is concerned, the matter has been under consideration by the Committee appointed by the Medical Research Council to investigate silicosis and other forms of pulmonary disease, and I am informed that schemes of research drawn up by this Committee have now been approved and are being put in operation.

Mr. Train asked the Home Secretary (1) what sums had been contributed by Scottish quarry masters to the Workmen's Compensation (Silicosis) Fund; and what claims, if any, had been made on the fund from quarrymen in Scotland; and (2) whether he was aware that after a medical examination by the medical board appointed under the Sandstone Industry Silicosis Scheme, 1929, no case of silicosis had been found among the quarry workers in Scotland; and whether he had taken, or proposed to take, any steps to implement his promise to the Scottish quarry masters that, following on the medical examination, the question of their liability for levies under the scheme would be reviewed.—Mr. Clynes replied: The levies paid by the Scotch quarry masters to the Sandstone Silicosis Fund between April 1st, 1929, and March 31st last, amounted to £3931. Claims have been made in Scotland on the fund in one case of death, where the workman left dependants, and in two cases of partial incapacity. The promise given to review the rates of levy on completion of the first periodic medical examinations will be duly observed, but the examinations will not be completed for some time yet.

Vagrants' Accommodation in Leicestershire.

Mr. Winterton asked the Minister of Health whether he was aware of the conditions at Loughborough poor-law institution where men on tramp were required to sleep in hammocks instead of proper beds; and whether he would intimate to the poor-law authorities in Leicestershire that they must comply with the regulations of the Ministry of Health in that and other respects.—Mr. Greenwood *replied*: I am aware that at present the cubicles and one of the men's dormitories of the Loughborough casual wards are supplied only with hammocks or mattresses. *In the* other men's dormitory and in the women's ward there are proper bedsteads. I have called the attention of the Leicester County Council and the Leicester and Rutland Joint Vagrancy Committee to the requirements of the new Public Assistance (Casual Poor) Order, 1931, in this matter, and I am glad to say that the appropriate subcommittee have now recommended the supply of bedsteads throughout the wards.

Housing Survey in Islington.

Mr. R. S. Young asked the Minister of Health if the housing survey undertaken by the medical officer of health for Islington, on behalf of the joint committee, had yet commenced; what were the areas to be surveyed; and by what date was the report to be presented.—Mr. Greenwood replied: The reply to the first part of the question is in the *affirmative*. *The* areas to be surveyed are areas selected by the joint committee to which may hon. friend refers and, though no date can be fixed, it is hoped the report of the survey will be presented in the near future.

MONDAY, MAY 11TH.

Road Passes for Medical Practitioners.

Mr. Marjoribanks asked the Minister of Transport whether he would consider issuing to registered medical practitioners special road passes, or whether he would authorise the attachment of special signs, horns, or lights to the cars of registered medical practitioners, so that police officers on point duty should give them special facilities through traffic in cases of emergency.—Mr. Herbert Morrison replied: I would refer the hon. Member to the reply which I gave on this subject on Feb. 25th to Mr. Hore-Belisha.

[The question and reply referred to are as follows:—Mr. Hore-Belisha asked the Minister of Transport whether, in view of the urgent nature of calls made on doctors, he would consider allowing a distinctive sounding horn on their cars, as in the case of ambulances, so that the police in control of traffic would be enabled to afford them special facilities for proceeding on their way.—Mr. H. Morrison replied: Fire engines and ambulances are vehicles which are readily recognisable, and both the police and the general public do what they can to facilitate their expeditious passage when answering a summons. There is no distinction in appearance, however, between a doctor's car and an ordinary private car; and I should *deprecate any attempt* to establish a priority of right of way by the use of a distinctive type of motor horn or any other similar means, as such a course would *be open to serious abuse.*]

Mr. Marjoribanks: Is the right hon. gentleman not aware that this has become a matter of public controversy since then, and is he *also aware that Canada has adopted* this system, that it has worked well, and that I believe the terms for penalties in the case of improper use have also worked well, and will he look into the *matter in view of* Canadian *experience*?

Mr. Morrison: I have carefully considered the matter, but the number of priorities which would have to be issued would be so large that I am afraid it would involve serious interference with the free flow of traffic.

Mr. Marjoribanks: Will the right hon. gentleman look into the Canadian experience and see how it has worked?

No further reply was given.

Indian University Students in Britain.

Commander Oliver Locker-Lampson asked the Secretary for India how many Indian students are now in residence at English and Scottish universities and enjoying educational hospitality.—Mr. Benn replied: According to figures supplied by the institutions concerned, the total number of Indian students at present studying at universities, colleges, medical schools, and other educational institutions of similar standing in Great Britain is approximately 1740.

War Pensioners and Tuberculosis.

Mr. Hore-Belisha asked the Minister of Pensions (1) the number of men in receipt of disability pensions in respect of tuberculosis during the years 1928, 1929, and 1930, respectively, who had had their pensions increased as a result of the findings of the medical board that their conditions had deteriorated, and the number of men during the same period who had had their pensions decreased as a result of the findings of the medical board that their condition had improved; and (2) the number of reviews during the years 1928, 1929, and 1930, respectively, by medical boards of cases where disability pensions had been granted in respect of tuberculosis; and the *number of* cases during the same period where the disability pension had been withdrawn *on the* ground that the effects of tuberculosis had passed, or by reason of the pensioners having died as a result of the disease.—Mr. F. O. Roberts replied: The records of the Ministry do not enable me to state precisely the number of disabled officers and men pensioned for tuberculosis whose cases have been reviewed in the years referred to and, consequently, I cannot state the number whose pensions have been increased or decreased. I understand, however, that normally in a majority of the cases the pension either remains the same or is increased, while the number of cases in which the pension has ceased to be drawn on the ground that the effects of war service have passed away, is in comparison negligible. The deaths of tuberculosis pensioners reported during each *of the three* years were in 1928, 1450; in 1929, 1400; and in 1930, 1050; but the number of these cases in which death was due to the disability cannot be stated.

Veterinary Medical Research.

Lieut.-Col. Fremantle asked the Minister of Agriculture when it was proposed that the scheme now being prepared for the development and coördination of veterinary medical research should be *put into operation*; and whether an opportunity would be given to the House to discuss it before the details were finally decided.—Dr. Addison replied: The scheme is still under consideration and I cannot yet say when it will be put into operation. The subject can, of course, be raised when the appropriate Vote is before the House.

Mental Defectives in England and Wales.

Mr. Gordon Macdonald asked the Minister of Health the number of certifiable mental defectives in England and Wales for each of the five years ended Dec. 31st, 1930.—Miss Lawrence replied: Statistics are not available as regards the number of persons certifiable as mental defectives, but the number of persons detained under certificates under the Mental Deficiency Acts on Dec. 31st in each of the last five years is as follows: 1926, 20,091; 1927, 21,598; 1928, 23,275; 1929, 25,076; 1930, 27,811.

Ingredients of Margarine.

Mr. McElwee asked the Minister of Health the names of the various ingredients used in the manufacture of margarine in Great Britain during 1930; and the principal sources from which they were obtained.—Miss Lawrence (Parliamentary Secretary to the Ministry of Health) replied: My right hon. friend is not able to give information specifically relating to the year 1930, but he is advised that the principal ingredients normally used in the manufacture of margarine are various vegetable oils and fats, such as rachis, coconut, palm kernel, soya bean, and cotton seed oils, and rendered animal fats such as oleo oil and hardened marine animal fats. The ingredients are obtained from various sources, home and foreign, including West Africa and Manchuria for vegetable oils, and South America for *oleo.*

Inspection of Private Schools.

Mr. Marjoribanks asked the Prime Minister whether he would consider the introduction of legislation to make proprietary private schools subject to inspection by the Board of Education and the Ministry of Health. Mr. Morgan Jones (Parliamentary Secretary to the Ministry of Education) replied: My right hon. friend regards this *as a matter for consideration* when a report has been received from the departmental committee which was appointed by his predecessor last December to consider the position of all schools not in receipt of grant from public funds.

TUESDAY, MAY 12TH.

Women and National Health Insurance.

Mr. Morley asked the Minister of Health the number of women contributing to health insurance in this country in the years 1920 to 1921 and 1930 to 1931.—Mr. Greenwood *replied*: *The number* of women in Great Britain who were contributing for national health insurance purposes on Dec. 31st, 1920, was 5,061,000, and the corresponding figure on Dec. 31st, 1930, was 5,750,000.

Licensing in Scotland.

Mr. Duncan Millar asked the Secretary for Scotland when the Report of the Royal Commission on Licensing in Scotland would be issued.—Mr. Westwood replied: I understand that the Commission hope to be able to make *their report* towards the end of this month, and arrangements will be made for its presentation and issue as soon as possible thereafter.

MEDICAL NEWS

University of Cambridge.

On May 9th the following degrees were conferred :—

M.D.—H. K. Goadby, Alexander Sandison, S. E. F. Gooding, and W. G. S. Brown.

M.Chir.—R. W. Butler.

B.Chir.—V. H. Ellis.

At a congregation on May 9th approval was given to reports on the establishment of a university lectureship in pharmacology and a university demonstratorship in the department of experimental psychology.

Royal College of Physicians of London.

On May 7th diplomas of L.R.C.P. were conferred upon 58 candidates (50 men and 8 women) who have passed the final Examination of the Conjoint Board and have complied with the by-laws of the College. These candidates had not completed their examinations in time for the College meeting on April 30th.

The following are the names and medical schools of the successful candidates :—

Margaret Abernethy, Royal Free ; R. E. Adam, Oxford and St. Thomas's ; Margaret H. Banks, Royal Free ; G. Barwell, Guy's ; J. S. Batchelor, New Zealand and Guy's ; R. J. V. Battle, Camb. and St. Thomas's ; Jessie G. Belilios, King's Coll. ; L. P. B. Chamberlain, Univ. Coll. and St. Bart.'s ; S. Cimmering, St. Bart.'s ; G. T. Cook, Camb. and King's Coll. ; K. M. Cooper, Royal Free ; G. J. Cunningham, St. Bart.'s ; L. E. A. Dearberg, Guy's ; W. De Lacey, Cardiff and London ; S. D. De Silva, L.M.S., Ceylon and Univ. Coll. ; N. B. Fadia, M.B., Bombay ; L. Farris, Liverpool and Charing Cross ; A. C. Frazer, St. Mary's ; W. G. Glassco, McGill and St. Mary's ; T. N. Gledhill, Oxford and Westminster ; H. Goldenberg, London ; D. G. Gower, Camb. and Westminster ; L. J. Hackett, St. Bart.'s ; Kathleen M. L. Hall, Royal Free ; H. T. Halper, St. Bart.'s ; M. Halperine, M.D., Paris and London ; A. C. Hauptfleisch, Cape and Guy's ; N. Heath, Oxford and Westminster ; G. Holroyd, Leeds and Guy's ; J. H. Hunt, Oxford and St. Bart.'s ; A. L. Jacobs, Oxford and Univ. Coll. ; C. D. P. Jones, Univ. Coll. ; M. S. Khan, Middlesex ; Janet Y. Laidlaw, Royal Free ; M. M. Landau, Middlesex ; R. C. Langford, Camb. and St. Thomas's ; G. F. Lashmore and A. J. D. Lewis, Guy's ; H. M. List, St. Bart.'s ; A. W. Littlewood, St. Mary's ; B. F. Longbotham, Camb. and London ; A. P. McEldowney, Camb. and St. Thomas's ; G. B. Malone-Lee, Oxford and St. Thomas's ; T. P. Mulcahy, Camb. and St. Thomas's ; B. S. Nanjiani, M.B., Bombay ; J. L. Parker, Camb. and St. Thomas's ; J. Ross, L.M.S.S.A., Toronto and Charing Cross ; Eileen M. M. Shaw, L.M.S.S.A., Royal Free and Westminster ; H. J. Shorvon, St. Thomas's ; M. Shorvon, King's Coll. ; E. G. Sibley, Middlesex ; J. H. Spence, Camb. and St. Thomas's ; A. L. Thomas, L.M.S.S.A., Cardiff and Guy's ; J. C. Wharton, Guy's ; Eva M. M. Willett, Westminster ; G. M. Willey, King's Coll. ; O. S. M. Williams, Oxford and Westminster ; W. G. Wright, King's Coll.

Royal College of Physicians of Edinburgh.

A quarterly meeting of the College was held on May 5th with Sir Norman Walker, the President, in the chair. Dr. Thomas Ferguson (Falkirk), Dr. Ronald Douglas Mackenzie (Edinburgh), Dr. Ernest Watt (Edinburgh), and Dr. George Matheson Cullen (Edinburgh) were introduced and took their seats as Fellows of the College. Dr. George Hector Percival (Edinburgh), Dr. David Lees (Edinburgh), Dr. Margaret Black Martin (Edinburgh), and Dr. Joseph Ryland Whitaker (Edinburgh) were elected to the Fellowship. Dr. Robert Thin was re-elected a representative of the College on the Conjoint Committee of management of the triple qualification. The Freeland Barbour Fellowship was awarded to Robert Henry Slater, Ph.D.

Scottish Conjoint Examining Board.

Of 81 candidates recently entered for the final examination of the Board, the following were successful and have been admitted licentiates of the Royal College of Physicians of Edinburgh, the Royal College of Surgeons of Edinburgh, and the Royal Faculty of Physicians and Surgeons of Glasgow.

Loutfi Ahmed, P. M. Ballantyne, Paul Barron, D. A. Black J. S. F. Botha, John Boyle, Robert Bulman, Parshotam Dass, A. C. Devaraj, Amin Fazary, J. T. M. Fenton-Fyffe, Klass Graftdyk, D. M. I. Harmar, M. D. D. Jayawardana, S. G. A. Malek, R. E. Mullarky, Alexandrina M. M. Parker, W. R. Parker, G. S. Robertson, Joseph Rosenberg, George Rosenbleitt, Manmanathanatt Sarkar, D. W. Semmens, Ahmed Shabten, J. A. Shehid, J. E. Sprunt, Helen V. Tindal, H. F. Tindal, A. W. Turnbull, Mary T. Wilson, and W. R. Young.

D.P.H.—The following candidates have been admitted Diplomates in Public Health :—

N. W. Ahin, Helena E. Barrett, A. D. Gorman, B. N. Khan, Mary L. Liston, and F. F. Main.

The Cancer Hospital.

At the annual general meeting of this hospital, held on May 1st, Mr. R. H. Jocelyn Swan spoke on the progress made in the treatment of cancer. He said that radium certainly holds a place in the treatment of cancer, but that its field of usefulness is being narrowed down to certain forms of cancer in particular organs. In his view the attack upon a cancer by burying multiple needles containing radium into it held out more promise than the external application or even that form of treatment supplied by the bomb, and work in this hospital had been carried out on these lines. There was no doubt that primary growths of the tongue and in the uterus might in a proportion of cases be made to disappear with radium, but to acclaim this as a cure was misleading and showed ignorance of the disease. Unfortunately radium did not seem to have such an effect upon the secondary glandular spread, so that in many cases in which the primary growth had been cleared away the secondary growths still continued. A number of cases of cancer of the breast and other organs had been treated with radium with encouraging results, but further time must elapse before they could speak of cures. In many cases relief of suffering was obtained by radium. Mr. Swan did not wish to appear pessimistic by any means: in fact, he was still optimistic, but he thought the general public should realise that radium was not the certain cure for cancer that they had been led to believe it was by premature reports both in the medical and in the lay press. At present, except perhaps as regards the tongue, the uterus, and possibly, the breast, they must rely on the orthodox widespread removal of the diseased organ together with its lymphatic areas of spread, rather than be too far fascinated by a form of treatment which might lead to disappointment and to sacrifice of human life. He was of opinion that in radium we had a valuable adjunct to our methods of treatment, but it was a dangerous weapon, and should be in the hands of those alone who know not only how to use it, but when to use it, and to use it with minute care and precision. Another recent innovation in the hospital was being carried out by Dr. S. Wyard. By means of a special instrument[1] a series of photographs of the interior of the stomach could be obtained with one flash exposure. From the enlargement of these small photographs they hoped to be able to detect those early cancers in the stomach which give rise to symptoms often few or deceptive until the disease has passed the range of operative removal. The new wing of the hospital was approaching completion, and the increased number of beds for free patients, and those allotted to patients who could afford something towards their maintenance and treatment, would, said Mr. Swan, add considerably to their work.

University of London.

At a meeting of the University Court on May 7th it was reported that the late Mr. Clifford B. Edgar had bequeathed £1000 to the London School of Hygiene and Tropical Medicine for the promotion of research. For the further extension of the London School of Economics and Political Science the Rockefeller Foundation has offered a sum up to about £140,000.

Lebanon Hospital for Mental Diseases.

The thirty-second annual meeting of this hospital will be held at 3.15 P.M. on Tuesday, May 19th, at Friends House, Euston-road, London, N.W., with the Rt. Rev. Herbert Bury, Assistant Bishop of London, in the chair. Among the speakers will be Dr. E. W. G. Masterman, chairman of the General Committee, and Dr. J. Tylor Fox. The secretary's address is 55, Wellington-road, N.W. 8.

University of London Medical Graduates Society.

The annual meeting and dinner of this society was held at the Langham Hotel on May 11th. Sir John Rose Bradford, the President, presided over a gathering which included the Vice-Chancellor (Rev. Scott Lidgett), the President of the Royal College of Physicians of London (Lord Dawson), and the President of the Royal College of Surgeons of England (Lord Moynihan), both medical graduates of the University. The next dinner of the society will be held on Nov. 13th at Bristol.

Medical Tour in Central Europe.

A tour is being arranged for medical men in Central Europe from August 24th to Sept. 11th. The party will arrive at Linz on August 26th, and sail down the Danube to Vienna, where two full days will be spent. Four days will then be devoted to Pistany (Czechoslovakia) and its neighbourhood, after which there will be a further four days at Luhacovice. At each of these centres the bath establishments and other medical institutions will be shown. The tour will continue via Prague and Nuremberg. Particulars and terms may be had from the Pistany Spa Representation, 38, Sackville-street, London, W. 1.

---

[1] See THE LANCET, Feb. 14th, p. 371.

Socialist Medical Association.

The first annual general meeting of this association was held at Conway Hall, Red Lion-square, London, on May 10th, when the President, Mr. Somerville Hastings, M.P., gave the address which appears on p. 1115. In the ensuing discussion Dr. Alfred Salter, M.P., said that there would be an enormous amount of prejudice to be overcome before the family doctor idea was swept away. The British public would resent dictation by a social directorate. The executive committee reported that since the inception of the association in October last a subcommittee had been collecting evidence in favour of a detailed policy for the establishment of a free socialised medical service. Another subcommittee had been organising lectures for members of the trades-union, labour, socialist, and coöperative movements. Representatives of the association were to attend the first International Conference of Socialist Physicians to be held at Carlsbad this month. It was agreed that the association should seek affiliation to the National Labour Party. Resolutions were passed opposing paying wards in, and charges being made at, municipal hospitals for infectious diseases, including tuberculosis, expressing the opinion that municipal and hospital treatment should at once be dissociated from the poor-law, and pressing for the establishment of nursing in the Ministry of Health and the raising of the income limit of national health insurance to £500 a year. The following were elected officers for the coming year:—

President, Mr. Somerville Hastings, M.P. Treasurer, Dr. Alfred Welply. Secretary, Dr. C. W. Brook, L.C.C. Trustees, Dr. Hector Munro, and Dr. V. H. Rutherford. Executive Committee, Dr. Bensusan Butt, Dr. Frank Bushnell, Dr. S. W. Jeger, L.C.C., Dr. Caroline Maule, Dr. A. V. R. Menon, Dr. J. Grant Morris, Dr. D. P. Murray, Miss Esther Rickards, M.S., L.C.C., Dr. M. Rose, Dr. Alfred Salter, M.P., Dr. John Powell-Evans (London branch secretary), Mr. F. Lawson Dodd (dentists' representative), Miss Gladys Le Geyt (nurses' representative), and Mr. Roy Dennison (students' representative).

The meeting concluded with an address by Prof. Major Greenwood, F.R.S., on the Municipal Hospitals, the University, and Medical Research in London.

Scientists' Tour in Russia.

Accounts of this tour were given in THE LANCET of Jan. 31st and April 18th (p. 887), and owing to the large demand for membership of the first party, the lists for which closed on April 30th, a second party will now leave London Bridge by Soviet ship for Leningrad on August 8th. The return fare will be £18 inclusive. The party will spend a total of 16 days in Russia—three days in Leningrad, five days in Moscow, half a day in Nizhni-Novgorod, and four days on the river down to Stalingrad (if desired). The cost per day will be £1 per head inclusive, the balance of the days being spent in travelling. Meetings will be arranged which members of the party will be invited to address, and there will be excursions with guides to scientific institutions of interest to the members. The Soviet authorities are prepared to give this tour second category accommodation at third category prices. The accommodation will be comfortable, and persons will sleep three or four in a room. Those wishing to sleep two in a room will pay 5s. per day extra. The party will consist of 25 persons. If there is a large demand for places the list might be extended. The latest date for receiving applications is June 15th. Inquiries should be addressed to the Secretary, Society for Cultural Relations, 1, Montague-street, London, W.C. 1.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MONDAY, May 18th.—8 P.M., ODONTOLOGY. Annual General Meeting at the Royal College of Surgeons, Lincoln's Inn-fields, London, W.C. *Election of Officers and Council.* Casual Communications: Dr. E. W. Fish: An International Nomenclature of the So-called Pyorrhœa Group of Diseases. Demonstration: Sir Frank Colyer will show upon the screen some of the older dental instruments in the Museum.

TUESDAY.—4.30 P.M., SPECIAL GENERAL MEETING OF FELLOWS. Abolition of the Sections of Balneology and Climatology, and Electro-Therapeutics. Creation of two new Sections of Physical Medicine and Radiology.—5 P.M., GENERAL MEETING OF FELLOWS. Ballot for Fellowship.

THURSDAY.—5 P.M., DERMATOLOGY. (Cases at 4 P.M.) Election of Officers and Council. Cases: Dr. H. W. Barber: Extensive Atrophic Lichen Planus. Dr. H. W. Barber and Dr. L. Forman: *Sycosis Treated with Intradermal Vaccine.* Mr. Percival P. Cole: Rhinoplasty *after Lupus of the Nose.* An apparatus to maintain Wolff grafts, or radium applicators in position on the face. Dr. *W. N. Goldsmith: Case* for Diagnosis: ? Lichen Planus Atrophicus. Specimen of Mycosis Fungoides of Internal Organs. Other *cases will* be shown.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, 11, Chandos-street, W.

THURSDAY, May 21st.—8.15 P.M. (preceded by a demonstration at 7.15 P.M.), Dr. G. W. M. Findlay, Dr. J. L. Dunlop, and Major H. O. *Brown: Observations* on Epidemic Catarrhal Jaundice.

ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION.

THURSDAY, May 21st.—2.30 P.M. (at B.M.A. House, Tavistock-square, W.C.), Quarterly Meeting. Papers. Dr. Norman Phillips: Mental Disorders associated with Pernicious Anæmia. Dr. W. F. Samuels: Antimalarial Work at Central Mental Hospital, Tanjong, Federated Malay States. Dr. Geoffrey Shera: Terminal Uræmia, with Notes on the Prevalence *of Renal Disease* among the Insane.

BIOCHEMICAL SOCIETY.

SATURDAY, May 16th.—2.30 P.M. (in Department of Biochemistry, Oxford), Communications and Demonstration.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, *Lincoln's* Inn-fields, W.C.

MONDAY, May 18th, and following WEDNESDAY.—5 P.M., Colonel Robert McCarrison: Experimental Research at the Pasteur Institute, India.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, May 18th to SATURDAY, May 23rd.—MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W. M.R.C.P. Special evening lectures at 8.30 P.M. Tues., Dr. L. J. Witts: Jaundice. Fri., Dr. W. J. Adie: Diseases of the Nervous System, I. ROYAL NORTHERN HOSPITAL, Holloway-road, N. Wed., 2 P.M., Demonstration in the Out-patient Department by Dr. Calvert. No fee.—QUEEN'S HOSPITAL FOR CHILDREN, Hackney-road, E. Fri., 10 A.M., Demonstration of General Cases by Mr. Coyte. No fee.—ROYAL EYE HOSPITAL, Southwark, S.E. Afternoon course. Demonstration daily.—ST. JOHN'S HOSPITAL, Leicester-square, W.C. Afternoon and evening demonstrations in skin diseases. Lectures four days a week at 5 P.M.—CITY OF LONDON HOSPITAL FOR DISEASES OF THE HEART AND LUNGS, Victoria Park, E. All-day course in Diseases of the Heart and Lungs. Lectures and demonstrations.—Further particulars from the Fellowship of Medicine.

NATIONAL HOSPITAL, Queen-square, London, W.C.

MONDAY, May 18th.—12 noon, Dr. Greenfield: The Cerebrospinal Fluid. 2 P.M., Dr. Riddoch: Out-patient Clinic. 3.30 P.M., Dr. Hinds Howell: Subacute, Combined Degeneration of the Cord.

TUESDAY.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Dr. Critchley: Cerebral Vascular Disease (2).

WEDNESDAY.—2 P.M., Dr. Martin: Out-patient Clinic.

THURSDAY.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Dr. Critchley: Cerebral Vascular Disease (3).

FRIDAY.—2 P.M., Dr. Adie: Out-patient Clinic. 3.30 P.M., Dr. Carmichael: Birth Palsies.

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith, W.

MONDAY, May 18th.—10 A.M., Gynæcological Ward Visit, Genito-Urinary Operations, Skin Department. 11 A.M., Surgical Ward Visit. 2 P.M., Medical, Surgical, Eye and Gynæcological Out-patients, Operations. Surgical Ward Visit.

TUESDAY.—Operations. 10 A.M., Medical Ward Visit, Dental Department. 11 A.M., Throat Operations. 11.30 A.M., Surgical Clinical Demonstration. 2 P.M., Medical, Surgical, Throat Out-patients, Operations, Medical Ward Visit.

WEDNESDAY.—Medical Ward Visit, Childrens' Medical Out-patients. 2 P.M., Medical, Surgical and Eye Out-patients, Gynæcological Operations. 4.45 P.M., Venereal Diseases.

THURSDAY.—10 A.M., Neurological Department. 11.30 A.M., Treatment of Fractures, 2 P.M., Medical, Surgical, and Eye Out-patients, Genito-Urinary Department. Operations.

FRIDAY.—10 A.M., Medical Ward Visit, Skin and Dental Departments. 12 noon, *Medical Lecture.* 2 P.M., Medical, Surgical, and Throat Out-patients. Operations.

SATURDAY.—9 A.M., Throat Operations. 10 A.M., Medical Ward Visit, Surgical and Childrens' Medical Out-patients.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION, St. James's Hospital, Ouseley-road, *Balham*, S.W.

THURSDAY, May 21st.—3 P.M., Visit to Clinic for Rheumatism, Peto-place, Marylebone-road, N.W. Dr. B. S. Nisse.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE, Keppel-street, Gower-street, W.C.

WEDNESDAY, May 20th.—Dr. Bernard Hart: Mental Hygiene.

FRIDAY.—Prof. E. L. Collis: Industrial Hygiene: Respiratory Diseases.

their ordinary avocations. Some kind of hostel where offenders on probation could live, under care, detached from a perhaps highly unsatisfactory home environment, yet continuing to earn their living, would be of the greatest possible value.

The question arises of who should provide these centres. Dr. Mary Barkas stated at the discussion that the Mental Treatment Act would empower local authorities to undertake this enterprise as part of their scheme for the mental health of the community. Others believe that it would not be satisfactory to leave an important national provision like this to local authorities; the failure of some of them to deal with their mental deficiency problem being quoted. The centres should most certainly not be part of the penal system of the country; Borstal is a part of this system, but industrial and reformatory schools and remand homes and all other provision for juvenile offenders come, as they rightly should, under the children's department of the Home Office. The observation homes would be part of the mechanism of the court to the extent that magistrates might use such powers of persuasion and force as they have at their command; otherwise the parent or guardian might be reluctant to allow the child to go to the centre. The psychopathology of crime—particularly juvenile crime—is a matter which doubly concerns the medical profession. It should make a strong appeal to every citizen, and it is time that there was sufficient pressure of public opinion to make a Children's Bill a first charge on any Home Secretary and not a measure that will get before the House only when there is nothing else in the way. The matter has also a peculiar appeal to doctors, in whose hands this delicate and difficult work of the future must almost inevitably be placed. Miss Cicely Craven, the Secretary of the Howard League, said very truly at the conference that the remand wards of our prisons are to the psychologist what the hospitals are to the physician and surgeon. They offer a collection of material—at present hardly realised—which could be investigated and treated, not only to the relief of the sufferers themselves, but also to the great good of the community as a whole.

AN AUTHORITATIVE LIST NEEDED.

To the Editor of THE LANCET.

SIR,—I note the reply in THE LANCET of April 18th (p. 896) to my question as to a list of persons properly qualified to offer certain assistance to practitioners. There seems to me no doubt as to the necessity of letting practitioners have the names of institutions or medical men to whom they may send patients for such service as reducing chronic dislocations, breaking down adhesions, resetting bones, manipulating joints, &c. But it should be required that the cases are treated *by someone on the Medical Register* who has experience in manipulative work. I think most of your readers will agree that this information should be supplied to medical men who require such assistance for their patients, in an authoritative list.

I am, Sir, yours faithfully,

May 6th, 1931. PHYSICIAN.

OUR OLDEST SUBSCRIBER.

To the Editor of THE LANCET.

SIR,—Under this heading Dr. James Gairdner in THE LANCET of March 14th says that he was born in 1846. He is by two years my senior. There are many medical men older than both of us I am sure, but my claim was that I was probably the oldest subscriber, as I have been a subscriber for 61 years without intermission.

I am, Sir, yours faithfully,

Bombay, April 16th, 1931. TEMULJI B. NARIMAN.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.—The Cavendish lecture will be given at the Kensington Town Hall at 8.15 P.M. on Friday, June 5th, by Prof. Julian Huxley, whose subject will be Development in Relation to Heredity and Evolution. The reception begins at 7.45 P.M. and the annual conversazione will follow the lecture.

Births, Marriages, and Deaths

BIRTHS.

COPE.—On May 3rd, at Welbeck-street, W., the wife of Dr. C. F. Cope, Pulborough, Sussex, of a daughter.

LISTER.—On May 1st, at Clifton, Bristol, the wife of William A. Lister, M.B., of a son.

LE MARQUAND.—On May 2nd, at Lima House, Reading, the wife of Dr. H. S. Le Marquand, of a daughter.

LOCKE.—On May 5th, at "Elmcroft," The Causeway, Potters Bar, to Dorothy Norah, the wife of Robert Gibbs Locke—a daughter.

MAITLAND-JONES.—On May 9th, 1931, at 31a, Weymouth-street, to Miriam, wife of Dr. A. G. Maitland-Jones—a son.

THWAITES.—On May 7th, the wife of Dr. W. G. Thwaites, Brighton, of a son.

MARRIAGES.

TASKER—BUCKMASTER.—On May 6th, at St. Paul's Church, Clifton, Bristol, Dr. Ronald Henry Tasker, to Dr. Dorothy E. B. Buckmaster, only daughter of Prof. and Mrs. Buckmaster, of Victoria-square, Clifton, Bristol.

DEATHS.

BAHADURJI.—On May 3rd, at Lexham-gardens, London, Dr. J. N. Bahadurji, M.R.C.S., L.R.C.P., aged 61 years.

BONTOR.—On May 8th, at a nursing home, Hampstead, Sidney Algernon Bontor, M.D., of Lancaster-road, Hampstead, late of Great Berkhamsted, Herts.

DUKE.—On May 4th, at Fernhurst, Sussex, Arthur Stanley Duke, L.R.C.P.

HOPKINS.—On May 9th, at Glenorchy, Parkstone, Dorset, Arthur Henry Hopkins, M.B., C.M.

JENKINS.—On May 9th, at Ranelagh-villas, Hove, Arthur William Jenkins, M.B., B.S., aged 60 years.

LATCHMORE.—On April 1st at Taupo, New Zealand, in his 61st year, Arthur Thomas Latchmore, M.R.C.S., L.R.C.P., sometime surgeon to the Princess Christian Hospital, Freetown.

MUGLISTON.—On May 7th, at Chy-an-Dreath, Newquay, Cornwall, after a long illness, Thomas Crichton Mugliston, M.R.C.S., L.R.C.P., R.N. (retired), formerly of Singapore and Penang, aged 77.

ODELL.—On May 5th, at Bengeo, Hertford, Robert Odell, M.D., F.R.C.S., aged 63 years.

SCHOFIELD.—On May 10th, at The Homestead, Grosvenor-road, Caversham, Gerald Schofield, M.D.

THOMAS.—On May 9th, at Greystones, Sea Front, Hayling Island, Cadogan Thomas, M.R.C.S., L.R.C.P. Lond., in his 69th year.

TONKS.—On May 4th, at Chesterfield, John Wilson Tonks, M.A., M.D., B.Chir. Camb., F.R.C.S. Eng., aged 43.

WEIR.—On May 4th, at Park-road, N.W., Henry Bright Weir, M.A., M.B., B.Chir. Camb.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages and Deaths.

MEDICAL WOMEN'S FEDERATION: ANNUAL MEETING. The annual general meeting of the Medical Women's Federation was held on May 7th at the Apothecaries' Hall, where the members were welcomed by Lieut.-Colonel C. T. Samman. The President of the Federation, Miss L. Martindale, M.D., thanked the Master for his welcome and the Court of Apothecaries for their permission to hold the meeting in these historic surroundings. The hon. secretary, Miss M. Ramsay, F.R.C.S., in presenting the annual report, pointed out several events of interest to medical women. Aberdeen Infirmary had appointed its first woman ophthalmic surgeon; a woman regional medical officer had for the first time been appointed by the Minister of Health, and a woman had been made a Commissioner of Lunacy under the new Board of Control. 127 new members had joined the Federation this year. A discussion, opened by Miss G. Herzfeld, F.R.C.S. Edin., took place on the facilities at present available for medical women for gaining post-graduate experience as members of resident staffs in general hospitals. The conditions existing in this respect in different parts of Great Britain were described by local representatives. In the evening a large gathering of members and their friends were entertained in the Great Hall of the British Medical Association house at a reception and cabaret supper. Amongst the resolutions passed at the Council meeting held on March 8th were a request that all post-graduate courses and facilities for study in medicine, surgery, and special subjects shall be available to men and women alike; a request that the Government should make provision that on the Governing Body of the Post-graduate Hospital and Medical School one of the governors shall be a medical woman nominated by the Medical Women's Federation; and the expression of an opinion that in areas where two venereal disease officers are appointed one should be a woman. In regard to the last resolution, it was added that in areas where such a course is impracticable, medical officers of health should take every opportunity of having female maternity and child welfare officers trained in the diagnosis and treatment of venereal diseases. In the evening the President entertained the members of Council to dinner at the De Vere Hotel.

ADDRESSES AND ORIGINAL ARTICLES

THE NEUROLOGY OF OLD AGE.*

By Macdonald Critchley, M.D. Brist.,
F.R.C.P. Lond.,
JUNIOR NEUROLOGIST TO KING'S COLLEGE HOSPITAL; ASSISTANT PHYSICIAN TO THE NATIONAL HOSPITAL, QUEEN SQUARE.

LECTURE I.

The subject of old age has never been a popular one with the medical profession. Among both savage and civilised peoples a certain lack of interest, and even of sympathy, is associated with the infirmities and maladies of the aged. Problems of diagnosis and of therapy tend to be neglected, to the detriment of the individual and still more of the community. Most contributions to the study of old age have been of a speculative nature, dealing with such aspects as causation and even prevention. A certain number of writers have devoted themselves to the more tangible problem of disease in old people, and within the last century a small series of monographs has accumulated.

Thus, ten years after Canstatt's work[1] which appeared in 1839, came Dr. G. E. Day's[2] "Domestic Management and Diseases of Advanced Life." The well-known work of Durand-Fardel[3] was issued in 1854 and Geist's[4] monograph in 1860; three years later Maclachlan,[5] who was the medical officer in charge of the Royal Hospital, Chelsea, published his "Practical Treatise on the Diseases and Infirmities of Advanced Life." Two important French monographs followed—namely, Charcot's[6] Clinical Lectures (1868) and the "Étude Clinique et Anatomo-Pathologique sur la Vieillesse" of Demange[7] (1886). At about the same time in this country Sir George Humphry[8] published his monograph on "Old Age," containing the results of a systematic investigation of the health and habits of a large number of centenarians. No further contributions appeared until 1909 when Schwalbe's[9] "Lehrbuch der Greisenkrankheiten" was published, and also in France Rauzier's monograph.[10] In 1913 Saundby's[11] book on "Old Age" was published, and in the same year Schlesinger[12] wrote his treatise on "Alterskrankheiten," a reprint of which was issued a few months ago. Nascher's "Geriatrics"[13] was published in 1919. In a class by itself is the delightful and informative Linacre Lecture delivered by Sir Humphry Rolleston[14] in 1922 on Some Medical Aspects of Old Age, and which is surely the most thoughtful and inspiring monograph on this subject.

I have been unable to trace, however, any volume dealing with the neurological aspects of senility, and the only contribution on the subject which I know is the Bradshaw Lecture delivered before this College in 1915 by Dr. Michell Clarke, on the Nervous Affections of the Sixth and Seventh Decades of Life.[15] Although monographs devoted to this problem are few, many brief but valuable contributions have appeared from neurologists who have been privileged to work as directors of institutions for chronic nervous disorders. Thus the work of Lhermitte and his pupils, and that of Schuster, are monuments of clinical observation and breadth of vision in this particular aspect of neurology.

To preserve this study from the pitfalls of discursive speculation we must content ourselves primarily with the mere collection of data; an exact knowledge of the clinical and anatomical facts is essential before we can discuss the neurological aspects of old age in a scientific and dispassionate manner. For this reason I have thought it wise to reverse the usual order of descriptive technique and to deal first with the pathological side of the problem. Furnished in this way with a picture of the anatomical processes we are better able to evaluate what we encounter at the bedside.

The Senile Brain.

In this first lecture we will consider the morbid changes seen in the nervous system of individuals who have died at an advanced age.

Contributions to the pathology of the senile brain have not been numerous. The earliest record which I have been able to trace was made by William Harvey[16] in the *Philosophical Transactions* for 1635. At the command of King Charles I., Harvey conducted a post-mortem examination on the famous Thomas Parr, of Great Wollaston, Shropshire, who died at the age of 154 years. Harvey mentions, after describing the various viscera, that the brain was "healthy, very firm and hard to the touch." In the fifth volume of the *Philosophical Transactions*, covering the period 1700–20, Dr. James Keill[17] recorded the autopsy appearances in one John Bayles, a button-maker of Northampton, who died at the age of 130. "The brain" we are told "was more firm and solid than usual, and, in cutting, hardly moistened the sides of the knife. The ventricles were full of serum." Dr. Keill relates that the patient had been blind for some years, but that the hearing was good. For some years prior to death the patient's bowels had been opened, on an average, once every 10 to 12 days.

Dr. Edward Holyoke, a respected physician at Salem, Massachusetts, died in the year 1829, having attained the age of 101. After his death, a committee of friends wrote a short appreciation and adding a collection of his letters and notebooks, published a little monograph[18]; a copy of this rare work is upon the shelves of the library of the Royal College of Physicians. Herein is included a description of the autopsy, and we learn that the dura was adherent to a very dense calvarium. The sulci were widened and deepened, and the cortex was unusually dark. The brain felt unduly hard . . . . "as if subjected to the action of alcohol." A disproportionate atrophy of the cerebellum was noted.

A short description was given by Berruti[19] in 1857 of the brain of an Italian who died aged 104 years. The chief point of interest was an extensive ossification of the dura mater.

Prof. George Rolleston's anatomical study[20] of John Pratt, who lived to 107 years, followed in 1884. Rolleston mentions that the meninges were adherent to the inner table of the skull and that the arachnoid was opaque in patches. The convolutions were atrophied, especially in the prefrontal lobe and the Rolandic gyrus. A moderate dilatation of the lateral ventricles was present, the lining membrane being smooth. Numerous corpora amylacea were visible microscopically beneath the ependyma.

Sir George Humphry's note in 1889[8] upon the pathological findings in a female of 103, makes the next contribution; we are told that the brain was shrunken, the fissures being broad and occupied by an excess of cerebro-spinal fluid. The skull was thick and heavy; weighing 28½ oz. In this paper Humphry quotes a personal communication from Prof. Cunningham, who in the same year had examined the organs of a woman of 106; he had found the brain firm and healthy in appearance, with wide separation of the gyri. A model of this brain was placed in the Museum of the University of Cambridge.

---

* The Goulstonian Lectures for 1931, delivered before the Royal College of Physicians of London on March 10th, 12th, and 17th.

The most important landmark in our knowledge, however, is the work of André Léri,[21] who in 1906 published his thesis on "Le Cerveau Sénile." This monograph is still in many respects the most authoritative presentation of the subject. It was followed one year later by the papers of Anglade and Calmettes [174] on the histology of the senile cerebellum.

Within the past 20 years a few short contributions have appeared, mainly based on isolated cases. Thus there are the papers of Costantini (1911) [22] on the brain of a man of 105; of Marinesco and Minéa (1921 and 1925), who examined a number of Roumanian brains, including one of a female aged 105; of Kuczynski and Kopylowa (1925),[23] who studied minutely the organs of a man dying at 118, and a recent description by Askanazy [24] of a woman who died at 101. Oseki [25 26] in 1924 had studied the minute changes in the cortex and basal ganglia in a series of octo- and nona- genarians.

In addition to these data, there are a few interesting studies of the brains of various eminent individuals dying in late life. Thus we have Louis and Chambardel's [27] investigation of the brain of Anatole France, who died at the age of 84½, Mauer and Weimann's [28] description of the brain of Ernst Haeckel, who was aged 86. The brains of Mommsen the historian (aged 87), and Bunsen the chemist (aged 89) were also examined minutely. Spitzka [29] made a careful anthropometric investigation of the brains of six eminent American scholars, and in his monograph detailed similar studies of 137 outstanding individuals, a large number of whom had lived to a great age.

The foregoing constitute most of the important contributions to our knowledge of the senile brain. Senile dementia has, of course, been studied histologically with the utmost detail by many brilliant workers, particularly Alzheimer, Simchowicz, Marinesco, Perusini, Rizzo, Uyematsu, and Grünthal.

My own contribution is based upon the histological examination of a series of 15 senile brains, at present under pursuit in collaboration with Dr. J. Godwin Greenfield, pathologist to the National Hospital, Queen-square. These brains are from individuals aged as follows: 75 (1); 80 (1); 86 (1); 90 (3); 92 (2); 93 (2); 95 (1); 96 (1); 101 (1); 102 (1); and 103 (1). In addition, we have studied the spinal cord from five octogenarians.

CRANIAL CHANGES.

The calvarium in old age is usually increased in thickness, an observation which was first made by Morgagni [175] in 1765. In the majority of cases this densification is uniform, but at times a focal osteophytic process is seen. Thus a hyperostosis of the inner table of the frontal bone is a characteristic—if somewhat rare—anomaly. According to Greig's excellent description,[30] this process starts as irregular excrescences on either side of the sagittal sulcus, midway between the foramen cæcum and the coronal suture. These multiply and, spreading fanwise, occupy most of the frontal bone, but never extend posteriorly into the parietal area. Microscopical examination reveals a thickening of the inner table, the cancellous bone becoming overlaid with compact bone which later becomes eburnated.

Numerous hypotheses have been hazarded to explain this peculiar change. Characteristically present in old age, it is much commoner among females, in the ratio of 7 : 1. Although it is often said to be unaccompanied by symptoms, Morel has drawn attention to a group of clinical manifestations which he associates with this osteophytic process. The features of the so-called Morel's syndrome will be discussed later.

Greig has suggested that intracranial hyperostosis is the result of a disuse-absorption of calcium and phosphorus salts from the skeletons of senile individuals, whose muscular activities are limited; the excretion of these salts is inadequate and there results a deposition of osteophytes. Humphry, as well as Thoma [33] and Morel, drew attention to the presence in the majority of these cases of atrophy of the cerebrum, particularly in the frontal lobes. Adherence of the meninges to the inner table will, therefore, set up a more or less constant traction upon that region of the calvarium, stimulating bone formation. In the case of isolated small exostoses, Thoma suggests that some local circulatory or nervous disorder may be responsible.

Much less frequently an atrophy of the skull bones may be encountered in advanced life, a process which was first reported by Koehler in 1768. Humphry states that all the bones of the cranium and face may be reduced in calibre and thickness. This is produced by the outer table receding and encroaching upon the diploë, so that ultimately only one brittle table is left. At other times the atrophy may be localised usually with strict symmetry to the parietal bones. The atrophic areas merge into normal bone by a gentle shelving. Several excellent specimens of this anomaly are contained in the Museum of the Royal College of Surgeons. Occasionally, the two processes of parietal atrophy and hyperostosis of the inner table may coexist. The genesis of cranial atrophy is obscure, and Humphry suggests that the pressure or traction of the occipito-frontalis tendon may be important, a view later supported by Chiari.[34]

THE MENINGES.

Alterations in the meninges are practically constant. The dura mater is almost always thickened, and in many cases adherent to the inner table of the skull. Longitudinal densifications may occur along the course of the blood-vessels. The Pacchionian bodies are often hypertrophied. Calcareous patches are not infrequent and at times areas of ossification may exist. Bony plaques are, however, less common in the cranial dura than in the spinal leptomeninges; they occur, of course, in conditions other than senility, and Leopold [35] stresses arterio-sclerosis as a causative factor.

Proliferative changes in the dura were usually described, following Carpentier and others, as chronic meningitis, and when there was an associated increase in vascularity of the tissues, the term pachymeningitis hæmorrhagica interna used to be applied. This word is rarely employed nowadays, however, and the modern description is that of chronic subdural hæmatoma. It is well known that this lesion may supervene in the aged after very slight injury; it was present in four out of the 50 senile brains examined by Campbell.[36]

The leptomeninges may also be thickened and may be œdematous in appearance. Opaque areas are common, resembling the milky patches in the pericardium. Léri, however, insists that the pia arachnoid may become thinned in old age and show numerous perforations.

Usually the meninges strip off the hemisphere with particular ease in old age, except over the occipital poles. But when foci of softening exist in or immediately beneath the cortex, an adhesion results; in cases of diffuse vascular disease the meninges may be everywhere so adherent as to leave a pock-marked surface to the cortex (= the *état vermoulu* of Pierre Marie).

The histological appearance of the meninges in old age comprises a proliferation of all elements with concomitant regressive changes. There is often a conspicuous cellular infiltration with fibroblasts, macrophages, and pigment cells. Clusters of proliferating mesothelial cells are frequently seen. The innermost layer of the pia-arachnoid may be invaded by numerous corpora amylacea, and there is often a large amount of pigment visible.

When the meninges have been stripped the brain usually shows a striking diminution in volume. The convolutions are reduced and the fissures are widened and occupied by an excess of subarachnoid fluid. Although the shrinkage is universally distributed, it is always most evident in the anterior two-thirds of the brain. Spielmeyer states that the left hemisphere is usually more atrophied than the right, but I have not been impressed by any such difference. The pons, midbrain, and cerebellum usually show a less obvious wasting, but a reduction in the size of the medullary olives is common (v. Braunmühl).[37]

SHRINKAGE OF THE BRAIN.

The consistency of the brain may be altered. At times it is described as harder than normal, but quite often—particularly when multiple vascular lesions are present—the brain feels soft to the touch.

Some index of the brain shrinkage is afforded by weighing the hemispheres. Numerous statistical tables have been compiled—by Parchappe, Huschke, Broca, Rey, Boyd, and others—which suggest that after the age of 40 or 50 there is a progressive reduction in weight. In advanced age a loss of 160–200 g. may be encountered. According to M'Gaffin[38] the reduction is greater in the female than in the male. Exceptions are numerous to the rule that the brain loses weight with increasing years, and one must remember that the cerebrum may vary considerably in normal subjects, and that the presence of vascular disease would profoundly alter the results. None of this statistical work is recent, and I know of no extensive study of the weight of the brain in advanced years, carried out with the elaborate and accurate technique of Reichardt.

The results in those of my cases where weights were noted are as follows:—

Case	Sex.	Age.	Hemisphere.		Pons and cerebellum.	Total.
			Left.	Right.		
1	M.	75	503	497	163	1163
2	M.	80	550	525	165	1240
3	F.	86	488	472	146	1106
4	M.	90	542	548	163	1253
5	F.	90	496	473	144	1109
6	F.	92	392	392	129	913
7	F.	92	450	459	127	1034
8	F.	93	408	409	145	962
9	F.	93	—	—	—	1043
10	M.	96	465	469	133	1067
11	M.	101	501	502	166	1169
12	F.	102	336	358	121	815
13	F.	103	457	462	132	1051

It must be realised that brain weights are unreliable indices of the reduction in volume, because many variable factors are present. Thus the length of time over which the brain has been immersed in fixative is important. Moreover, there may occur with advancing years an alteration in the specific gravity of the cerebral substance so that the normal standards of volume and weight no longer apply.

Further alterations are apparent when a horizontal section is made through the hemispheres. The reduction in volume is now emphasised by a dilatation of the lateral ventricles. It will be evident that the ribbon of cortical grey matter is narrowed, particularly in the frontal and temporal areas. Still greater wasting is seen in the white matter, and the distance between the cortex and the cornua of the ventricles is markedly reduced. The corpus callosum constantly shares in this atrophy.

The central grey nuclei of the basal ganglia are smaller than normal and appear compressed by the state of internal hydrocephalus. It is apparent also that the grey matter is everywhere of a slightly darker tint than usual.

Another common naked-eye change consists in numerous lacunes of disintegration scattered throughout the basal ganglia, and to a lesser extent throughout the white matter. These appear as small perforations which may be few in number or in extreme cases so numerous as to constitute a true *état criblé*.

The wall of the ventricles is often studded with small granulations and markings of various types. Four distinct kinds of subependymal change may be described: (1) *granulations* which differ from those seen in general paresis in their greater size; (2) parallel *ridging* resembling the markings on a dog's palate; (3) dead-white *plaques* recalling patches of buccal leukoplakia; and (4) circular warty *excrescences*.

Microscopical Appearances of the Senile Brain.

The histology of the senile nervous system can best be discussed along four main heads—*viz.*, changes in the nerve-cell and fibre; neuroglial alteration; abnormal depositions of amorphous material; and vascular changes.

THE NERVE-CELL AND FIBRE.

Neuronal changes consist primarily in a cell atrophy. This is of a numerical character, as the occurrence of a pure volumetric atrophy—i.e., reduction in the size of the constituent elements with maintenance of a full numerical complement, has never been proved. It is well known that with advancing years there is a generalised diminution in the nerve-cell count which is roughly proportional with age and also with the severity of concomitant mental deterioration. This diffuse cell-atrophy must be clearly distinguished from the patchy areas of atrophy in cerebro-vascular disease. This particular feature of senility has been studied statistically in both human and animal brains. Thus Ellis[39 40] has found a progressive decrease in the number of Purkinjé cells within the cerebellum after the age of 30 to 40. His own figures show that within an equivalent unit area there is to be expected at the age of 42, 823 cells; at 65, 591; at 79, 500; at 94, 462; at 100, 445. According to Inukai,[41] the number of Purkinjé cells in an albino rat 1000 days old is about 80 per cent. of the complement at birth. Harms[42] found in the cerebellum of a woman of 80 only 25 per cent. as many cells as in a young adult. Ellis says that though this cell-atrophy is a diffuse process, it is especially evident in the anterior lobe and less marked in the dentate nucleus.

A cell-atrophy is constantly present in the cerebral cortex, particularly in the frontal and temporal regions. This outfall is perhaps most evident in the third layer of the cortex, but the deepest laminæ may also show extensive atrophy. There is, however, no essential disturbance of the stratification. A similar reduction in the number of cells is found within the corpus striatum, the locus niger, and the olives.

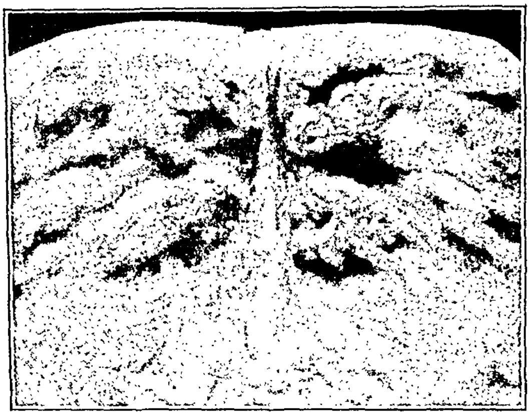
Consequent upon the outfall of neurones there is a diminution in the number of myelinated fibres revealed by shrinkage of the white matter. The dendritic processes are also reduced in number, especially in the tangential fibre layer.

Important histological changes are recognisable in the surviving nerve-cells. The neurone is usually diminished in size. Less commonly there is a process of gigantocytosis, whereby neurones attaining the dimensions of Betz cells are seen in the second and third cortical laminæ, particularly in the cornu ammonis, the hippocampus, and the frontal lobe. (Minéa [43]; Marinesco and Bistriceanu [44]). The nerve-cell is often the seat of extensive pigmentary change caused by an increase in the number of lipofuchsin granules, and also by transformation of the mitochondria. This view is supported by the work of Bertrand and Hadzigeorgiou [45] who, by their infra-red technique, found an absence of mitochondria associated with an excess of lipochrome, in two morbid conditions only—namely, amaurotic family idiocy and senile dementia.

Pigmentary surcharge is also very evident in the striatal cells and in those of the dentate nuclei. Lhermitte [46] has described, in addition, an infiltration of the Betz cells with iron in old age.

Associated with the lipoid change, and yet distinct, is a fatty degeneration of the nerve-cells. This is usually most apparent in the superficial layers of the cortex, and at times the cells are converted into sacs filled with fatty droplets. Grünthal [47] finds this type of change most marked in the cornu ammonis, and least evident in the occipital lobe. In the cerebellum fatty deposit is most obvious in the upper and outer granular layers, and occasionally in the Purkinjé cells.

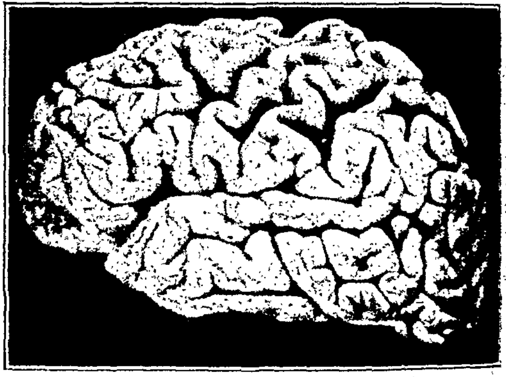
FIG. 1.



Inner aspect of the skull from a patient suffering from senile dementia, to illustrate the hyperostosis of the inner aspect of the frontal bone.

Although Vallée [48] and also Manouélian [49] have compared the type of neuronal alterations in the nervous system of senile dogs with those seen in rabies, it is the general experience that the senile type of neuronic decay is essentially different from that of toxi-infective processes. In old age the nerve-cell atrophy belongs to the so-called abiotrophic type, described by Simchowicz as "granulovacuolar degeneration." Here the cell body is small and globular with a peripherally situated nucleus; the nucleolus is deformed and may be surrounded by basophil inclusions. Later the cell shrinks to a ghost-like, shadowy area without recognisable structure. At the same time the dendrites alter, at first increasing and later diminishing in size and becoming tortuous.

FIG. 2.



Outer aspect of left hemisphere of a female (non-demented) aged 103. Weight of left hemisphere, 457 g.; right hemisphere, 462 g.; pons + cerebellum, 132 g.; total, 1051 g.

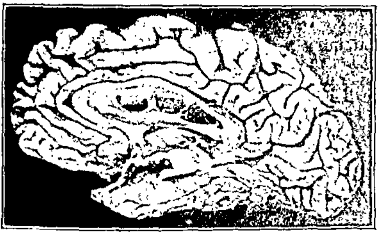
Of particular importance is the appearance of peculiar changes within the intracellular fibrillary network, first described by Alzheimer.[50] In the words of the original description ". . . . in the interior of the cell, which is otherwise normal, one or more fibrils are conspicuous on account of their special thickness and the density of their impregnation. Later, other neighbouring fibrils participate, and these form thick bundles lying in the periphery of the cell. Finally, the cell with its nucleus disappears, and the site becomes marked by a spiral-like bundle of fibrils." Every stage of this process is demonstrable, from simple intensification of the intracellular fibrils up to a mere "skeleton" composed of tangled, densely stained coils. The nature of these Alzheimer "tangles"—as they are called—was formerly under much dispute; certain histologists believed they were of neuroglial nature and situated outside the cell; to-day they are usually regarded as neurofibrillary in origin.

It is interesting to recall that Metchnikoff [51] regarded senescence as a conflict between the connective tissues (neuroglia) and the noble elements (nerve-cells), in which the former were victorious by reason of a process of phagocytosis. This, he claimed, was histologically demonstrable in the presence of macrophages surrounding and ingesting the ganglion cells. The problem was specifically investigated by Saigo [52] with entirely negative results. His experience tallies with that of all other workers, and a process of phagocytosis has never yet been demonstrated in the senile cortex.

A peculiar change in the Purkinjé cells has been described by Bouman [53] within the brains of aged subjects, particularly when mental change is present. There occurs in the proximal portion of the axons a spindle-shaped swelling of homogeneous appearance but with a peripheral net-like structure and sometimes vacuolation. Bouman speaks of these swellings as "torpedoes."

Vacuolation and degeneration may occur in the intracellular neurofibrils, forming tangled heaps. Lafora found peculiar changes in the dendrons of the cells of Ammon's horn in a senile dog; a large number of branching collaterals sprouted at a little distance from the cell body, like feathery tufts. Hortega found this change in a large number of aged animals, but discovered that it was not limited to states of senility. Prados y Such confirmed this finding in the polymorphic zone of some monkeys and regarded it as a proliferative change associated with the process of growth. Berlucchi's [54] conclusions were in general agreement.

FIG. 3.



Mesial aspect of the right hemisphere of a male dement aged 90, showing atrophy of the paracentral and fornicate gyri and gross wasting of the corpus callosum. Weight of right hemisphere, 542 g.; left hemisphere, 548 g.; pons + cerebellum, 163 g.; total, 1253 g.

In the process of disintegration the myelin sheaths become thinned and later break up into fatty globules.

THE NEUROGLIA.

Neuroglial alterations are constantly present, and proliferative as well as regressive changes may be recognised. The former comprise an overgrowth of neuroglial fibres which, though diffuse in extent, has certain sites of predilection. Thus an intense gliosis may occur in the cortex immediately under the pia and in the perivascular tissues. A reticulated appearance may result, and "monster cells" may be visible.

Gliosis in the regions of the locus perforatus posticus and lateralis may cause a shrinkage of the brain away from the basal arteries and a wide dilatation of the perivascular spaces. This change takes part in the formation of the *état criblé* in the basal ganglia and internal capsule. Holzer and also Grünthal found a noteworthy increase in the glial fibres in the white matter of the occipital lobe. A subependymal gliosis is characteristic and may be uniform or nodular, giving rise in the latter case to the subependymal granulations visible to the naked eye. There is a moderate proliferation of microglia cells with an increase in the amount of protoplasm.

Regressive changes in the glia include the appearance of rod cells, especially in the molecular layer of the cornu ammonis; lipoidal changes; Grynfeltt's mucocytic degeneration of the *oligodendroglia.* Hortega has described in the amœboid glia cells of the senile brain rolled-up glia fibrils resembling Alzheimer tangles in the neurones. The microglia cells are often altered, the nuclei being pale and swollen and often show little protuberances; the cell processes may be increased in size (Creutzfeldt and Metz).[55]

In the cerebellum the gliosis is more patchy, being restricted to the perivascular zones, the depths of the fissures, the white matter surrounding the dentate nuclei, and the regions immediately around the Purkinjé cells. Rod cells may occur in the white matter.

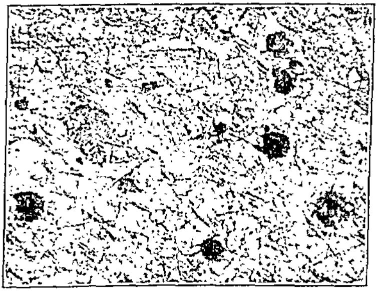
Certain authors have described "Klasmatodendrosis" or fragmentation of the neuroglial prolongations as a senile change, but Bonfiglio [56] has concluded that this is an artefact.

AMORPHOUS DEPOSITS.

The amorphous depositions which occur in the senile brain include corpora amylacea, ferruginous accumulations, and senile plaques.

Corpora amylacea, which were first described by Purkinjé in 1837, may be defined as "degenerative products of diverse form and origin, with concentric lamination, giving a typical iodine reaction" (Bertrand).[57] These appear as spherical bodies, usually stratified, measuring 15–20 μ in diameter. Each body may be surrounded by a glial proliferation. The chemical composition is believed to comprise a complex albumin with free chains which may fix molecules of sugar, calcium, and pigment. They are well demonstrated by Gram's stain and by Nile blue. Siegert [58] distinguishes two varieties: *corpora versicolorata,* giving a metachromic reaction with iodine, and *corpora flava* which responds to tests for hyaline. Amyloid bodies occur only rarely in the normal brain, but are numerous in old age. They are seen usually lying outside the nerve-cells, throughout the central nervous system, and particularly around the vessels, under the pia and ependyma, the external medullary layer of the cornu ammonis, and the fimbria. The pathogenesis is uncertain; Alzheimer, Stürmer,[59] and others regard them as "neuronic concretions," or products of cerebral metabolism, while Obersteiner and Redlich favour a glial origin. Iwata,[60] supporting the latter hypothesis, believes they are remote products of neuroglial involution, and that their presence indicates that the glia fibrils must be at least ten years old. Recent studies by Ferraro and Damon [61] suggest that the amyloid bodies are derivatives of the oligodendroglia cells.

FIG. 4.



Senile plaques in the cortex of a senile dement aged 91. Bielschowsky's stain.

Deposits of free iron are common in the brain after middle life. They occur as "degeneration bodies" in the perivascular spaces of the globus pallidus and probably arise by an unmasking of the intracellular iron normally present in that nucleus. Weston Hurst[62] regarded this change as "an expression of the proclivity of the globus pallidus to undergo degeneration in the second half of life," and this conclusion has been supported by Hadfield,[63] who believes that "pallidal siderosis is the expression of a slow evolutionary atrophy affecting the nuclei in at least 60 per cent. of people over the age of 30."

We now come to the most striking and important feature in the histological study—namely, the so-called "senile plaques."[64] Tilney has aptly referred to these formations as "the black marks of the aged brain" . . . . "the peculiar badges of old age." Their discovery dates from 1892, when Blocq and Marinesco[65] found in the cortex of an aged epileptic curious circular masses, about 60 μ in diameter, staining intensely. Other important observations followed, notably by Redlich, Perusini, and Alzheimer, and many descriptive terms were adopted. Miyake spoke of them as "glial rosettes," Léri as "sclérose névroglique miliaire"; we owe the term "senile plaque" to Simchowicz. A series of papers by Fischer[66] from 1907 to 1910 form important landmarks, and this author proposed the word "Drusen" or "drusigen Nekrosen" and also—from their resemblance to mycotic lesions—"Sphärotrichien."

Senile plaques appear as circular areas of densification scattered throughout the cerebral cortex, staining deeply with silver. They vary in individual appearance, but certain form-constants recur—viz., rings, radial figures, star-shaped structures, and circular homogeneous areas. A nuclear-like body of amorphous or cellular structure often lies in the centre. Histochemical study reveals the presence of some substance allied to amyloid, and lipoid may also be demonstrable. Macroglia and oligodendroglia are concerned in these plaques to a minor degree, but microglia cells are important constituents; neurofibrils and sometimes myelinated fibres are seen.

The topographical distribution of the plaques is of interest. They are practically confined to the cerebral cortex especially in the frontal lobe, the cornu ammonis, and the island of Reil. They have also been described in the basal ganglia and in the cerebellar cortex. The deeper layers of the cortex show the greatest number of plaques.

The important question which arises in connexion with the senile plaques concerns their association with senility on the one hand and psychosis on the other. It is indubitable that in the majority of cases of senile dementia as well as in Alzheimer's disease senile plaques occur in large numbers. Cases are encountered, it is true, in which few plaques, if any, are seen in the brains of aged individuals who are grossly demented; such instances are quite exceptional, however, and it is arguable that they might represent some peculiar clinico-pathological grouping outside the category of true senile dementia. In cases of general paralysis of the insane occurring in the aged, Prof. Jakob informs me that senile plaques occur in abundance. Plaques may occur without doubt in the brains of aged individuals who have never shown obvious mental symptoms; Simchowicz[67] believes that they are essentially associated with advanced age, but do not develop before 90; according to his view, they multiply with advancing years and are especially numerous in cases of dementia. This generalisation is acceptable on the whole, but it must be remembered that brains of extremely aged subjects have been examined without revealing plaques. Lewy[68] found no plaques in the brains of aged Turks, and even in two cases of senile dementia among Turks Schükry[69] found no plaques. This fact suggested to Spatz[70] that there may be racial variations in the degree of susceptibility to the formation of plaques. Marinesco failed to discover plaques in individuals of 99; Kuczynski made no mention of plaques in the cortex of his patient aged 118; Costantini, in the brain of a normal old man of 105, found only a few plaques; the same held true of two of my patients who were aged 101 and 103 respectively.

Verhaart[71] distinguishes "benign" plaques which provoke either no glial reaction at all or else contain healthy Hortega cells, from "malignant" plaques containing a great number of degenerated Hortega cells. The former type may be seen in mild cases of senile dementia, and Verhaart has also seen them in small numbers in the cerebrum of a normal old man of 103; the latter are characteristically present in Alzheimer's disease.

The present conception of the problem may be expressed somewhat as follows: senile plaques occur in the normal senium provided the individual had attained a very great age (? over 90); they occur very sparsely, however, so long as the mental condition is good. In cases of senile psychosis they appear at a much earlier age and may be very numerous indeed; cases of dementia in old age occasionally show no plaques, and such cases may well belong to a psychological category of their own. In Alzheimer's psychosis plaques occur in great numbers and at a relatively youthful age.

It is obvious that the problem is complex and much remains to be explained. We need more information as to the occurrence of plaques in conditions other than dementia and senility; and whether the number, size, and arrangement of the plaques bear any relationship to particular clinical pictures.

Laignel-Lavastine and Tinel[72] have described "fernleaf" argentophil depositions within the senile cortex which resemble the ordinary plaques, but differ slightly in the details of their staining reaction and physical properties. These "fatty plaques," as they were called were regarded originally as immature senile plaques and intermediate forms were described between the two types. Tinel looked upon the classical senile plaque as a "vestigial, cicatricial, and dystrophic relic" left by the reabsorption of his type of fatty plaque. The consensus of modern opinion, however, regards the latter as artefacts.

Within the cerebrum of the patient aged 118 studied by Kuczynski and Kopolowa, mention is made of albuminous depositions, reacting to some extent to tests for iron, scattered in the glial fibre layers, especially under the ependyma.

THE BLOOD-VESSELS.

The involutional changes in the blood-vessels and the lesions resulting therefrom, may be enumerated in the very briefest terms.

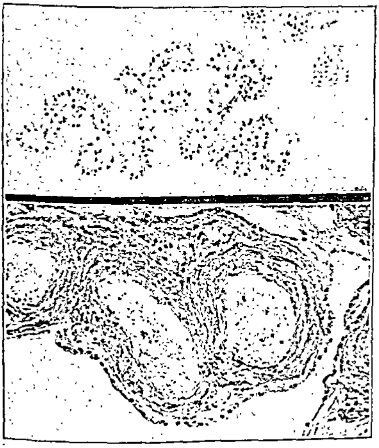
Arterio-sclerotic changes—of the type described by Allbutt under the term "decrescent"—are, of course, very commonly present. It is important to notice, however, that they may be entirely absent in a particular case. The changes when present are almost always more marked in the larger vessels of the base—i.e., the vertebral and basilar arteries and the circle of Willis.

Distinct from the lesions of arterio-sclerosis are certain minor histological alterations which must be regarded as typical of advanced life. At the present time we are engaged at King's College Hospital in a histological study of the cerebral arteries at all periods of life, with a view to determining the characteristic involutional picture. Among the commoner changes in advanced life may be mentioned: thickening of the media and intima (Triepel)[73]; hyaline changes (Klissurow)[74]; splitting of the internal elastic lamina (Hackel).[75] Deposition of iron in the adventitia and media of the pallidal arteries is of very common occurrence (Weston Hurst).

Of more particular interest are the alterations which are commonly encountered in the choroid plexus with advancing years. This, too, is a problem which is at present under investigation at King's College Hospital, and which has already been studied in recent years by von Zalka[76] and others. The more usual changes include cyst formation; proliferation of connective tissue; vacuolation and pigmentary degeneration of the epithelium; depositions of calcareous, hyaline, and psammomatous bodies.

It will suffice merely to mention the diverse effects—immediate and remote—produced by vascular disease within the nervous system, as a full description would be irrelevant. Areas of softening—of every dimension; small hæmorrhagic foci; lacunes of disintegration; the worm-eaten cortical change of Pierre Marie—these are all obvious macroscopic features. Disseminated areas of atrophy are often seen and comprise, according to Lhermitte and Klarfeld,[77] three histopathological variants—viz., reticulation, areolation, and miliary necroses. Spielmeyer[78] has stressed the occurrence of "bleaching" or cortical areas which fail to fix with various stains; it is believed that these zones represent ischæmic areas without, however, gross narrowing or occlusion of the nutrient vessels.

FIG. 5.



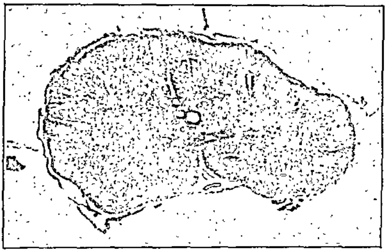
The choroid plexus in youth and old age: above, from a boy aged 11; below, from a non-demented woman of 102, showing the great proliferation of connective tissue and vascular hypertrophy.

Under the microscope a typical glial increase is to be recognised, most often perivascular in arrangement. A gliosis in the frontier between cortex and white matter is not rare, and is spoken of as the encephalitis subcorticalis of Binswanger. Various glial derivatives are encountered, such as scavenger cells and astrocytes.

Regional Pathology of the Senile Nervous System.

The foregoing description outlines the more striking changes common in the brains of folk dying at an extreme age. A short consideration may now be directed towards certain specialised regions of the brain, such as the pituitary body, as well as the spinal cord and peripheral nerves.

FIG. 6.



Trans-section of the lower cervical cord from a case of senile dementia in a man aged 82. A marginal gliosis is visible to the naked eye. (Greenfield-Mallory's stain.)

PITUITARY GLAND.

The pituitary gland, according to Lucien,[79] shows in old age no reduction in size or weight and no decrease in the parenchymatous elements, though Scheele[80] described a progressive cell atrophy and a diminution in specific gravity. Some increase in the amount of connective tissue is common, localised to the region of the hilus. Colloid—mainly of the basophil type—accumulates to a marked degree (Bolsi),[81] especially in the pars posterior (Cooper),[82] and pseudo-acinous formations are common.

THE SPINAL CORD.

The histological alterations within the spinal cord in old age have received far less attention than those of the senile brain. Although some of the earlier pathologists such as Cruvielhier, Rokitansky, Leyden (1875),[83] Demange (1881),[84] and Campbell (1894) mentioned briefly a few of the outstanding pathological changes, it was not until the appearance of Nonne's paper[85] in 1899 that a detailed study was undertaken. In 1900 Sander's important monograph[86] was published; since when Fluegel[87] (1927) has contributed to this chapter in pathology.

Meningeal proliferation may be seen around the spinal cord and calcareous plaques are not uncommonly attached to the pia-arachnoid; Sander has seen the whole cord completely encased by chalky deposits as by a suit of armour. Ossification may also occur in this situation.

The spinal cord itself may be obviously shrunken on naked-eye inspection, and on trans-section the normal contrast between white and grey matter may no longer be apparent. The more important pathological alterations within the cord are, however, microscopic in character.

Weigert-Pal's technique reveals an undue pallor which is particularly evident in the marginal zone. In some cases this process extends inwards and encroaches in particular upon the cerebellar efferents as well as Gowers's tract. Occasionally wedge-shaped areas of pallor are seen, the base of which is peripheral. Patches of perivascular demyelinisation constitute important changes, revealed by the methods of Weigert-Pal and of Marchi.

There also occurs an obvious reduction in the number of nerve-fibres, especially in the lateral and posterior columns.

Neuroglial proliferation is constantly present and always in the areas in which the myelin has degenerated. Thus the marginal zones, the perivascular areas, the lateral and posterior columns, are all the seat of a marked gliosis in which the nerve-fibres are frequently strangulated. Cuneiform areas of gliosis correspond with the demyelinated regions. The anterior and posterior commissures are also hypertrophied.

Widespread changes occur in the ganglion cells. Accumulation of intracellular pigment is constantly seen, a process which commences at one pole and later fills the nerve-cell. The nucleus stains darkly and becomes eccentrically placed; the nucleolus is angular and shrunken. Later, nucleus and nucleolus both disappear, leaving an amorphous mass of pigment. So widespread is this change that according to Sander, after 85 scarcely a normal ganglion cell can be seen. Fluegel has seen typical Alzheimer changes within the cells on one or two occasions.

The blood-vessels are also altered; their lumen may be increased but usually it is reduced or even obliterated. The vessel walls are thickened, especially the intima, and splitting of the elastica is usual. A shrinkage of the parenchyma away from the blood-vessel is often apparent, and there may be a mild perivascular infiltration with lipoid-laden cells.

Corpora amylacea are usually present in large numbers, especially near the entry of the posterior roots, along the septa and in the region of the blood-vessels. Senile plaques are rarely, if ever, present in the spinal cord.

Demange drew attention to a proliferation of the cells of the ependyma lining the central canal.

The foregoing pathological changes may exist in varying intensities, and we are told that they are not necessarily associated with abnormal clinical manifestations. Sander differentiates three varieties of pathological process within the spinal cord: (1) A slight form, characterised by a moderate and diffuse outfall of myelin, slight cell degeneration, and slight secondary glial increase. This type he associated with "physiological senility." (2) A severe form with diffuse demyelination and also focal lesions with gross neuronic decay and sclerosis. (3) A more acute type of degeneration characterised by numerous focal lesions; this variety may occur at a pre-senile age and is regarded by Sander as a form of arterio-sclerotic degeneration of the cord.

PERIPHERAL NERVES.

Still less is known about the involutional lesions of the peripheral nerves. Joffroy and Ackard in 1889 recorded degeneration of the sciatic nerves with a thickening of the vasa nervorum in a paraplegic woman of 63. Similar cases were quoted by Lorenz (1891) and by Ducil and Laury (1893). Campbell (1894) made a more detailed investigation; he found acute parenchymatous degeneration of some fibres in a peripheral nerve, and a great reduction in the number of larger axis-cylinders. Aggregations of fibrocellular débris and collections of minute nerve-fibres possessing an attenuated sheath of Schwann occupied the gaps. The peri- and epineurium were thickened and infiltrated with fat. The walls of the vasa nervorum were distinctly thickened. Both motor and sensory nerves showed these changes, especially in the more peripheral regions; the vagi in particular were severely affected.

Polyneuritis of the senile arterio-sclerotic type has also been recorded and studied pathologically by Schlesinger (1895)[88] and Franceschi (1903).[89]

THE ADEQUATE TREATMENT OF SYPHILIS.

BY E. TYTLER BURKE, D.S.O., M.B. GLASG.,

DIRECTOR OF SALFORD MUNICIPAL CLINIC (V.D.); INSTRUCTOR IN DIAGNOSIS AND TREATMENT OF VENEREAL DISEASES, VICTORIA UNIVERSITY OF MANCHESTER.

IN the article entitled The Modern Treatment of Syphilis in the *Practitioner* for February, 1931, Colonel L. W. Harrison rightly states that "a question of considerable importance is whether, in early cases, bismuth or mercury should be given concurrently with (*i.e.*, in the same course as) the arsenobenzene compound." He is convinced that in early cases concurrent treatment should be adopted; and he gives reasons for his belief. Whether these reasons are good and sufficient is another matter. He is, furthermore, of the opinion that "those who are now treating their early cases on the plan of alternating courses of arsenobenzene with courses of Hg or Bi are laying up for their patients a heritage of neurosyphilis."

The last statement is very plain and very definite. Such an opinion, coming from so high an authority, is one to which much heed must be given, and one which must cause those who advocate the alternating method furiously to think. If Colonel Harrison's view is correct, then it is time indeed that the principles held by the alternating school were discarded for ever. If, on the other hand, he is wrong, then it is equally necessary that his error should be *demonstrated*.

While no scientific authority claims to be infallible, yet such is often practically assumed, acted upon, and adopted as a doctrine, by those who have hitched their wagon to that particular scientific star. The position of an individual may be so high that there is a distinct tendency for those who are his disciples to give an ex-cathedra value to all his opinions upon his special subject—to accept them without question, and to stigmatise as heretical any views to the contrary. The great John Hunter, by virtue of the high position he occupied in the medical world of his time, fixed upon venereology for many decades the error that syphilis and gonorrhœa were one and the same disease. Those who, like Benjamin Bell, held the diametrically opposite view, were regarded as scientifically lost souls. The authority of Hunter and his misinterpretation of his own ill-conceived and unfortunate personal experiment, completely eclipsed clinical experience and the more numerous and more scientific experiments of the comparatively obscure Bell.

To one who was originally of the concurrent school, but who for the last ten years has consistently advocated the alternating method, the statement by Colonel Harrison that such a method is a sure receipt for the manufacture of neurosyphilis is of the nature of a challenge which must be taken up. With my provincial rushlight I teach, and try to show, that arsenobenzene and bismuth should *never be given concurrently*; and since many of those whom I teach, and whom I have taught, will read Colonel Harrison's recent article, I am compelled without delay to present the other side of the case.

Reasons for the Alternating Regimen.

The main reasons why I adopt and teach the alternating method are:—

(1) Under the concurrent regimen, when arsenobenzene and mercury were exhibited simultaneously,

it was found—in my former experience—necessary to interrupt treatment after the first eight or ten weeks in order to prevent the patient showing signs of intolerance. During the treatment period approximately 4·65 g. of arsenobenzene compound (Ab.C.) and grs. 8 of mercury were given. This was not enough to cure the patient; and yet an interval of from two to four weeks had to be allowed in which no therapy was given, so that the patient could recover from the toxic effects of the remedial agents administered. During this time the parasite was permitted, unmolested, to entrench itself in deep-seated visceral structures, chiefly in the cardiovascular and central nervous systems. It therefore seemed to me more in accordance with common sense to try to arrange therapy so that rest-periods were abolished, and so that the parasite would be continuously subjected to an intense chemotherapeutic bombardment. This could only be done by exhibiting the drugs in alternate courses.

(2) It was found that under concurrency there were many patients who developed jaundice, nephritis, and exfoliative dermatitis. This was considered to be due probably to the double assault upon the hepatic, renal, and cutaneous systems. On changing over to the alternating system, the incidence of these complications almost reached vanishing point—especially nephritis. Jaundice and dermatitis became exceedingly rare and were only found in those cases who had apparently an idiosyncrasy to the drugs. In the few cases of jaundice which did occur, the condition could, in a large proportion, be attributed to causes other than therapy; and in every instance the type of jaundice was much less severe than formerly. Furthermore, it was found that, more often than not, after the condition had cleared, alternating therapy could be resumed without any recurrence taking place.

(3) Under the concurrent method many patients were found to have become drug-resistant or Wassermann-fast. This was thought to be due to the *Treponema pallidum* having developed an immunity to the action of the remedial agents. Akatsu and Noguchi[1] and also Klauder[2] showed experimentally that such resistance could take place. It seemed natural, therefore, to reason that it would be better to administer the drugs in separate series so that no sooner was the parasite threatening to develop a resistance to one agent, than a new weapon was brought into action; and when the efficacy of that began to wane, a change was made back to the original one—or to another new one if such were available. Experience has shown this reasoning to be correct, for, since the adoption of the alternating method, drug-resistance and Wassermann-fastness have ceased to appear as practical difficulties.

(4) A study of the mode of action of Ab.C. and of Bi—for mercury has been discarded as being inefficient and a mere waste of time—also forced me to give up concurrent treatment. Ab.C. and Bi do not act directly upon the parasite. When injected into the body they stimulate the tissues to produce toxalbumins—conveniently termed *arsenoxyl* and *bismoxyl* respectively—which are lethal to *Tr. pallidum*. In other words, the Ab.C. and the Bi are the raw materials supplied to the body-factory which produces the finished article capable of destroying the parasites. The manufacture of these proteo-arsenic and proteo-bismuth combinations inevitably throws some strain upon the producing-tissues of the patient. Where the two raw materials are exhibited simultaneously, twice the load is cast upon the productive mechanism than when only one is given. The tissues are thus, under concurrency, more easily exhausted, and finally cease altogether to produce the lethal toxalbumins. Thus we have another cause for drug-resistance and Wassermann-fastness.

By the alternating system this tissue exhaustion is prevented. The body is not overworked; and so the machinery is not so liable to break down. Before the production of arsenoxyl threatens to peter out, the Ab.C. is withdrawn, and another raw material in the form of Bi is introduced for a different class of machinery to work upon.

(5) Many cases, which formerly had become Wassermann-fast under concurrency, have been treated during the past ten years by the alternating method. A large proportion of these as a result became permanently negative.

Therapeutic Economy.

(6) Under the alternating method there is a saving in time and of the amount of remedial agents necessary to cure a case of early syphilis, say, in the sero-negative primary stage. For example, the course for such a case which is routine at Salford Municipal Clinic reads:

	Ab.C.	Bi.
Stabilarsan once weekly for 6 weeks ..	3·45	—
Bivatol twice ,, ,, 4 ,, ..	—	0·64
Stabilarsan once ,, ,, 6 ,, ..	3·45	—
Bivatol twice ,, ,, 4 ,, ..	—	0·64
Stabilarsan once ,, ,, 6 ,, ..	3·45	—
Total 26 ,, ..	10·35 g.	1·28

There have been analysed some 136 cases of sero-negative primary cases who have completed the above course according to the time schedule and during a period not exceeding 30 weeks. The majority of these were treated with bismuth preparations other than bivatol which has only recently been introduced. These have been under observation for periods of from three months to five years. In no instance has there been any clinical or serological relapse. Upon the above course the cure-rate is 100 per cent. for sero-negative primary syphilis. The expenditure is 26 weeks of time, 10·35 g. of Ab.C. and 1·28 g. of metallic bismuth contained in a bismuth compound—in this case, bivatol.

Now, the St. Thomas's minimum treatment prescribed for sero-negative primary cases consists of three courses as laid down by Colonel Harrison (loc. cit.). The first course may be tabulated thus:

Weeks.	Days.	Grammes.		Weeks.	Days.	Grammes.	
		Ab.C.	Bi.			Ab.C.	Bi.
1	1–7	0·45	0·32	11	71–77	—	—
2	8–14	0·45	0·32	12	78–84	0·90	—
3	15–21	0·60	0·32	13	85–91	0·90	—
4	22–28	—	0·32	14	92–98	—	—
5	29–35	—	0·32	15	99–105	—	—
6	36–42	—	0·32	16	106–112	0·90	—
7	43–49	0·75	0·32	17	113–119	0·90	—
8	50–56	0·90	0·32				
9	57–63	—	0·32				
10	64–70	—	0·32		Total..	6·75	3·20

An interval of six weeks is now allowed to elapse and the course is repeated. Another rest-period of six weeks then occurs, and again the course is gone through. The total time taken is thus 63 weeks, during which 20·25 g. of Ab.C. and 9·60 g. of bismuth metal are given. The two courses may thus be compared:

St. Thomas's ..	63 weeks	20·25 Ab.C.	9·60 Bi.
Salford	26 ,, ...	10·35 ,, ...	1·28 ,,

The Salford course thus shows a saving of 37 weeks, of 9·90 g. of Ab.C., and of 8·32 g. of metallic bismuth. The cure-rate is the same for both courses.

As I pointed out in the *British Medical Journal* for Feb. 21st, 1931, the method of computing therapy in terms of quantity given—Ab.C. in one case and Bi metal in the other—is practically meaningless, and does not permit of comparison between different courses to be made. Reckoning the therapy in terms of therapeutic units based upon the chemotherapeutic indices of the agents used, and taking into account the two-dimensional time-quantity factor, we find that during the 63 weeks of the St. Thomas's course (assuming that the therapeutic unit value of the bismuth is 0·75) in all 49·5 therapeutic units are given. In the Salford course, on the other hand, 24 therapeutic units are given in 26 weeks. The respective efficiency indices of the two courses therefore are:

$$\text{Salford E.I.} = \frac{24 \times 100}{26} = 92 \text{ (approx.)}$$

$$\text{St. Thomas's E.I.} = \frac{49{\cdot}5 \times 100}{63} = 79 \text{ (approx.)}$$

There thus appears to be a balance of 13 points in favour of the alternating Salford course. The end-results may be equally good, but the St. Thomas's course occupies an additional 37 weeks and requires 25·5 more therapeutic units. The latter must therefore be more prone to cause defaulting—i.e., uncured syphilis—because patients are more likely to attend regularly for 26 weeks than for 63 weeks. The St. Thomas's course is less economical, in so far as to get equal results a greater quantity of remedial agent is required. And apparently, since rest-periods are so necessary, it is more productive of toxic effects. During these periods, as has been already indicated, the parasite is free to do what damage it can.

Neuro-recurrence.

A great deal has been made of the alleged frequency of neuro-recurrences under the alternating method as contrasted with their rarity where the concurrent principle is adopted.

Working under the former method, my experience is identical with that of Colonel Harrison who proceeds on the concurrent principle—namely, that I have not yet seen a case of clinical neuro-recurrence. In this respect then there is no difference between the two lines of treatment.

Colonel Harrison quotes Moore and Kemp's[3] analysis of cases treated on the alternating plan at the Johns Hopkins Clinic. Out of 402 cases of early syphilis these workers found 59 relapses of a neuro-recurrent nature. What Colonel Harrison fails to explain is that all of the 59 cases who relapsed received utterly inadequate treatment, and that of the 71 patients who completed their course according to the schedule laid down by Moore and Keidal,[4] in no single instance did a neuro-recurrence or other relapse take place. In other words, neuro-recurrence only happened among early defaulters. It is a striking thing that in this Salford Clinic the experience is that even among defaulters under our alternating regimen neuro-recurrence has not yet been recorded. One factor in producing this type of relapse in America may be racial difference. I am more inclined to think, however, that the incidence in Moore and Kemp's series is more likely to be due to the use of 606 instead of 914, and of mercury instead of bismuth. There is much to support the belief that while 606 has a more powerful effect upon the parasites in the cutaneous structures than has 914, it has at the same time a greater traumatic toxic effect upon nervous tissue. Trauma forms a locus minoris resistentiæ, and so it is that the undestroyed parasites in the defaulter's body settle down in these damaged areas and give rise to neuro-recurrences. The 914 preparations, on the other hand, do *not* cause this nervous system damage, hence patients *treated* by such compounds are not so prone to neuro-recurrence. The relative potency of bismuth *in the form* of bivatol to mercury is as 12 is to 1, so that here is a very patent reason why neurological and other relapses are more likely to occur when mercury is used in preference to bismuth.

Another point of great importance is illustrated by the Moore and Kemp analysis, and it is that while the striking feature of the 59 cases was the inadequacy of the treatment given, all the *neuro-recurrences* happened within the first year, and *in* 97 per cent. within the first six months. The average lapse was only 2·7 months. Moore and Kemp state:

> "That precocious neurosyphilis can develop under these conditions is one of the strongest arguments for the continuous treatment of early syphilis. After once beginning treatment it is absolutely unsafe to permit a patient with primary or secondary syphilis to pass a single day without the influence of a treponemicidal drug."

As will be seen from an examination of concurrent schemes of treatment, continuous therapy is impossible because rest-periods are absolutely necessary. In the St. Thomas's course there is a no-treatment gap during the eleventh week, and a fortnight's interval during the fourteenth and fifteenth weeks. In addition there are the two intervals of six weeks each between courses—making 15 weeks in all during which nothing whatever is done.

Those who examine the St. Thomas's course might be tempted to ask: If concurrency is so right and alternation so utterly wrong, how does it come about that in this course *concurrent treatment is only given during five out of the 14 weeks of actual therapy?*

Effect of Combining Bismuth and Arsenic.

With respect to Kolmer's[5] paper on Bismarsen, it is stated that "while the arsenical content of 606 is 2·4 times greater than that of bismarsen, its trypanocidal activity is only twice as great, although bismuth alone is without trypanocidal activity." This is somewhat obscure; and it might not seem terribly wrong to some to interpret this as meaning that since the arsenical content of 606 is 2·4 times as great, while its trypanocidal power is only twice as great as bismarsen, the latter is thus of lower value than the former, and that this is due to the combined bismuth. It might be argued that so far from there occurring a summation of the respective activities of arsenic and bismuth, there is, when they are combined, actually a decrease.

There is, moreover, a serious fallacy in Colonel Harrison's—or is it Kolmer's?—argument. He clearly premises that trypanocidal and treponemicidal power increases directly with the arsenical content of the compound. From that he argues that since the arsenic content of 606 is 2·4 times greater than that of bismarsen, the therapeutic activity of the former should also be 2·4 times greater than that of the latter; but, since it is only twice as great, therefore the addition of bismuth to the latter has increased its therapeutic value. The fallacy lies in the assumption that the greater the metal content the greater the curative value. Such, however, is not the case either in respect of arsenical or of bismuth compounds. All that Kolmer's work shows is that the bismuth—which is inert as a trypanocide—has the effect, by some physico-chemical means, of making the arsenic more usable for the production of arsenoxyl. Bismuth and its compounds, it is true, have little or no effect against trypanosomes; but, as is well known, agents which may be quite devoid of trypanocidal activity may have a remarkably high treponemicidal value. It was pointed out a long time ago that trypanocidal tests are only of value so far as organic arsenicals are concerned in the chemotherapy of syphilis.

With respect to bismarsen, it is important to consider the experience of O'Leary.[6] The acute signs of syphilis were slower to disappear than under arsphenamine, and so likewise the treponemicidal effect was less rapid. O'Leary records severe exfoliative dermatitis, and Schoch[7] mentions a similar occurrence with bismarsen. This condition developed after 14 injections of 0·2 g. twice a week by the intramuscular route. Kolmer states in his communication that in four cases of primary syphilis 0·2 g. of bismarsen caused the treponemata to disappear in from 36 to 120 hours. The lesions themselves, however, vanished more slowly than is usual after the intravenous injection of 606 or 914.

It is difficult to see from all this where the advantage of this combined arsenic and bismuth compound comes in.

There is no doubt, however, as was shown by Lehnhoff-Wyld,[8] that the addition of certain other metals to an arsenobenzene compound increases the "usability" of the arsenic. But Lehnhoff-Wyld found that the metal which gave the highest degree of enhancement was zinc, which by itself has no treponemicidal power. It is a matter of opinion whether it is necessary or advisable to raise the treponemicidal power of the arsenobenzene with the risk of increased toxicity and so on; but in any case, if it is so desired, there is no objection to the use of another metal provided it has no treponemicidal effect of its own, has no similar tissue reaction to that of arsenic or bismuth, and does not cause any great extra load to be thrown upon the eliminatory mechanism.

In my view, whatever metals are used in conjunction with arsenic or bismuth, they should not be members of Group V. of Mendelieff's periodic table. I have no insuperable objection to the concurrent use of Ab.C. and Hg because, whatever infinitesimal treponemicidal power the latter may possess, its mode of action upon the parasite differs radically from that of arsenic and bismuth. The Hg may make the arsenic more usable, and similarly with respect to silver-salvarsan. But after a combined course of Ab.C. and Hg—the latter being regarded as an enhancement for the arsenic and not as having a therapeutic value of its own—there should follow a series of bismuth injections alone, and so on in the alternating fashion. The concurrent school must finally accept the principle that, if they are correct, there is no limit to the number of treponemicidal agents which can—and ought—to be exhibited simultaneously. Thus, if compounds of the other members of Group V. of the periodic table—phosphorus, vanadium, niobium, antimony, tantalum, &c.—are synthetised and possess safe chemotherapeutic indices, they should all, according to the advocates of concurrency, be given together. Why is it that even those who still believe in mercury do not give Ab.C., Hg, and Bi simultaneously?

The alternating school will, if and when such compounds become available, exhibit them in successive series of injections, utilising those earliest and by preference which have the highest chemotherapeutic indices.

I do not say that the advocates of concurrency are utterly and irrevocably wrong—because syphilis can be cured not only by the simultaneous giving of divers remedial agents, but even by the exhibition of only one. But what I do submit is that concurrency, like monotherapy, is essentially unsound, that it is much more dangerous, is less successful, is more wasteful of time and material, and is therefore productive of a greater number of defaulters—uncured syphilitics—than is the alternating system.

BLOOD CULTURE IN TUBERCULOSIS

By H. Moos Schwabacher, M.R.C.S. Eng.,

ASSISTANT PATHOLOGIST TO THE FRENCH HOSPITAL, LOND
CLINICAL ASSISTANT TO THE PATHOLOGICAL DEPARTMENT,
KING'S COLLEGE HOSPITAL.

The growth of tubercle bacilli on artificial med has always presented difficulties. Many metho have been advocated but have been too complicat to be of use in the ordinary work of a laborator Further, in animal experiments when tuberculo material has been injected into guinea-pigs, t animals may die from secondary infection or sho before the tubercle bacilli can establish their typi lesions.

Although cultures have been obtained fr sputum and caseous material, bacilli have on rarely been grown from the blood stream. Recent however, Löwenstein and Reitter have publishe one of many instances in which they have succes fully cultured tubercle bacilli from the blood, a since seeing their paper I have investigated cas of suspicious and established tuberculosis for t existence of a tuberculous bacillæmia. I ha repeated Löwenstein's experiments, and in t following note I propose to give an account of t technique employed and of the results obtained.

Löwenstein's Egg Medium.

This medium offers but one difficulty in its p paration—that is, the exclusion of moulds a contaminating organisms. By slightly modifyi Löwenstein's apparatus I suggest this shortened a simplified technique.

1. Three newly laid eggs are thoroughly cleansed w cotton-wool saturated in methylated spirit.
2. The top and bottom of each egg is pierced with sterile scalpel, and pieces of the shell removed with ste forceps, allowing the contents to fall into
3. A stout glass bottle containing 2 oz. of small gl beads. (It is essential that all glassware and instrume should be thoroughly sterile.)
4. A well-fitting stopper is inserted into the bottle a the contents are shaken by rotary movement for three four minutes.
5. The egg mixture is transferred to a graduated cylin and one-third of its volume of
6. 5 per cent. glycerin broth is added (pH 6·8).
7. By means of a separator 5 c.cm. of this mixture is r into test-tubes.
8. These tubes are inspissated at 84° C., and when t medium has set they are left to stand upright in racks.
9. To each tube 1 c.cm. of broth is added (pH 6·8) means of a graduated pipette.
10. The test-tubes are capped and incubated for 48 hou

Tests of the Efficacy of the Medium.—Fourteen spu were examined, in five of which tubercle bacilli we seen in direct smears, and these all grew colonies visil

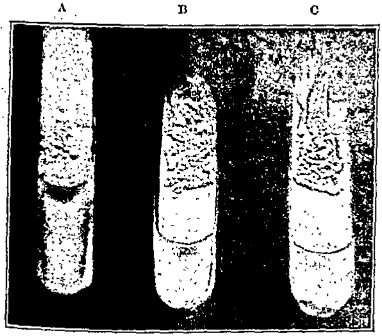
---

[1] Löwenstein, E., and Reitter, O.: Münch. med. Woc Feb. 13th, p. 261.

to the naked eye by the fourteenth day; of nine in which no tubercle bacilli were found in direct smears, one grew a pure culture in 17 days, eight remained sterile.

2 c.cm. of sputum were shaken with 10 c.cm. of 10 per cent. sulphuric acid in a stout glass test-tube containing five or six beads. After 20 minutes of occasional shaking, the emulsion was centrifuged and the supernatant fluid decanted. The remaining sediment consists of a layer of disintegrated lung tissue, and below this, a layer of amorphous debris. By means of a wide pipette the layer of lung tissue was transferred on to the egg medium (see Figure and tube A). By means of a large platinum loop the underlying layer of debris was inoculated in two other tubes (tubes B and C).

On the eighth and ninth days, although macroscopically there was no growth detectable, stained preparations showed massive colonisation. In the illustration tube A demonstrates how the lung tissues hinder the growth of the colonies, and tubes B and C show the freer growth from the amorphous debris.



Three tubes showing growth of tubercle bacilli on Löwenstein's culture medium under conditions explained in the text.

In recovering organisms from urine sufficient urine is centrifuged to obtain 2 c.cm. of sediment, which is then shaken with 15 per cent. sulphuric acid. Lieberthal[2] reports on numerous cases in which, when using this medium, tubercle bacilli had grown on the tenth day, whereas with the old potato medium three to five weeks were required. Pus, cerebrospinal fluid, and pathological tissues (the latter having been first pounded with 10 per cent. sulphuric acid) have all given pure cultures of tubercle bacilli on the egg medium.

Blood Culture.

Variations have been made in the technique for culturing the tubercle bacilli from the blood. The principles laid down by Lichtenstern[3] have mainly been followed.

Technique.—Under sterile conditions—

1. Mix 10 c.cm. of blood (obtained from a vein) with 3 c.cm. of 10 per cent. sodium citrate.
2. Centrifuge, decant the supernatant fluid.
3. Hæmolyse the red blood corpuscles with 5 per cent. acetic acid.
4. Centrifuge, discard the supernatant fluid.
5. Wash the sediment with distilled water and centrifuge (twice).
6. Decant supernatant fluid and transfer the whole of the deposit by means of a wide capillary pipette on to Löwenstein's egg medium.

Control Experiment.—A heavy suspension of human tubercle bacilli, obtained from a culture grown from sputum on this medium, was added to citrated blood and subsequently treated as above. Colonies were visible on the sixth day. This very early growth can be accounted for by the acclimatisation of the bacilli to their artificial medium.

So far, out of 11 cases under investigation, I have only succeeded once in a case of tuberculous bacillæmia in culturing the tubercle bacillus direct from the blood. The case was as follows:—

Male, aged 27, admitted April 5th, 1931, to the French Hospital under Dr. Campbell McClure. Clinical diagnosis: Bronchitis and pleurisy without effusion. Several smears from sputum, negative. Blood culture in trypsin broth, negative. Blood culture on egg medium gave growth of tubercle bacilli in 16 days. The blood, cerebro-spinal fluid, urine, and sputum were examined cytologically and by cultures with negative results. The patient is still under observation, and cultures on egg medium have been made from blood, urine, and sputum to check these results.[4]

I believe this to be the first case of tuberculous bacillæmia recorded in this country in which tubercle bacilli were found in cultures as early as the sixteenth day.

It seems possible that with this method of culturing tubercle bacilli from the blood many cases of undiagnosed pyrexia and doubtful skin lesions will be recognised as tuberculous, and that earlier diagnosis will be obtainable. It is maintained by most authorities that a bacillæmia is precedent to any localised tuberculous focus. Blood culture may make it possible to ascertain the presence of an active or quiescent tuberculous lesion.

I have to offer my thanks to the French Hospital, to Dr. E. ff. Creed, of King's College Hospital, for giving me every facility and encouragement in carrying out these investigations, and in particular to Dr. K. E. Eckenstein, honorary pathologist and physician to the French Hospital.

CONSTITUTIONAL ANGIOHYPOTONY,

OR IDIOPATHIC PERMANENT ARTERIO-HYPOTENSION.

BY ANDREA FERRANNINI, M.D.,

PROFESSOR OF CLINICAL MEDICINE AND MEDICAL PATHOLOGY IN THE ROYAL UNIVERSITY OF NAPLES.

DURING the last 15 years there have appeared in the international medical literature a series of articles on a certain morbid condition that every author calls by a different name. The most important of these names are: hyposphyxy (Martinet, 1918), particular symptomatic triad (Vincent, 1918), arterial hypotony (Fritz Weiss, 1927), permanent arterial hypotension with an idiopathic course (Lian and Blondel, 1928), insufficiency of tension (A. Dumas, 1928), hypotension, (Garin, 1927, A. Strasser and W. Loewenstein, 1929), habitual hypotony (Jimenes Diaz), and low arterial tension and hypotony (Franz Kisch, 1929). One result of this multiplication of nomenclature has been that the identity of the phenomena described has escaped the observers. I was the first to describe this morbid picture, in a series of papers[6] beginning in August and September, 1903, when I gave it the name of "chronic arterio-hypotension," though later I preferred "constitutional angiohypotony."

---

[2] Lieberthal, F.: Surg., Gyn., and Obst., 1930, i., 985.

[3] Lichtenstern, R.: Münch. med. Woch., March 20th, p. 471.

[4] Since writing the above a scanty growth of tubercle bacilli has been obtained from sputum which was incubated on April 16th. A diagnosis of tuberculous peritonitis has been established clinically, and it may therefore be concluded that the patient had a primary focus in the lung and that, during seven weeks of pyrexia (temperature 101° to 103° F.), a dissemination of the bacilli in the blood stream occurred.

The outstanding features of the condition I described were:—

(1) Signs of lack of tone in the arteries and veins without any corresponding lack in the heart, which in some patients and at some stages is over-excited.

(2) Severe disturbance in the blood-supply and nutrition of the organs, especially the nervous system, kidneys, and liver.

(3) Sclerosis in the walls of the vessels, indicating the dystrophy and intoxication caused in their metabolism by the hypotony.

(4) General weakness, often combined with attacks of hyper-excitability; fits of vertigo; accentuated first sound in the mitral area and accentuated second sound in the aortic area due to over-excitability of the myocardium; a tendency to displacement of the heart; acrocyanosis without general stasis; a tendency to visceroptosis; hæmorrhoids; oliguria; hæmaturia; albuminuria; and the passage of casts.

(5) General alteration in the appearance and indication of the influence of general angiohypotony on the development of the body and the general metabolism.

It is possible to confuse the diagnosis with mitral stenosis and mitral inefficiency. The morbid picture originates from abnormal constitutional conditions, depending on intoxications and infections that have acted either in utero or during the first years of life, exerting a secondary influence on the organs regulating the development of the body generally and of the vascular tissue in particular, especially of the adrenals, pituitary, and thyroid.

I recommended dietetic, balneological, climatic, and endocrine treatment to tone up and detoxicate the walls of the vessels and the whole organism.

This abnormality in the function of the blood-vessels can induce a vicious circle and disturb the whole organism, beginning with the heart. I regard it as a general and local biological disturbance and not as a simple mechanical trouble, and this interpretation has explained as angiohypotonic a number of syndromes previously described under different names, such as congenital heart disease, hypertrophy of the heart, irritable heart, neurasthenia of the heart, and "effort heart."

Pagès[1] wrote in 1929:—

> "en la matière le professeur A. Ferrannini n'a pas été seulement un précurseur, mais véritablement un novateur"; "il peut à bon droit en revendiquer la paternité"; "il s'agit d'une consécration trop tardive d'un exceptionnel mérite." "Peut-être pourrait-on le consacrer d'une façon plus éclatante en désignant le syndrome d'angiohypotonie du nom de syndrome de A. Ferrannini."

Subsequent descriptions of the syndrome do not differ from my original picture, although naturally, since I first wrote, clinical and endocrinological knowledge has greatly progressed, and later observers have had the opportunity of noting phenomena which the laboratory technique of the time did not allow me to mention in my first articles.

In August, 1903, I showed that patients suffering from constitutional angiohypotony have a functional insufficiency of the adrenal capsules and the sympathetic nerve-supply, as a symptom of endocrine disturbance. Before that time neither Sergent nor Vaquez had studied disorders of the sympathetic and adrenal systems in chronic vascular abnormalities. The injection of the adrenal hormone as a means of investigation has been employed by various investigators recently in a study of the functional condition of the vessels; I used this method in July and August, 1911.[2][3][4] Laignel-Lavastine's observations only date from 1908, five years after my first articles.

The term "angiohypotony" indicates that the disorder is primarily to be found in the walls of the vessels, rather than in the heart and defines that disorder as a lack of tone. "Hypotension" and "arterio-hypotension" do not explain whether the hypotony depends on the heart or on the vessels. There is undoubtedly a constitutional or congenital tendency, and quite a number of observers have preferred to use the word "constitutional" in their title for this condition. Bishop in 1904 wrote of "constitutional low tension," and Garan in 1907 described six cases of hypotension in one family. At the meeting of the Medical College of Vienna in November, 1926, H. Kahler pointed out the underlying constitutional abnormality and lack of vascular tone in cases of variable blood pressure and arterio-sclerosis in youth. Prof. Ludwig Braun,[5] writing under the title "Konstitution und Kreislauf," lays emphasis on the importance of the general constitution in circulatory abnormalities.

Certain difficulties arise in the recognition of this constitutional picture. The first is the clinician's habit of mind; he is so accustomed to regarding arterial hypotension as a result of myocardial insufficiency that he automatically looks to the heart whenever he meets a case. A patient with arterio-sclerosis may have his heart in excellent condition and yet have a very low tension in his vessels, as I showed 30 years ago when I had the privilege of converting Henry Huchard, the chief exponent of the view that it was impossible to have arterio-sclerosis without angiospasm. Another difficulty arises from the presupposition which accepts angiospasm as a cause of hypertrophy of the myocardium but does not realise that enlargement of the vessels may also call for increased effort on the part of the heart. With modern instruments for clinical and laboratory work it is possible to bring experimental exactitude to studies at the bedside, and this difficulty ought easily to be overcome.

CHRYSANTHEMUM DERMATITIS.

By G. S. Nightingale, M.R.C.S. Eng.,
LATE HOUSE PHYSICIAN, SKIN DEPARTMENT, LONDON HOSPITAL

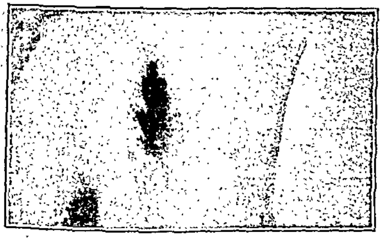
That certain people are supersensitive to chrysanthemums is vaguely recognised by the profession, but not by horticulturists, and the condition is rare enough to be worth recording.

Case Record.

A market gardener, aged 54, gave the following history. Twenty-five years ago, after having worked amongst plants, including chrysanthemums in season, for seven years, he noticed outcrops of small pin-head vesicles on the backs of his hands and on his wrists after contact with chrysanthemums. This later changed to a dry erythema, and was very irritable. The next year (24 years ago) a patch of "eczema" occurred on his left forearm where the plants lay as he carried them; this spread to his face, which also became swollen. Since then, each year about October, similar lesions have appeared, becoming gradually worse each season. At first only some varieties of chrysanthemum affected him, notably those with the strongest smell, but more recently all varieties have had the same effect, and latterly even the handling of the roots has been sufficient to bring on an attack.

Once, on the advice of a doctor, he obtained work where none of these plants was grown, and had no trouble, but on returning to chrysanthemums he relapsed. The present season's attack started in early October, 1930, on his hands and face, and then spread to his forearms and legs. Irritation was severe. No other plants are known to affect him, and no member of his family is similarly affected. He does not suffer from asthma or hay-fever.

He was admitted into the London Hospital under Dr. W. J. O'Donovan on Dec. 31st, 1930, when he presented the following picture. He was a well-built man, healthy apart from pyorrhœa alveolaris. The skin of his face was dry but no swelling was seen. His hands and forearms showed sheets of dry scaly lichenised papular erythema, with a few scattered relics of small furuncles. His legs were eyrthematous and excoriated on both shins. No other abnormalities were seen, and his blood count was normal except for a 10 per cent. eosinophilia; his blood pressure was 150/95 mm. His condition improved after the application of a 1/3 S.B. dose of X rays to all his lesions, and the administration of protein shock with T.A.B. 1/8 c.cm. intravenously (800 million bacteria), which gave rise to a temporary pyrexia of 103° with a rigor. Locally, glycerin of lead lotion with acid carbol. liq. 1 in 60 eased the irritation.



Localised erythema produced by experimental application of a chrysanthemum leaf to the skin of the back for 24 hours.

To test the sensitivity of his skin, a piece of chrysanthemum leaf was strapped on to his upper arm for 24 hours, with a tulip leaf as a control. Leaves from the same plants, chrysanthemum and control, were also applied for a like period to the arms of two controls, one of them a patient with cheiropompholyx, who might, a priori, be expected to be supersensitive to external irritants. After 24 hours the market gardener showed a close-set vesicular eruption on an erythematous base on the exact area covered by the chrysanthemum leaf, and a scarcely noticeable erythema on the site of the control leaf. Neither of the two control subjects was affected by either leaf.

This leaf reaction was repeated on the patient with other control leaves on different skin areas with similar results. The one pictured was photographed approximately 72 hours after application. The lower surface of a leaf gave a much stronger reaction than the upper, and a petal similarly applied gave a local erythema without vesiculation. In each case the reaction developed into an area of dry, slightly scaly, crusted erythema similar to his original condition, without the lichenisation due to long-continued scratching. The lesions persisted as a scabbed erythema for over four weeks after contact. Three extracts were made from crushed chrysanthemum leaves, and were painted on to his skin. An alcoholic extract, and one made by soaking the leaves in normal saline for 24 hours, produced no skin reaction. An etheric extract, on the other hand, produced, after 24 hours, a slight erythema. His normal reaction time before the appearance of a rash was about 12 hours, this being accounted for by Smith[1] as the time taken by the irritant juices to penetrate the skin; it may, however, be merely the latent period to be observed in many exogenic skin affections (vide *Brit. Jour. Derm.*, 1920, xxxii., 223).

This reaction time can be influenced by X rays. A three-inch square was marked out on his back and subjected to a 1/3 S.B. dose, the surrounding skin being screened by a double layer of lead and rubber. Four days later, leaves were applied to this area and to adjacent normal skin. The reaction time was nearly doubled in both cases, and neither developed beyond a slight erythema with a few vesicles, the rayed area being slightly less marked. This experiment was repeated with the same result later. In no case did the reaction develop into the close-set vesicular eruption previously noted. From this it appears that the rays have at least a temporary effect upon the sensitiveness of the skin, both of the rayed area and of that surrounding it.

Discussion.

References to this condition, beyond mere mention, are not numerous. The London Hospital skin department has records of two cases, with photographs: one was a nurseryman in 1924, who had a dermatitis of his hands traceable to these plants; the other, in 1926, was a chrysanthemum specialist who for 15 years had an autumnal rash on his face described as a "sore, smarting, confluent erythema and thickening of the skin, with swelling round his eyes."

Prosser White[2] says that only certain chrysanthemums are irritant, and that these are used for making insect powders, the manufacture of which is sometimes attended by a mild dermatitis. Darier[3] also states that only certain varieties are irritant. Dawson[4] reports a case of a gardener on whose face an acute dermatitis appeared a few hours after contact with chrysanthemums, but which always cleared up over the week-end when he was away from work; his hands were never affected. Broers[5] states that chrysanthemum dermatitis was first reported by Howe in 1887 (I have not been able to trace this reference). He quotes Dawson's case in 1908, and says that in 1927 Kren noted a hypersensitivity in a woman of 34 who exhibited a rash on the exposed parts after contact with these plants. When the skin was rubbed with the flowers they caused no reaction, but the leaves and stems did. Kren thought that the small hairs to be found on the stalks and leaves were responsible, as the hairless varieties caused no rash; Broers's opinion is that the leaves and stalks give out a variety of essential oils, and that these are the cause of the inflammation. He says that *Chrysanthemum vulgare* gives out a brown-staining oil which consists of one of the terpenes or an isomeric modification of camphor, and has been used as an abortifacient; Lewin is said to have once seen a pustular rash caused by this oil. The petals contain pyrethrum-camphor, ethereal oils, and tannin.

McCord, Kilker, and Minster,[6] writing on "pyrethrum dermatitis" (pyrethrum being generally regarded now as a genus of chrysanthemum), say that insect powders are extensively made from both the pyrethrum and chrysanthemum, and have observed the following types of lesion in workers in these insect-powder factories: (*a*) a vesicular eruption—the commonest; (*b*) a quickly healing erythema on the exposed parts; (*c*) a papular dermatitis; (*d*) an anaphylactic type with reddening of the face and an erysipeloid rash.

They think that the dermatitis is caused by "pyrethrum," a neutral ester, and certain acids to be extracted from these plants, which are said to yield 13 per cent. of resinous substances and up to 30 per cent. of alcohol-ether extractives.

The Royal Botanical Gardens, Kew, fail to record any cases, nor have any cases been reported at a large firm of horticulturists (Messrs. Suttons, of Reading) where inquiries were made.

Chrysanthemums are classed botanically in the natural order "compositæ," a group of aromatic, stimulating, and carminative plants. Amongst those cultivated, of which there are many with widely differing characteristics, hairy varieties occur, and the leaves of the different species are said by Finnemore[7] to yield essential oils varying from 0·01 per cent. to 0·1 per cent., some of which are used by the Japanese for medicinal purposes. There is an alkaloid "chrysanthemine" which is found to be a combination of stachydrine and choline, the latter being also found in the betel-nut. Different writers therefore agree that there are several possible sources of toxicity in the chrysanthemum. Smith[1] says, of plant dermatitis, that "any rough surface or prickles may abrade a delicate skin, and that almost any cell-sap may act as an irritant."

In the case recorded, which comes under the heading of McCord's type A but which differs clinically from Dawson's case and experimentally from that of Kren, it seems evident that the main factor in producing the dermatitis is chemical. The ether-soluble oils have been shown to be mildly irritant, and the varying but positive reactions obtained with the two surfaces of a leaf and with the petals, together with the history of irritation by the roots, is in accordance with this, owing to the relative permeability of the parts to the juices. This is further borne out by the patient's statement that the stronger-smelling varieties affected him first. The condition demands a skin abnormally sensitive to a specific irritant, which makes the probability of a mechanical irritant the more remote, as other hairy plants do not affect him.

The diagnosis of the condition, which may be of importance in compensation cases, should present no difficulty if a careful history be taken, especially of the relationship between the onset and work amongst the suspected plants. In doubtful cases a simple controlled leaf test, as indicated, should be conclusive.

Treatment in mild and recent cases consists of mild lotions, but those of longer standing may require drastic measures, as in the case recorded, avoidance of the source of irritation being, of course, essential.

My thanks are due to Dr. W. J. O'Donovan for his suggestions and permission to publish details of the case under his care; and to the director of the Royal Botanical Gardens, Kew, for having kindly supplied me with some of the botanical references.

CLINICAL AND LABORATORY NOTES

THE MINIMAL FARADIC CURRENT AS AN AID TO DIAGNOSIS.

By Lieut.-Colonel J. K. McConnel, *D.S.O.*, *M.C.*, C.S.M.M.G.,

BIOPHYSICAL ASSISTANT, WORKING AT ST. THOMAS'S HOSPITAL.

The use of the faradic current for diagnostic purposes is well known in connexion with peripheral nerve lesions and with certain pathological conditions in muscles. The criterion in these cases is the muscular contraction, either by reason of its presence or its nature.

Besides this, faradic currents of weaker strength which do not elicit muscular contraction are of value in diagnosis, the sensations reported by the patient being the index. Unduly sensitive areas or spots may be located in muscles, fascia, ligaments, and joint capsules. As a rule these do not coincide with areas of tenderness to pressure, and where this is the case, the use of the minimal faradic current is of definite diagnostic value.

Spots unduly sensitive to faradism along the course of nerve trunks and hypersensitiveness at cutaneous levels may be of importance, but cannot be included within the compass of these notes.

TECHNIQUE.

The technique employed is similar to that which is well known in connexion with the localisation of spots suitable for galvanic acupuncture.[1] For the purposes under discussion, however, the testing electrode should be provided with a key, so as to differentiate between tenderness to deep pressure and sensitivity to weak currents, also as a check on the patient's replies. Usually the testing electrode should be of about 1·5 in. diameter, though a button electrode is required as well. Tests carried out before and during a course of treatment serve as a guide and check the progress at each stage.

CLINICAL VALUE.

The diagnostic use of minimal faradism falls under three principal headings: (1) the location of hypersensitive areas in recent and chronic trauma, especially in the back; (2) the discovery of certain areas from which pain is referred; (3) the differentiation between the origins of certain pains.

Characteristic examples of these have been found in patients treated under Dr. P. Bauwens in the Electrotherapeutic Department at St. Thomas's Hospital and in private practice. I am much indebted to Dr. Bauwens for permission to quote two of his cases.

1. *Recent or chronic trauma, especially in the back.*—When widespread tenderness to touch and extreme pain on movement is present or when localisation of tenderness to pressure is poor, the local treatment of small areas hypersensitive to faradism has been found to give marked relief.

Where residua of recent trauma exist, or when the site of origin of pain is hard to determine (either in subacute recent or chronic mild injury), minimal faradism fills a definite rôle, especially when tenderness to pressure is absent.

A case treated in the Electrotherapeutic Department at St. Thomas's Hospital demonstrates this point. A male, aged 40, had damaged his ankle whilst descending stairs some three months ago, during which time rest, fomentations, and physical treatment had been given. When seen there was no swelling and little tenderness, but the ankle ached on use. The external malleolus was not tender to pressure, but a spot (? in tibio-fibular ligament) was extremely sensitive to faradism; this was treated with a local dose of U.V.R.; three days later patient reported no pain in his ankle, though he had "tried it out."

2. *Referred pain.*—Pain may be referred from areas which are unduly sensitive to minimal faradism, although normal or only very slightly tender to pressure. Cases of this have been found in the Electrotherapeutic Department at St. Thomas's Hospital and also in private practice. With certain patients the local treatment of such an area, which had previously remained unsuspected, gave a speedy relief from referred pain.

3. *Differentiation of origins of various pains.*—This difficult task is often facilitated by minimal faradism. Pain long ascribed to osteo-arthritic joints has been found to clear up when soft structures unduly sensitive

---

[1] E. P. Cumberbatch: Essentials of Medical Electricity. Sixth edition, London, 1929.

to faradism have been treated. The value of this electrical test will be appreciated by those who hold that this type of joint may cause referred pain only in certain acute phases.

Pain which appeared to be referred may be shown to be of local origin. This has been found as regards pain in the knee, around the ankle, and *in the foot.* The following case demonstrates this point.

Male, aged 65. Six weeks' history of pain in gluteal region, back of thigh, and in calf. Improved under physical treatment (diathermy, radiant heat, and acupuncture) during five months, but for a further six weeks pain in calf tended to persist. Test with minimal faradism disclosed sensitive spot above external malleolus, probably independent of *original* trouble. One local dose of U.V.R. (Kromayer lamp) cleared up this and residual leg pain.

PREVENTION AND ATTENUATION OF MEASLES WITH SERUM OF ADULTS.

By Matthew Burn, *M.C.*, *M.M.*, F.R.C.P. Edin., D.P.H., D.T.M. & H.,

CHIEF ASSISTANT MEDICAL OFFICER OF HEALTH, CITY OF BIRMINGHAM.

It is felt desirable to publish the following results principally because of adult serum being used to carry out the prophylactic measures. Since this work was begun in October, 1930, supplies of serum have been derived from volunteers in the Public Health Department, Birmingham—mainly health visitors. It is to be noted that the serum is *not* from convalescent cases but from adults who have had measles, usually in infancy. As was to be expected, owing to the human origin of the serum, no anaphylactic or other serum phenomena occurred from its administration.

Suitable cases of measles are found through the agency of the health visitors, and any cases of contacts under 5 years of age who are in delicate health or who are either acutely ill or suffering from a chronic condition such as asthma, rickets, bronchitis, or who are in homes where there is grave overcrowding, are given the serum, after consultation with their medical attendant.

Sero-attenuation.

Number of cases.	Average incubation period (rash to rash).	Type of attack.
3	10 days.	Normal.*
20	11 days.	Mild.
33	12½ days.	Very mild.
14	—	No attack.
70	—	—

* One child, aged eight months, had rash for three days and mastoid operation 10 days later; grave overcrowding in house.

Mild = Where rash lasted two to three days, was faint, little catarrh and child well. Very mild = Temperature, and very faint sparse rash lasting about 24 hours; no bronchitis; child well during attack.

Sero-prevention.

Serum injected up to third day from rash.	Type of case.	Result.		
		Aborted.	"Failures."	
			Very mild.	Normal.
50	Hospital.	48	2	—
26	Home.	23	2	1

Above are tabulated the results of some 70 cases which received serum for attenuation purposes, their ages varying *from* a few months to five years. The day *of administration* of the serum varied from the fourth *to* the seventh day *from the appearance of the rash,* the average being 5·5 days. The dose of serum given varied according to the age of the child, its condition, and the day of administration, the average dosage being 8 c.cm. It will be seen that in reference to these cases, the incubation period cannot be considered to have been appreciably lengthened.

"*Failures.*"—Eleven contacts were injected in one ward on March 26th, 1931, but two previous cases of measles had occurred on the 21st and 25th, and in all probability these two "failures" were due to the double incubation periods which were "running" at the time. No further cases occurred.

Two of the three cases of "failure" at home had been exposed previously to measles which was prevalent in the court where they lived, while the third case inadvertently received 75 per cent. less than the recommended dose.

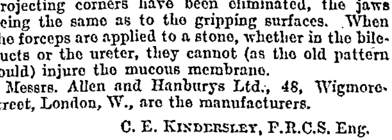
The average dose given to the above children, whose ages ranged from some months to six years, was 9 c.cm. These children were either post-operative cases or were suffering from some acute illness such as pneumonia.

From the experience above recorded it appears that the use of adult measles serum for either sero-prevention or attenuation gives comparable results to those obtained by other workers using convalescent measles serum. It is of course much more easily obtained.

NEW INVENTIONS

A MODIFICATION OF DESJARDIN'S FORCEPS.

Having been struck by the fact that the usual pattern of Desjardin's common duct forceps were smooth when closed, and presented some comparatively sharp corners on the blades when open, I have had a modification made to my own pattern. The only difference in the new pattern is that all the projecting corners have been eliminated, the jaws being the same as to the gripping surfaces. When the forceps are applied to a stone, whether in the bile-ducts or the ureter, they cannot (as the old pattern could) injure the mucous membrane.



Messrs. Allen and Hanburys Ltd., 48, Wigmore-street, London, W., are the manufacturers.

C. E. Kindersley, F.R.C.S. Eng.

Charing Cross Hospital.—In his speech at the annual meeting of the governors recently, Mr. George Verity, who presided, said that, in spite of watching over every penny of expenditure, the hospital had for the moment lost its proud position as the lowest in cost per bed of all the London hospitals. Pay wards are needed, but they would have to be additional to the existing beds, and nothing can be done in that direction until the cost of the new nurses' home (£60,000) has been completely dealt with. Mr. Verity expressed a fear that the payment of nine months' income-tax next January would have a serious effect upon subscriptions.

MEDICAL SOCIETIES

TUBERCULOSIS ASSOCIATION.

At a meeting of this association, held on May 15th, a paper on

Clinical Types of Hæmoptysis

was read by Dr. G. T. Hebert. Although hæmoptysis was, he said, one of the outstanding features of tuberculosis, the actual method of its causation was still uncertain, and, probably for that reason, treatment of the symptom was far from satisfactory. Any classification of hæmoptysis should be made not on purely academic grounds but with the definite object of enabling any particular case to be placed in its group so that the appropriate remedy shown by experience to be of value in that group might be applied without loss of time. Among the clinical features of hæmoptysis was the fact that it occurred both in ulcerative and in non-ulcerative conditions, and that it might be due to one of a number of causes. The amount of blood also varied from the minimal amount sufficient to constitute hæmoptysis up to a pint or more, the size of the hæmoptysis having no necessary relation to the extent or activity of the disease. Other variable features were the frequency with which it occurred in different patients and the stage of disease at which it might present itself—early, intermediate, or advanced. Tuberculous hæmoptysis was of varying importance, some cases having apparently little significance as regarded prognosis. It was impossible to say which were the factors determining a hæmoptysis. Fatigue, effort, trauma, and rise of blood pressure had all been incriminated, but in many cases these could be definitely eliminated. With regard to rise of blood pressure, Dr. Hebert pointed out that it was doubtful whether a rise in the systemic circulation, unless prolonged, was followed by a rise in the pulmonary circulation. A review of these clinical features made it evident that hæmoptysis was essentially fortuitous; a number of different causes must be responsible. Although arterial bleeding undoubtedly occurred in vessels exposed in cavities, a severe ulcerative process had been at work in such cases, and in fact the arteries had proved to be the most resistant of all of the pulmonary structures. In cases of quiescent or calcified or apparently arrested disease, arterial hæmoptysis was difficult to explain, especially when the duration of the bleeding was short and no subsequent evidence of activity obtainable. Some cases of hæmoptysis in tuberculosis as in other non-tuberculous conditions might be caused by capillary or congestive bleeding, due to back pressure.

A SUGGESTED CLASSIFICATION.

After a brief review of some classifications of hæmoptysis already proposed by various workers, Dr. Hebert suggested that a rational division would be into (1) large and small (or brisk and sluggish), and (2) arterial and venous, with the four subdivisions: large arterial, small arterial, large venous, and small venous. The large *venous* hæmoptysis was the distinguishing feature of the classification, and he enumerated some of the arguments in its favour, showing also that on the clinical side it would account for cases of a large hæmoptysis occurring in an apparently healthy individual. The hypothesis assumed that when a perforation occurred in a vein blood would flow out rather than air enter. It was difficult to assess the probabilities of the occurrence of these two events from arguments based on intrapulmonary pressure, but it might perhaps be admitted that air would be sucked into a large vein, but a vein of smaller size, yet large enough to give a brisk flow of blood, might bleed. Dr. Hebert went on to show how the suggested classification would explain without difficulty the clinical features mentioned above, including hæmoptysis occurring at any stage of the disease. He then put forward a few general indications for assigning a given case of hæmoptysis to its proper group. A brisk hæmoptysis in an apparently healthy individual was probably a large venous; in a chronic case probably a large arterial. A small hæmoptysis in an active case should be regarded, and treated, as small arterial, but might be small venous if there had been previous evidence of pulmonary congestion. Finally, the speaker dealt briefly with the way in which the suggested classification might be applied to treatment. Large hæmoptyses required mental and physical rest, suitable posture, and, where the bleeding showed after 15 minutes no sign of cessation or appeared to be arterial, morphia might be indicated and the use of salt or calcium to increase the clotting power of the blood, and compression by artificial pneumothorax considered.

At the evening session a discussion on the

Surgical Treatment of Extrapleural Complications

in pulmonary tuberculosis was opened by Mr. P. H. Mitchiner. Very few non-pulmonary tuberculous lesions, he thought, called for surgical interference. In only three situations surgery was called for as primary treatment: (1) Tuberculosis of the kidney where the other kidney was healthy and there was no evidence of tuberculous disease elsewhere; (2) old tuberculous glands in the mesentery; (3) tuberculous glands in which abscesses had *just* broken down and the skin over them was perfectly healthy. It was worth while here to attempt to dissect out the gland whole. In regard to tuberculous bones and joints, no good was likely to be done if there was surgical interference when any pulmonary lesion was present. Sinuses must be kept aseptic; surgery was, of course, called for if sepsis had occurred, but in aseptic cases ultra-violet rays for superficial and X ray for deeper lesions were better than surgical treatment. He referred to Rollier's success with non-surgical methods, perfectly normal bones and joints being obtained in about four years. The ideal treatment was sun treatment when possible. Where time was an object, fixation by plaster-of-Paris was necessary. The most intractable type was primary synovial tuberculous disease of the joint. This might be cured in four to five years, but about 60 per cent. of patients would probably relapse.

Discussing the value of tuberculin in non-pulmonary tuberculosis, Mr. Mitchiner said he had found it of definite use in genito-urinary tuberculosis, but not in peritoneal, glandular, bone or joint tubercle. The commonest situation of non-pulmonary tuberculosis was in the cervical lymph glands. A search should immediately be instituted for a local source of infection. In addition to those generally recognised, he believed impetigo to be a potent source of tuberculous glands. He did not believe that any normal healthy lymph node could become tuberculous. General hygienic treatment was important, and exposure to X rays was valuable if the patient could not be got away. With regard to surgery, it should be undertaken only when it was obvious that a broken down abscessed gland could be dissected out whole. If the skin was involved, he personally would leave it alone. If the resulting sinus had not healed up after three months, he always took an X ray photograph for the presence of any calcified tissue which would have to be removed. Neglected sinuses with superadded sepsis required thorough curetting of the track. In tuberculous peritonitis he was against surgical interference unless there was any intestinal obstruction.

Genito-urinary tuberculosis was of two types. The first was that of a patient who started with blood-borne renal lesions. These gave few signs in the early stage. The bladder was healthy, although the urine might contain many tubercle bacilli. Immediate removal of the diseased kidney should be undertaken, before the bladder, vesicles, prostate, and the other kidney were involved. The prognosis in such cases was good; about 70 per cent. of such patients operated on at St. Thomas's Hospital were still alive. The other type was where a patient with pulmonary disease had some secondary focus, however small, in the genito-urinary tract. No surgical interference whatever was justified in these cases; epididymal tuberculosis was always secondary to disease either of kidney or of lung. Fixation was important here; a suspender was not sufficient—the testicle must be strapped.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF LARYNGOLOGY AND OTOLOGY.

A MEETING of this section was held on April 17th, with Sir ROBERT WOODS, the President, in the chair.

Vallecular Dysphagia.

Dr. R. R. WOODS read notes on a condition—hitherto, he thought, undescribed—which he called vallecular dysphagia.

The patient, a man aged 54, first asked advice in June, 1930, complaining of 18 months' dysphagia. Solid food could not be taken with comfort; it stuck in his throat, and could be brought up by a kind of cough. Radiography showed that barium was held up in the valleculæ, and that when these were full the epiglottis was pressed against the pharyngeal wall so that breathing was impeded. On two occasions (February, 1930, and September, 1930) the floors of the valleculæ were burned by diathermy in an effort to cause cicatricial contraction and closure of the valleculæ. After each treatment he experienced great relief but the condition recurred. In February, 1931, the pharyngo-epiglottic folds were cut in an attempt to allow the food to pass more easily to the pyriform sinuses and thence to the œsophagus but this also gave only temporary relief.

The patient was now as bad as ever said Dr. Woods, and the question was whether palliative treatment by diathermy should be continued or whether some more radical treatment such as amputation of the epiglottis or an attempt to stitch it to the base of the tongue should be tried.

Dr. HORACE LAW suggested removal of the epiglottis in this case.—The PRESIDENT advocated the same procedure, through a suprahyoid pharyngotomy, and said he thought it a unique case.

Lateral Sinus Thrombosis.

Dr. T. O. GRAHAM showed two cases on which he had operated for lateral sinus thrombosis. In the first, since the diagnosis was obvious before operation, he had cut down and divided the jugular vein, and then cleared the large clot out of the lateral sinus. In the second case mastoidectomy had revealed an extradural abscess and lateral sinus thrombosis. Both were streptococcal.

Dr. PATRICK DEMPSEY advocated routine exposure of the lateral sinus in cases of simple mastoidectomy.—The PRESIDENT said that in his cases it had been the rule rather than the exception for an abscess to form in the deep tissues of the neck, around the divided ends of the jugular vein.

Dr. LAW reported a case of lateral sinus thrombosis with fatal termination.

The patient, a girl aged 18, was brought into the Adelaide Hospital on August 4th, 1930, suffering from pain in right ear and high fever. The attack had lasted only a fortnight; it was accompanied by grave constitutional disturbance. On examination acute tenderness and some swelling was found behind and above right ear; copious discharge was present, and acute inflammation of the drum was seen. There was no swelling over the mastoid, nor in the tissues of the neck, nor could the internal jugular vein be palpated. There was no sense of discomfort on deep pressure in the neck.

An ordinary radical mastoid was done, a large periosteal abscess was found, and cholesteomatous debris in the antrum and middle ear. Enough had been found to account for the high temperature and pain, and there was no indication to proceed further. However, three days later the patient had two rigors, and Dr. Law at once laid bare the lateral sinus over a large area, and found an abscess round it; the sinus was soft and showed no signs of thrombosis, and the condition of the neck was exactly as already described.

This interference seemed to make no difference in the condition of the patient, who still ran an extremely high temperature, going up most nights to 104° F. Injections of S.U.P. 36 and scarlatinal antitoxin were tried, but had no effect. Eleven days after the last operation the patient had another rigor, and her condition was so serious that Dr. Law decided to cut down on the jugular vein and see what the condition was. He opened the sinus above and it bled freely. The jugular vein was not easy to locate, for the tissues were extremely disintegrated and the vein itself very soft. It was opened and followed down right to the root of the neck and was found to be full of pus as far down as it could be followed. The wound was plugged and left open. A probe was passed up to meet another in the jugular bulb and proved this portion to be patent

The local condition steadily improved, but the patient developed definite pulmonary symptoms and began to expectorate evil-smelling sputum. This went on to hæmorrhages, one of which proved fatal on Sept. 6th.

Intracranial Abscess.

Dr. LAW also described the case of a girl of 17, who was brought to the Adelaide Hospital on Nov. 21st, 1930, in an unconscious condition, having complained of pain and discharge in right ear.

The history was that she had had an acute otitis some days previously and then got rapidly worse and became unconscious on the morning of the 21st. Beyond the discharge from the ear it was not possible to make any definite diagnosis. Dr. Geoffrey Bewley saw the patient and found reflexes fairly normal and there were no gross eye signs. He did a lumbar puncture and withdrew 50 c.cm. of fluid, under pressure but quite clear. Dr. Law at once proceeded to open up the ear, doing a radical mastoid, laying bare the sinus and breaking down the tegmen tympani. In both the groove of the sinus and under the tegmen were found fairly large subdural abscesses. When the first one, that of the tegmen, was opened, the patient at once stopped breathing, though the heart remained strong and pulse regular. She was kept alive partly by artificial respiration and partly by intratracheal oxygen, and Dr. Law completed the operation leaving the area wide open. In various attempts to make her breathe use was made of oxygen, carbon dioxide, stimulants, strychnine gr. 1/10th, pituitrin and sterile saline intrathecally. These attempts were continued for four hours and the pulse remained good throughout. After that time, as there seemed to be no prospect of any natural respiration, the attempts were given up. Permission for necropsy was refused.

Dr. T. G. WILSON said that when respiration ceased in these circumstances a cerebellar abscess was usually present, and its evacuation was usually followed by restoration of respiration.

Dr. GEOFFREY BEWLEY said he did not think cessation of respiration was due to the lumbar puncture, notwithstanding the large amount of fluid drawn away. He thought some more serious intracranial trouble was present.

Mr. A. A. MCCONNELL suggested three methods of restoring respiration, which had proved successful with him in cases of cerebellar tumour. These were: changing the position of the head, from flexion to extension or vice versa; putting the patient into the Trendelenburg position; and opening the foramen magnum.—Dr. GRAHAM mentioned cases in which he had used similar methods with success.

Dr. WOODS read notes on a case of temporal lobe abscess.

The patient had had right chronic suppurative otitis media since boyhood. On Oct. 29th he vomited and had a temperature of 103° F.; there was no rigor, and the pulse-rate was 70. He was almost deaf in the right ear, but there was no mastoiditis. The nervous system was normal except for a suspicion of facial weakness on the left side. On Oct. 31st the radical mastoid operation was performed. There was a defect in the tegmen tympani. During the following week he became drowsy, the pulse fell to 60, and the facial weakness increased, and on Nov. 7th the temporal lobe was opened, a large abscess was evacuated, and the cavity syringed out. Drainage was maintained by a rubber tube, which was removed 11 weeks later. The ear is now dry.

Mr. MCCONNELL, referring to the fact that gas was present in the abscess cavity, advocated the use of X rays in diagnosis.

Dr. WILSON read notes on a case of temporal lobe abscess in a child aged 9 months.

This child was admitted to the Royal City of Dublin Hospital with acute left mastoiditis, and ptosis of the left upper eyelid. Fourteen days after simple mastoidectomy complete left oculomotor paralysis occurred, and twitching of the right arm and leg was noticed. The temporal lobe was freely exposed and the dura incised preparatory to exploring the temporal lobe next day, but the child died a few hours later. Post mortem an abscess pressing on the right crus cerebri was found.

Dr. WILSON drew attention to the preciseness with which it was possible to locate the abscess in this case and to the fact that no macroscopic track of infection was found, either at operation or post mortem. He also read notes on a case of perisinus abscess with purulent meningitis.

The patient, a farmer aged 26, was admitted to hospital almost comatose. Lumbar puncture yielded turbid fluid under pressure, from which the *Streptococcus hæmolyticus* was isolated. At operation a large perisinus abscess was evacuated. After operation the patient's pulse and temperature became normal, and 11 days later he was sitting up in bed reading newspapers. Next day an acute exacerbation of the meningitis took place, and proved rapidly fatal.

These cases were discussed by Dr. LAW and the PRESIDENT, who pointed out the importance of "twitchings" as an early sign of intracranial trouble in children.

Papilloma of the Vocal Cord.

Dr. P. J. KEOGH showed a case of papilloma of the right vocal cord. The patient, a man aged 34 years, complained of hoarseness and cough for five months previously. The Wassermann reaction was negative and no tubercle bacilli were found in the sputum. Dr. Keogh demonstrated a papillomatous swelling the size of a split pea in the middle of the right vocal cord. He proposed to remove this growth by direct laryngoscopy, but was prepared to do a laryngofissure if necessary.—The PRESIDENT and Dr. LAW expressed the opinion that the more radical method of removal might be necessary.

Dr. DEMPSEY showed a case of epithelioma of the fauces treated with diathermy. No recurrence had taken place after ten months, and the affected area was occupied by soft scar tissue.

ISCHÆMIA OF MUSCLE AS A CAUSE OF ANGINAL PAIN.

A LECTURE BY SIR THOMAS LEWIS.

THE St. Cyres Lecture was delivered by Sir Thomas Lewis at the National Hospital for Diseases of the Heart on May 14th, with Dr. Frederick Price in the chair.

Sir Thomas said that throughout his address he proposed to use the term "angina pectoris" in the sense employed by Heberden, denoting a distinct disease. He wished to consider only the origin of the pain in angina, and not the general pathology of the condition. Since the first description of angina pectoris by Heberden the cause of the pain with which it was associated had formed the basis of much theoretical discussion; the first person to suggest that the disease arose from an affection of the coronary arteries was Edward Jenner, and this view was later put more plainly by Parry. Parry recognised that the blood-supply to the heart muscle was impeded by the rigidity of arterio-sclerotic coronary vessels, and that though sufficient blood might pass to nourish the resting heart, the quantity might be inadequate for vigorous exertion. This theory, however, offered no explanation of anginal pain. He also believed that the power of the heart failed during the attack and that consequently "syncope anginosa" was a common symptom of angina pectoris. Subsequent observation, however, has shown that syncope is rare in anginal attacks. Allan Burns in 1809 was the first person to draw a comparison between angina pectoris and the condition of a limb "begirt by a ligature," but he made no mention of the pain in a limb working under conditions in which the blood flow was impeded. Benjamin Brodie, in 1846, compared cases of arterial disease in the leg, showing gangrene of the toes, with angina pectoris, but he, too, made no reference to pain. It was not until 1866 that Potter drew an analogy between intermittent claudication in a limb and the pain of angina pectoris.

Various experiments had been undertaken to decide where the pain arose in a ligatured limb. Some observers had attributed it to a spasm of the arterial walls, but Sir Thomas had found that when the blood-supply *to a limb* was cut off and the muscle exercised until pain developed, the release of the ligature produced flushing of the skin over the muscles with the first pulse beat, while the pain persisted for several seconds longer. Charcot, who had observed a patient with intermittent claudication, had attributed the pain to cramp which he thought comparable to cadaveric rigidity, but although the pain could be obtained readily by the exercise of a ligatured limb, true cramp was rare, and there was no increase in the tone of the muscles.

EXPERIMENTAL PRODUCTION OF PAIN.

To establish the pain Sir Thomas and his co-workers had gripped a small instrument which recorded the force used by means of a spring. The circulation was cut off by means of a sphygmomanometer, and the grip was tightened once a second in time to a metronome. They had found that the pain arose after 30 to 35 seconds and became unendurable after 72 to 78 seconds; these times were remarkably regular and did not vary much between different individuals. The pain was diffuse and aching, and situated in the neighbourhood of the acting groups of muscles; tenderness developed in these muscles, which persisted after the pain had disappeared.

Pain had also been attributed to lack of oxygen in the muscle. Sir Thomas had found, however, that if the circulation was stopped in a limb kept at rest, no pain would arise. Moreover, if, with a ligatured limb the observer worked his muscles until he was within two or three *contractions* of the onset of pain and then *stopped, no pain* would develop. Yet in both these cases the muscles would be requiring oxygen, and the usual supply was not available.

Whether the load on the muscle or the rate of contraction was increased it was observed that the onset of pain and the point at which it became unbearable were expedited, so that the onset was clearly determined by the energy expended by the muscle. A clue to the origin of the pain had been obtained by a series of simple experiments. In the first of these the circulation had been cut off and the limb was worked until the pain had reached a certain level of intensity; work was then stopped, and it was found that as long as the ligature remained in place the pain persisted at the same level of intensity. When the ligature was removed the pain disappeared in from two to four seconds. For this reason, Sir Thomas said, he had concluded that the pain had a chemical or physicochemical origin; he believed that processes arose in the muscle-fibres during experiment which led to a change in the conditions in the tissue spaces around the fibres, and that it was the change in the tissue spaces which gave rise to the pain. Further experiments had helped to confirm this view; for example, when the ligature was released the pain disappeared within a few seconds; if, however, the ligature were replaced as soon as the pain had gone, and exercise was recommenced the onset of pain would be expedited. The shorter the rest interval the earlier the onset of pain, and it could be assumed that the process occurring in the muscle required longer to subside than the process arising in the tissue spaces. Another experiment bore this out; exercise was performed in a ligatured limb until pain arose; the ligature was then released but the exercise maintained until the pain disappeared, when the ligature was reapplied and the exercise stopped. It was found that pain developed again within 20 to 30 seconds, showing that some change had been engendered in the muscle which gave rise to the collection, in the tissue spaces, of the factor responsible for pain. So long as the circulation was free no collection of this physicochemical factor could arise, and therefore pain could not develop.

PAIN IN CORONARY THROMBOSIS.

If anginal pain was due to ischæmia then pain ought to arise either when the work of the muscle remained constant and the blood-supply was diminished, or else when the work of the muscle was increased and the blood-supply became inadequate. There were certain similarities between the pain produced in coronary thrombosis, where there was no increase of work but part of the blood-supply to the muscle was cut off, and the pain of angina pectoris. In both conditions pain was severe and continuous, not spasmodic, and the situation was the same in both, involving the præcordium and the upper and lower regions of the sternum. Epigastric pain was commoner in coronary thrombosis, and the pain persisted for a longer period than in angina. Coronary thrombosis offered the best clinical evidence that occlusion of a coronary vessel gave rise to pain. Sutton had borne out this finding by passing a ligature round the coronary vessels of anæsthetised dogs; *traction* on the ligatures when the dogs regained consciousness gave rise to pain, and he had not been able to elicit the symptom by experiments on neighbouring structures.

If coronary thrombosis were considered in terms of muscular ischæmia it would be realised that the part of the heart muscle supplied by the occluded vessel *continued to work*, heaping up the pain-producing *factor* in the tissue spaces. This would explain the gradual onset of the pain and its long duration.

EXCITING FACTORS.

The theory of anginal pain originally suggested by Parry had supposed it to be due to an increase of tension in a sore or irritable aorta, and in this case a rise of blood pressure should always precipitate an attack. In certain cases of paroxysmal tachycardia, associated with angina, however, there was no rise of blood pressure, but anginal pain might arise during the paroxysms; there could be no question of strain on the aorta here. Nor must it be assumed that in the angina of effort the pain was necessarily due to a rise in blood pressure unless this was confirmed by observation. In some cases where the patients had severe heart disease, usually aortic regurgitation, the early anginal attacks occurred on effort, but later they developed while the patient was in bed, often in the early hours of the morning; the rise in blood pressure in these cases was conspicuous, and the attack was usually relieved by inhaling amyl nitrite.

That changes in the blood pressure were not the only exciting cause of an attack could be shown by the case of a man who developed no pain after exercise but in whom attacks were readily induced by food, especially anything which required chewing. It was found that although the blood pressure rose slightly during the attack, it did not fall when the pain disappeared, and a much higher blood pressure was produced by exercise, though this did not provoke an attack.

Amyl nitrite was usually supposed to relieve an attack by causing a marked fall of blood pressure, but observations in the ward had shown that this was by no means always, or even often, the case. The fall, where it occurred, was usually slight, and in some cases the blood pressure actually rose. It was far more probable that amyl nitrite acted by dilating the coronary arteries; the consequent increased flow of blood to the heart muscle swept away the pain-producing factor from the tissue spaces. In coronary thrombosis, as might be expected, amyl nitrite gave no relief because it could not open up the occluded vessel.

HARROW HOSPITAL.—The Stuart Memorial extension of the Harrow and Wealdstone Hospital, which has been erected and equipped at a cost of nearly £38,000, was opened by the Duke and Duchess of York on May 6th. In reply to an address of welcome the Duke of York said that there could be no finer memorial than a hospital, and the descendants of the late Mr. and Mrs. J. N. Stuart would be glad that a name so closely linked with the hospital would ever be held in remembrance through the new extension. Mr. Stuart was a former president and secretary, and both he and Mrs. Stuart were generous in gifts and services. The hospital is electrified in almost every respect; no fireplaces or radiators are to be seen, all the heating being done by the wall panel system. There is a contributory scheme by which persons with incomes of less than £750 a year can secure hospital treatment in return for an annual subscription.

obtain Certificate E on the strength of the post-mortem examination without inquest, under Section 21 of the 1926 Act. Such examination, as a safeguard in cremation cases, should, in Dr. Waldo's opinion, never be made by the medical practitioner in attendance on the family, nor should it ever be conducted in a private house. The third main modification in the law is the provision in Section 20 of the Act for adjourning inquests when criminal proceedings in murder, manslaughter, or infanticide cases are under way in the magistrates' courts. The total of such adjournments in 1929 was almost the same as that for 1928.

Too many inferences must not be drawn from the Home Office statistics, least of all in items where the figures are small and subject to sharp fluctuations. Just as there is no special significance in the drop in treasure trove inquests from five to one in 12 months, so also no firm deduction can be safely made if the verdicts of deaths due to drink, or of deaths due to disease aggravated by other people's neglect, are twice as high for 1929 as for 1928. But undoubtedly the figures of verdicts of accidental death, which have been mounting by roughly 1000 per annum, reflect the dangers of modern traffic which the "Safety First" movement is endeavouring to reduce. The heavy drop in verdicts of death due to natural causes (including old age) can be explained by the new procedure, already mentioned, of substituting a post-mortem examination for an inquest. The total in this respect has fallen by about 5000 when compared with the total four years ago. Verdicts of stillbirth are dropping steadily; so also are verdicts of death due to want of attention at birth, and verdicts of accidental death where children have been suffocated while in bed with their parents or others. In one of the final paragraphs of the official Introduction to the Statistics it is stated that only one inquest out of 32,612 was followed by a second inquest on the order of the High Court. This fact the Home Office considers a remarkable testimony to the manner in which coroners and their juries perform their duties. It is a fitting tribute to the *officium coronatoris*, an office which, in the City Coroner's words, has throughout many centuries contributed in no small degree to the protection of the lives of our countrymen.

APICAL INFECTION OF THE TEETH.

When the importance of dental sepsis as a factor in general disease was first emphasised by Dr. William Hunter, attention was chiefly concentrated on pyorrhœa as the obvious form of infection. But improved radiography often showed teeth with areas of rarefaction round the apices. Nearly always these teeth were pulpless, and when one of them was extracted a small mass of tissue, attached to the root and corresponding to the rarefied area seen in the radiogram, came away with the tooth. Though these masses of tissue, which are now termed granulomata, had long been familiar to the dental surgeon, and their structure had been studied, yet since the condition was usually painless, it had not been realised how common they were. The conception of dental sepsis had therefore to be widened by the inclusion of the granuloma. Since no drainage into the mouth was possible in this form of infection, the view was put forward, and soon became popular, that the granuloma was more serious than pyorrhœa, since the passage of toxins was directly into the blood, whereas in pyorrhœa the passage of toxins was chiefly into the mouth. The distinction between open and closed infection thus assumed great significance in connexion with systemic infection.

From this time onwards increasing interest has been taken in the bacteriology and histology of the dental granuloma. Weston Price has suggested that it is a defensive barrier against infection arising in the tooth and may thus indeed indicate a successful reaction. This point of view has attracted much attention, for it has implied the possibility that "dead" teeth may not always need extraction. Some observers have reported that granulomata might be sometimes sterile, but often their technique has not inspired complete confidence in their conclusions. The most recent work on apical infection is contained in a series of four papers in the *British Dental Journal*[1] by Mr. Arthur Bulleid, which form by far the most exhaustive study yet made in this country, and represent an important advance in dental pathology. Mr. Bulleid has examined a large number of teeth which showed a granuloma radiographically. The teeth were extracted and cultures taken under strict precautions against contamination. Both aerobic and anaerobic methods of culture were used, and this proved highly desirable, for in eight cases granulomata which were sterile by aerobic methods showed a growth of streptococci on anaerobic culture. Bacterial infection was found in all 80 granulomata examined, and in every case streptococci were isolated, though other organisms were often present as well. A further interesting point revealed by this investigation is that granulomata are relatively common in pulpless teeth which have had their root canals carefully filled. It would be unfair to assume from this that treatment of pulpless teeth ought not to be undertaken, but it is at least possible that the principle of filling the canals up to the apex, which many dentists have regarded as fundamental, may have to be modified.

Besides his bacteriological work Mr. Bulleid has studied the minute structure of the granuloma and sets out his results in a series of microphotographs of high technical excellence. His research carries our knowledge a definite stage further, and should long be a standard for reference.

SMALL-POX PREVENTION AND LOCAL AUTHORITIES.

In April of last year the administration of the Vaccination Acts passed from boards of guardians to local public health authorities, and like other duties thus transferred was left unamended. The

---

[1] Brit. Dent. Jour., Jan. 16th et seq.

Ministry of Health has now issued a review[1] of certain present aspects of small-pox prevention, to assist them in considering the necessity or otherwise of any modifications in the administration of these Acts. The review assesses the different factors in the epidemiology and clinical characters of small-pox which have been experienced in recent years, records the results and extent of vaccination and the incidence of small-pox in this country, and correlates this information with the findings of the Rolleston report and with the extension of the practice of other forms of immunisation against disease. This country, it is pointed out, is now and has long been intrinsically more vulnerable to the spread of severe epidemic small-pox than are European countries, like France and Germany, where the population is immunised compulsorily against small-pox by repeated vaccinations. On the other hand, the protective methods which are part of ordinary English administration, and include vaccination, have proved themselves on many occasions sufficient to prevent the development of epidemics of severe small-pox when introduced, either by extinguishing it at the start or by circumscribing the local epidemic which occurs and ultimately setting the community free of the results of the invasion. There is no reason, the review states, to expect that these will not be as efficacious in the future as in the past, but it demands vigilance not only from the local health authority but from the central authority which has to treat severe small-pox in the same way as other exotic diseases such as plague, cholera, or typhus, from the point of view of surveillance, if it is to be extinguished.

There are, however, modifications of procedure which may be considered by health authorities in any district invaded by the present type of mild small-pox. When small-pox first appears it is argued that the question of whether it is major or minor is of little consequence, seeing that the action required is in all respects identical for the two varieties. No effort should then be spared to notify, isolate, disinfect, vaccinate, and trace contacts, as is done when a severe type of disease has been imported from the continent. Happily any kind of small-pox control is favoured by the absence of ability to infect until the first symptoms of illness have occurred and by the possibility of immunising any contact if vaccinated within 48 hours of exposure to infection. Practically speaking, there is no "healthy carrier" problem in small-pox. But when this first stage has passed no authority need work on the principle of doing everything applicable in the case of a major small-pox epidemic. The question may arise whether the risk can justifiably be taken of allowing a patient to remain at home if he can be reasonably isolated there and all other occupants of the dwelling can be protected. Some feel that variola minor might be treated in an isolation block or in special wards of a general fever hospital whose staff is fully protected by vaccination. It is open to doubt whether public health authorities at present obtain as they might the coöperation of medical practitioners in the district. The issue to them of up-to-date clinical accounts of variola minor would have its advantages, and in return vaccine lymph might be supplied from the health office for immediate use in suspected cases, particularly now that a smaller area of vaccinated surface is officially advocated. Should procedure in these and other directions become more elastic there would, the report suggests, still remain one situation not included in present legislation for which compulsion would seem justified on every ground of preventive medicine. This is the case of the person, unprotected by recent vaccination or by previous small-pox, who is known to have been exposed to small-pox infection, at a time when his prompt vaccination will in all probability prevent the development of the disease.

In a brief summary the report indicates the kernel of this administrative position. Variola minor can usually be effectively and speedily extinguished on its first appearance in a district by the same methods as those applicable to variola major. When once it has taken hold the only workable procedure is to keep the disease under a reasonable degree of control, relying on its low infectivity and tendency to die out from an area in a few years. Such practicable control, in addition to insistence on prompt notification and provision of aid in diagnosis, includes hospital isolation, the tracing of direct contacts and offers of vaccination to them, as well as popular and unbiased education of the population on the safeguards which the individual can secure by vaccination against any variety of small-pox, and on the way in which he can obtain a vaccination with the minimum of inconvenience and risk. The report recognises that in this country at the present time it would be impracticable to secure a population so vaccinated as to render all other measures against small-pox redundant. It may be found by public health authorities that they derive little advantage from the Vaccination Acts that could not be obtained more satisfactorily if the Acts were replaced by voluntary measures. It would, of course, be out of the question to use the present machinery for maintaining protection at several stages of life by repetition of the one-mark vaccination. On the other hand, in its normal work of infant welfare the local authority is advising mothers on the general care of children and should more readily secure voluntary acceptance of vaccination. Public vaccinators would vaccinate as officers of the health department. The numerous occasions on which local authorities advise or influence adult communities on health questions could then be utilised. After they have observed the working of the Vaccination Acts under the new conditions the Ministry of Health looks to these authorities to formulate such proposals as seem to them desirable for preventing the spread of small-pox.

ANNOTATIONS

NARCOTIC DRUGS AND THE LEAGUE OF NATIONS.

On May 27th there will assemble at Geneva yet another international conference on the traffic in dangerous drugs. A draft convention, submitted by the Opium Advisory Committee of the League of Nations, will form the basis of discussion by the conference, while alternative plans favoured by certain nations will not be precluded from consideration. The draft convention purports to supplement the provisions of The Hague Opium Convention of 1912 and of the Geneva Convention which was elaborated, after lively discussions, only six years ago. The main problem to be solved is how to give practical effect to the provision (Article 9) of The Hague Convention, which required the contracting nations to limit exclusively to medical and legitimate purposes the manufacture, sale, and use of the alkaloids and their derivatives of the opium poppy, and the coca leaves, and to coöperate with a view to preventing their use for any other purpose. Although the Geneva Convention of 1925 was claimed to have strengthened and improved the original provisions of The Hague Convention of 1912, it was officially admitted that "during the next five years the *illicit* traffic assumed alarming proportions." While the Opium Advisory Committee appeared to be content to proceed under the Geneva Convention, the Assembly of the League, impressed by the disclosures in regard to the alarming extent of the illicit traffic, urged the need for directly limiting the manufacture of the narcotic drugs to the amounts required for medical and scientific purposes, and directed steps to be taken to implement the Geneva Convention to that end. The scheme implied the ascertainment of the annual world requirements, the quota to be allotted to each manufacturing country, and the appropriate distribution of supplies by some central organisation. A conference held in London last November failed to agree either on the principle or the amounts of the quotas, and postponed the question for further investigation. The advisory committee, with an enlarged membership to include non-manufacturing countries, has reported to the council on the present situation and on the draft convention which it has prepared for consideration, rejection, or amendment by the conference. In as much as objections have been raised by the Japanese, Turkish, and Yugo-Slav delegations, as well as by certain non-manufacturing countries, the conference bids fair to be an interesting one. While it appears, from a reply recently given in the House of Commons, that the limitation of production of raw opium and of coca leaves, the original sources of the drugs in question, is not regarded as relevant, it would seem impossible to exclude from consideration a question of such fundamental importance.

RADIOGRAPHY OF INTRACRANIAL BIRTH HÆMORRHAGE.

Post-mortem examination of the brains of new-born infants is well known to be difficult, and the only really satisfactory method is that in which the severed head is hardened in formalin. This, of course, is usually impracticable, at any rate in this country, but L. Schoenholz has devised a means of obtaining radiological evidence of intracranial hæmorrhage in cases where autopsy is not permitted. Both jugular veins are severed, and a mixture containing gelatin and red lead is injected into one of them until it appears in the other. Stereoscopic radiograms are then made, and have been held to localise the hæmorrhages accurately. Dr. F. M. B. Allen and Dr. H. I. McClure,[1] of Belfast, now describe a method which they have adopted, and reproduce radiograms which are said to demonstrate intracranial birth hæmorrhages. The opaque solution which they used was röntyum, which has the advantage that it does not gravitate. The röntyum was injected into the carotids or umbilical vessels, and the radiograms show that it penetrates the small arterioles; they also make it clear that there have been extravasations from the vascular system. Allen and McClure seem to deduce from this that arterial hæmorrhage is met with in the new-born—a supposition which must be received with great caution, since it is unsupported by the mass of evidence derived from examination of hardened brains. Similar results were obtained in 1929 by M. H. Roberts by a somewhat different method, and Prof. H. Ehrenfest, in his authoritative work on "Birth Injuries of the Child" (1931), makes the following comments on Roberts's results: "Roberts, however, in an endeavour to improve upon Schoenholz's technic, substituted metallic mercury as an injection fluid, incidentally forgetting that intracranial hæmorrhages practically without exception originate from veins. He injected this heavy metal into the carotid arteries, and believes that his very clear roentgenograms actually show intracranial hæmorrhages, although it is more reasonably assumed that they only represent artefacts resulting from the injection of this heavy substance into the notoriously fragile vessels of the brain." Though the solution used by Allen and McClure has advantages over metallic mercury, Prof. Ehrenfest's comments probably apply with equal cogency to the results they describe. Further, the radiographic demonstration of *apparent* arterial hæmorrhages raises a measure of doubt whether extravasations revealed by injection of the venous system really correspond to ante-mortem hæmorrhages.

DISCOUNT BY DENTISTS.

Sir Francis Dyke Acland, prevented by illness from opening in person the twentieth session of the Dental Board of the United Kingdom on May 12th, sent an unusually racy presidential address which was read by Sir Holburt Waring. After commenting on the unbelievable size of dental announcements in Glasgow which he had made a special journey to inspect—in many cases they were, he said, larger than most tradesmen in most towns would consider self-respecting—he warned dentists against directory touts and went on to consider whether it is proper for dentists to give commission or discount to, or in connexion with the treatment of, any particular class of persons. The question had lately been raised in slightly differing forms in connexion with the Benevolent and Orphan Fund of the National Union of Teachers, the Irish Bank Officials Guild, the Marine Engineers Association, the Sheffield Civil Service Guild, and Co-operative Societies at Kidderminster and Ynysybwl. "It may be useful," said Sir Francis, "if I summarise, in the form of a simple working rule for the profession to observe, what has been our view since the question first came up. We express it habitually when our advice is asked in individual cases, but I cannot remember whether it has previously been publicly stated. May I put it in this way: When it is suggested to a dentist that he should allow a discount from his usual fees, let him ask himself this question. 'Can I prove without any question that this discount is simply a discount for cash and fairly represents my saving in trouble and expense in collecting my accounts? If not, I had much better have nothing to do with it.' This is a simple rule to follow, and I believe it to be perfectly sound and justifiable, for our experience shows that there are only two classes of discounts, one the discount for cash, and the other the discount for the introduction of patients. The second may be variously and sometimes heavily disguised, but on examination always appears as the underlying motive, and to give commission for the introduction of patients is clearly a wrong thing to do between man and man." Sir Francis added that it was also, of course, one of the matters which might cause difficulty for a practitioner with the Board, for it was specifically covered in the words of the Important Notice: "The Board do not approve of a dental practitioner paying, or allowing, a commission or discount to any other person or body of persons as a return for patients being sent or recommended to him, or for dental services rendered by him to such patients."

AVERTIN AND "RINAROM."

WRITING with an experience of 1200 cases of avertin narcosis Max Wülfing,[1] who has used the drug for four years, shows himself one of its staunch supporters. Like most others, he has given up trying to get true anæsthesia with avertin alone, but he finds that the drug does in fact produce it in a small proportion of cases. Employing a dose of from 0·06 to 0·1 g. per kg. body-weight—except in children for whom he uses the higher dosage of 0·15 g.—he always obtains perfect amnesia, and usually unconsciousness before any additional anæsthetic is administered. This additional anæsthetic he supplies in the form of a mixture of ether (12 parts), chloroform (1 part), and ethyl chloride (2 parts) with a balsam perfume, and he gives it from an Ombrédanne mask. The additional CO_2 necessarily inhaled by the use of this instrument he values for its stimulant effect on the respiratory centre, and he finds that pulmonary complications are rare and trivial. The mixture evokes, of course, less mucous secretion than pure ether. It goes by the name of Rinarom.

AXEL HOLST.

THE death of Prof. Axel Holst, full of years and honours, removes the man who probably ranked higher than any other living Norwegian in the world of medical science. His associates had, indeed, hoped that his pioneer work on scurvy and beri-beri would have won him the Nobel prize. Between 1904 and 1910, with the help of his assistant, Frölich (now Prof. Frölich), Holst examined the evidence of the then common belief that beri-beri and scurvy are caused by an infection or some other poison existing in foods supposed to have become contaminated. Feeding tests on fowls and guinea-pigs showed that their response to a diet of polished rice was not one and the same, the guinea-pigs developing symptoms similar to those of human scurvy, while fowls developed polyneuritis. It was also found that scurvy could be produced in swine by feeding with rye bread, or rye bread plus cooked beef, or rice and dried cooked fish. Most of the swine thus tested also developed polyneuritis, and Holst and Frölich came to the conclusion that this combination of the symptoms of beri-beri and scurvy must be identical with the symptom-complex known as "ship beri-beri." During the last seven or eight years of his life, Holst made extensive investigations into the ætiology of pernicious anæmia, a summary of which we published on Feb. 7th. His studies of scurvy, beri-beri, and pernicious anæmia, constituted only a small fraction of his activities; he played an important part in housing, sanitation, medical education, and many other departments. He used often to classify his fellow beings as Yes-persons and No-persons. He was essentially a Yes-person himself. Overcharged with intellectual electricity, he could be relied on to provide a shower of sparks on coming in contact with kindred minds, and his interests were so wide that their number was great.

TUBERCLE BACILLI IN THE BLOOD.

Prof. Otto Kren and Prof. E. Löwenstein have made further progress[1] in the elucidation of cutaneous lesions of suspected tuberculous origin. Their work is based on the production by Löwenstein of a new culture medium for the tubercle bacillus, announced at the International Dermatological Congress held at Copenhagen in August last. It was there reported that of the 44 cases examined no less than 33 (or 75 per cent.) yielded positive blood cultures—a result which is the more surprising when it is realised that the laboratory workers were uninformed of the clinical nature of the cases from which blood had been withdrawn, and were even unaware which were submitted as controls and which were to be tested for cultural evidence of active tuberculosis in the circulation. An additional 22 cases in the present communication brings the total up to 66, which may be tabulated thus:—

	Total.	Pos.	Neg.
Erythema induratum (Bazin) and tuberculous phlebitis	23	16	7
Papulonecrotic tuberculide	4	4	—
Acne telangiectodes	4	2	2
Granuloma annulare	3	1	2
Lupoid	1	1	—
Scrofuloderma	3	2	1
Miliary tuberculous ulcer	1	—	1
Lupus vulgaris	10	5	5
Lupus erythematosus	17	10	7
Total	66	41 (62%)	25 (38%)

There was a striking difference between the proportion of positive results obtained on a first examination in the spring (100 per cent. positive), summer (75 per cent.), and autumn (62 per cent.), which the authors interpret as a seasonal variation in the quality of the blood. Summarising the results so far obtained they conclude that every suspect case of tuberculosis cutis (and this may well include other forms of tuberculosis met with in practice) should be submitted to cultural tests, which in their opinion are more reliable than complement fixation, agglutination, or precipitation tests, and which can be carried out in 4–5 weeks as compared with the 6–12 months of guinea-pig experiment. Reaction tests, such as those of Pirquet and Mantoux, do not tell us, in the event of a positive result, whether the focus is active, latent, or eradicated. A positive cultural result, on the other hand, affords definite evidence which is not easy to explain away. The absence of such evidence in clinically obvious tuberculous cases would depend, according to the Viennese authors, on the evolutionary phase of the lesion, whether it is in fact "open" or "closed," as in a certain proportion of cases of lupus vulgaris, erythema induratum, and granuloma annulare. That 10 out of 17 cases of lupus erythematosus should yield positive results supports the tuberculous ætiology of this affection. Löwenstein's technique for the preparation and inoculation of blood specimens introduces a new principle in bacterial culture. He maintains that hæmoglobin is inhibitory to the growth of the tubercle bacillus, and that its presence in earlier cultural experiments explains the large percentage of negative results.[2]

[1] Med. Klinik, May 1st, p. 655.

[1] Wien. Klin. Woch., March, 1931, p. 405.

Ten cubic centimetres of blood are drawn into 3 c.cm. of 10 per cent. sodium citrate and centrifugalised. The plasma is drawn off and the blood-cells are hæmolysed with acetic acid; 15 per cent. sulphuric acid is added, and the mixture thoroughly shaken for five minutes. After washing out the acid with sterile water several times, the whole sediment is floated on to the culture medium, and the tubes incubated in the usual way. The culture medium itself is by no means easy to prepare. It contains in various proportions egg albumin, potato flour, asparagin, glycerin, potassium phosphate, and magnesium sulphate, and to this complex mixture a 2 per cent. solution of Congo-red is added before filtration and sterilisation, as for Löffler's serum. The inventor, who has been working on his subject since 1905, states that peptone should never be used if good results are to be obtained.

One difficulty in preparing Löwenstein's medium is the exclusion of moulds and contaminating organisms. On another page of our present issue Dr. H. M. Schwabacher describes a shorter and simpler way of preparing this medium, by means of which she has obtained a culture of tubercle bacilli from the blood recognisable as such on the sixteenth day. Dr. Schwabacher agrees with R. Russew,[3] who has worked in Löwenstein's clinic, in expecting the method to discover the tuberculous origin of many doubtful skin lesions.

ATTENDANCE OF HONORARY HOSPITAL STAFF AT INQUESTS.

It is the sensible practice of coroners, when investigating hospital deaths, to be content in ordinary cases with the evidence of the house surgeon and to refrain from summoning members of the honorary staff. A correspondent has lately asked what is the authority for this practice. The answer is that it is founded upon reason and on the desire of coroners not to make their proceedings vexatious. No class of witnesses, of course, can claim exemption from attendance at an inquest; the coroner must always obtain the proper evidence which his court requires. But, unless in exceptional cases, the evidence of the house surgeon suffices. There is neither statutory nor judicial authority on the point, but the practice received some confirmation through an incident at Oxford, over 50 years ago, summarised in our columns at the time and perhaps worth rescuing from oblivion to-day. Edward Law Hussey, surgeon to the Radcliffe Infirmary from 1850 to 1878, became coroner for Oxford city in 1877 and did good work in that capacity. He was, however, a man of unaccommodating temper. At the end of 1878 he held an inquest on a labourer whose leg had been crushed in a threshing machine and who had died in the infirmary of exhaustion after amputation of the limb. Hussey had been informed of the death merely because the patient had been admitted in consequence of the accidental injury. An experienced house surgeon, who had apparently seen the patient on admission, and who was the last medical officer to see him before his death, was available as a witness but was not subpœnaed. Hussey preferred to summon his former colleague, Horatio Symonds, who had performed the amputation. Symonds wrote a polite note to the coroner saying that he had an appointment elsewhere at the day and hour mentioned, but that the house surgeon would be able to give all necessary information. Hussey replied that, if Symonds did not attend, process would be issued against him. The day of the inquest came and Symonds did not appear; Hussey adjourned for two days and issued a warrant for Symonds's arrest. The explanation given to the jury was that evidence from the operating surgeon was required in order to decide whether the operation was necessary. The foreman of the jury agreed and said the witness should attend so that the jury could ascertain whether the patient was fit to undergo the operation. One can imagine the chaos which would ensue if the propriety of every serious operation were to be referred to a coroner's jury when death followed. At the adjourned inquest Symonds appeared in the custody of the police, but his counsel succeeded in persuading the coroner to order his release. A few weeks later another death in the infirmary was reported, a man having broken his back through falling from a wagon. Hussey again summoned Symonds, instead of the house surgeon, to give evidence at the inquest where there was apparently some altercation which did not enhance the dignity of the proceedings. Symonds began an action against the coroner in respect of the circumstances of his arrest. According to Victor Plarr's account of Hussey in the Lives of Fellows of the Royal College of Surgeons, Symonds also appealed to the Home Office and managed to obtain a ruling that it was sufficient in ordinary cases that the house surgeon should attend an inquest to give evidence. Nice questions of law might have arisen had the action proceeded. As he is the judge of a "court of record," a coroner is immune from actions for trespass for turning a man out of his court or for slander in a summing-up; but he may be liable in an action for false imprisonment if he has acted in excess of his jurisdiction. Hussey settled the action by making an ample apology to Symonds (published in the *Oxford Times* during February, 1879) and paying £20 towards his preliminary legal expenses, which sum Symonds forthwith gave to the infirmary. As we observed at the time, Symonds deserved the thanks of the profession for his bold resistance to a vexatious innovation.

The incident is hardly likely to recur. If it does, a word of warning should perhaps be given. A coroner's summons is not to be ignored by the honorary surgeon of a hospital merely because it is vexatious; some other solution should be sought than flat disobedience. The coroner has three different powers of enforcing his requirement of attendance. Under Section 19 of the Coroners Act of 1887 he can summarily impose upon any person who fails to appear after being duly summoned a fine of 40*s*. which in 1926 was increased to £5. This section is taken to include medical witnesses, though Section 23 gives the coroner the special power to prosecute a medical practitioner who fails to obey a summons. Under Section 23 the practitioner, unless he shows good and sufficient cause for not having obeyed the summons, may be fined £5 by the magistrates; this section, however, is the less likely to be used because the coroner would prefer to impose the fine himself directly under Section 19 rather than undertake a prosecution under Section 23 on the issue whether there was "good and sufficient cause," especially as the issue would be for the magistrates and not the coroner to decide. Thirdly and finally, the coroner's inherent power of punishing defaulting witnesses by fine or imprisonment as for a contempt of court is expressly preserved in the Coroners Act as an alternative to the statutory fines under Sections 19 and 23. The risk of disobedience, therefore, is by no means limited to a maximum of £5, though it is hard to imagine the circumstances in which a coroner would have recourse to such powers against a medical practitioner.

AN EXPLOSION AT OPERATION.

THE latest reported instance of explosion at an operation does not seem to present any fresh problem in connexion with this accident or to show any unsuspected dangers which may occasion it. The inflammable nature of the anæsthetic vapours used is not in doubt, for ether had been inhaled a little time before, although it was not being taken at the time of the explosion; but the exact manner in which they were detonated is here uncertain as it has often been before. No actual cautery or open flame was brought into contact with inflammable vapours, but merely an electric "pencil-lamp." Defective contact is suggested as the explanation for the exploding spark, but it is permissible to wonder whether a mere lamp, if sufficiently hot, cannot cause explosion of a mixture of oxygen and ether, supposing this to be in its most susceptible proportions. In other cases, notably in that most recently reported[1] from across the Atlantic, there is the same difficulty of accounting for the presumed spark. There was an explosion of nitrous oxide, ether and oxygen, and static electricity was the assigned explanation. This explosion was a violent one and the patient died outright. In the Birmingham case the explosion was less and the patient died only some days afterwards from putrid bronchitis. Prof. Haswell Wilson, who made the post-mortem examination, said that the appearances suggested that the flame had been transmitted down the bronchial tree. The facts, as we gather them from the press reports, are briefly these: A fitter, aged 60, was admitted to the General Hospital, Birmingham, for a second operation for cancer of the œsophagus. During March he had been in the hospital, and the growth being regarded as inoperable, radium had been inserted. He returned to the hospital on April 14th and on the 15th he was taken to the operating theatre in order that some dilatation might be attempted, since only the thinnest liquids could be swallowed. The surgeon used a pencil light with current derived from an accumulator. The explosion occurred while he held the pencil in the patient's mouth. It was, he said, deafening and upset his hearing for the rest of the day. It appeared to start in the apparatus, which went up to the ceiling. His own hair was singed and the side of his face burned. The damage in the patient's throat was caused by the explosion, not by any instrument. The anæsthetic had been first a mixture of chloroform and ether, then ether, and later, chloroform only. It was stated by experts that the lamp could have caused an ignition by fracture of the glass or by a spark occurring in the lamp socket, owing to the slackness of the bulb. Mr. Smithles, of the research department of the General Electric Company, said that the type of bulb used in the pencil lamp was not advocated for medical or surgical use. The lamp in its present condition was dangerous for use with an explosive mixture.

HOSPITAL ENTRANCE SCHOLARSHIPS.

THE medical schools of Guy's and St. Thomas's Hospitals, and the medical college of St. Bartholomew's Hospital have recently had under consideration the methods of award of university entrance scholarships, and are unanimously of opinion that, in the interests of medicine, scientific merit and attainments should be the determining factors. They have therefore agreed that their university entrance scholarships shall be awarded as a result of open competitive examination, and they have arranged to hold a common examination for the purpose. Each school offers annually a scholarship of £100 and an exhibition of £60, and the scholarships and exhibitions will be awarded by the deans of the three schools sitting in conference, after receiving reports from the examiners. The scheme will come into operation in July, 1932, when the examination will be held at St. Thomas's Hospital Medical School. Thereafter, the examination will be held at each of the schools in rotation. Candidates will, of course, be entitled to express their preference for any particular school and the stated preference will be taken into consideration when the scholarships are awarded. The scholarships will be open to students who have completed their examinations in anatomy and physiology in a British school or university outside the London metropolitan area.

ENDEMIC ERGOTISM.

Dr. Julius Kaunitz[1] points out that epidemic ergotism has been almost extinct since the end of the last century, owing to the more careful cleaning of the rye seed before planting and milling, and the long period of storage of the grain whereby the toxicity of ergot decreases. It has occurred to him, however, that some of the vaso-motor and trophic diseases such as thrombo-angiitis obliterans, Raynaud's disease, erythromelalgia, scleroderma, sclerodactylia, and dermatomyositis, may possibly be due to endemic ergotism. In investigating cases of thrombo-angiitis obliterans he has been able to find a good deal of evidence of the disease appearing in persons who consume rye bread. Moreover, in the other diseases mentioned—especially Raynaud's disease and erythromelalgia—the vaso-motor and trophic disturbances are the same as those found in ergotism. In his experimental work Kaunitz was able to produce both acute and chronic ergotism in fowls. In the acute stage the arteries near the base of the comb were found to be contracted and the media was swollen and hyaloid. The capillaries, on the other hand, were markedly dilated and contained stagnant blood which was probably the cause of the gangrene in the comb. In a more chronic case in which many of the vessels of the comb showed endarterial hyperplasia the comb was swollen to about twice its natural size, and showed vaso-motor and trophic changes. Kaunitz comes to the conclusion that owing to the known effects of toxic ergot more stringent prophylactic measures are advisable. He admits, however, that further investigations are necessary and that it is not at present proved that many cases of vaso-motor or trophic disease are due to ingestion of ergot.

Arch. Intern. Med., April, 1931, p. 548.

HOSPITAL OPHTHALMIC CLINICS.

THE scheme inaugurated by the ophthalmic hospitals of London to provide consultations and, when necessary, glasses for persons of limited means has now received the official sanction of the Ministry of Health and of King Edward's Hospital Fund, the latter body giving its consent on the understanding that the hospitals are reimbursed for any administrative charges. The scheme originated owing to the hardship involved in refusing treatment to patients coming from a distance unprovided with a certificate from their approved society for ophthalmic benefit. Under the scheme insured persons entitled to benefit and certain other groups will be admitted to a private consultation by an ophthalmic surgeon at a fee of 10*s.* 6*d.* and the provision of any necessary glasses, after which they will be referred to local doctor or out-patient clinic for further treatment. Special evening clinics for this purpose have been established at the Central London Ophthalmic, Royal Eye, Royal London Ophthalmic (Moorfields), Royal Westminster Ophthalmic, and Western Ophthalmic Hospitals, the facilities at Westminster being available only for members of approved societies entitled to ophthalmic benefit and other insured persons willing to pay a fee of 10*s.* 6*d.* At the other hospitals members of the Hospital Saving Association and non-insured persons are eligible under certain conditions. The inauguration of the scheme has enabled the hospitals to emphasise the desirability that those who require an examination of their eyes should have it done by an ophthalmic surgeon. It is hoped that the same principles will be followed by other eye hospitals and departments throughout the country.

APPARATUS FOR ARTIFICIAL RESPIRATION.

THE University College Physiological Society met on Tuesday at the London School of Hygiene to see Prof. Philip Drinker, of Harvard, demonstrate his apparatus for prolonged artificial respiration. He soon convinced his hearers that something of the kind is a necessary part of hospital equipment, and we hope his visit will serve its purpose and draw attention to favourable reports which have appeared in the United States and Canada. In brief, the patient is put to bed in an airtight iron tank from which his head projects through a close-fitting rubber collar. An electrical pump, controlled by an attendant, rhythmically produces a small negative pressure within the tank, and this expands the lungs as in normal respiration. Conscious patients can eat, drink, and sleep while in the respirator, and portholes allow the attendant to change clothing or to hand in a bedpan. Where anything more elaborate is required the negative pressures may be increased for a few minutes so as to produce hyperventilation of the lungs and consequent apnœa. Removal from the tank for a few minutes is thus made comfortable and safe. Children with intercostal paralysis following poliomyelitis have been kept in the respirator for months until their normal muscular function has been restored, and the apparatus has also saved life in cases of electrocution, severe carbon monoxide poisoning, and incomplete drowning. A smaller tank has been devised for artificial respiration in infants and has been used with fair success in 30 cases of neonatal asphyxia. If the child does not breathe within a minute it is placed in the respirator and may begin to breathe spontaneously after as long as an hour. For poisoning in adults, Mr. Drinker was careful to point out, the method is not intended to take the place of Schafer's artificial respiration; it begins where Schafer's leaves off. But as Dr. G. P. Crowden, the chairman, remarked, there is room for additional means of treatment of accidental asphyxia, which causes about 4000 deaths every year in this country. At the close of the meeting Dr. Richard Ellis was able to give independent testimony to the great relief afforded by Drinker's respirator to children struggling for breath in poliomyelitis. We hope to give further details of the apparatus in a forthcoming issue.

THE Inter-State Post-Graduate Assembly of North America meets in London next week. Arrangements for the morning lectures, to be given at the house of the Royal Society of Medicine, will be found in our Medical Diary. In the afternoons visits will be paid to hospitals and institutions.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE.

C. O. Gange to be Surg.-Lt.

The following appointments have been notified:—Surg. Comdrs. A. C. Paterson to *Victory*, for R.N. Hospital, Haslar, for four months' general professional course; and O. D. Brownfield to *President*, for three months' post-graduate course.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Lt. J. B. Oldham to be Surg. Lt.-Comdr.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. G. A. Kempthorne, having attained the age for compulsory retirement, is placed on ret. pay.

Maj. G. F. Rudkin to be temp. Lt.-Col.

Maj. (temp. Lt.-Col.) O. R. McEwen to be Lt.-Col. vice Lt.-Col. G. A. Kempthorne.

E. Hicks, to be Lt. (on prob.).

G. A. M. Knight is granted a temp. commn. in the rank of Lt.

ARMY RESERVE OF OFFICERS.

Lt.-Col. C. H. Straton having attained the age-limit of liability to recall, ceases to belong to the Res. of Off.

TERRITORIAL ARMY.

Capt. R. H. Hadfield having attained the age-limit retires and retains his rank, with permission to wear the prescribed uniform.

Capt. W. A. D. Drummond, R.A.M.C., to be Divl. Adjt., 47th (2nd Lond.) Div. and Sch. of Instrn., vice Maj. D. W. M. Mackenzie.

Lt. R. McI. Gordon to be Capt.

I. G. W. Hill, (late Offr. Cadet R.S.M., Edinburgh Univ. Contgt., Sen. Div., O.T.C.) to be Lt. with seniority.

INDIAN MEDICAL SERVICE.

Lt.-Col. W. F. Brayne retires.

ROYAL AIR FORCE.

The undermentioned Flight Lieutenants are promoted to the rank of Squadron Leader: W. E. Barnes and C. A. Lindup.

SEAMEN'S HOSPITAL SOCIETY: ANNUAL REPORT.—The report for 1930 states that the expenditure was £106,241, and the receipts £99,065, and that the alterations to the Dreadnought Hospital are well under way. As a result of these works there is a heavy overdraft, and as soon as the times become more propitious the board will be compelled to make a special appeal to meet the expenditure. Extensive internal rebuilding and alterations at the Hospital for Tropical Diseases were completed during the year, and cost nearly £30,000. At the annual court of governors on May 12th, with Lord Lloyd in the chair, the Norwegian Minister thanked the society for its kindness to Norwegian seamen, and Mr. P. P. Cole, the senior surgeon, expressed the hope that they would this year be able to open wards for women and children, primarily for dependants of seamen.

SPECIAL ARTICLES

SOME SURGICAL ASPECTS OF FAULTY NUTRITION.*

BY ROBERT McCARRISON, C.I.E., M.D., D.Sc.,
HON. LL.D., F.R.C.P.,

COLONEL, INDIAN MEDICAL SERVICE; HONORARY PHYSICIAN TO THE KING; DIRECTOR, NUTRITIONAL RESEARCH, INDIAN RESEARCH FUND ASSOCIATION.

Freedom of Well-fed Animals from Disease.

THE Laboratories of the Indian Research Fund Association, devoted to the study of diseases associated with faulty nutrition, are located at Coonoor in the Blue Mountains (Nilgiris) of Southern India, 6000 feet above sea-level. Their location is fortunate, for the temperature is equable, never very hot nor very cold; the mean winter temperature rarely falls below 50° F., the mean summer temperature rarely reaches 80° F. A good deal of rain falls in these hills, Coonoor coming within the range of both the south-west and the north-east monsoon; the former brings with it only occasional heavy showers, while the latter may involve us in heavy rainfall during November, December, and January. But it is rare that a day passes without sun. I have been content with corrugated-iron sheds, roofs, and floors tiled, sloped, and adequately drained. I am fortunate also in having a large staff of attendants who are highly skilled, and it is possible to ensure ideal conditions of hygiene and exposure of the animals to sunshine the whole year round.

In these conditions there live some 1000 stock albino rats. I use on the average 1100 animals a year. The pairs are kept in roomy, netted-wire, screened, and straw-filled cages, and have the peace and comfort necessary for fruitful breeding. As a rule, five or six litters are taken from each pair; and the older animals are thinned out at the age of 2 years—a life-span said to correspond approximately to the first 40 to 50 years of life in man. The average number in each litter is eight, but litters of 12 are frequent and those of 15 not uncommon. The mothers invariably rear the whole of their young.

This stock is fed on a diet similar to that eaten by certain peoples of Northern India, amongst whom some of the finest physical specimens of mankind are to be found. The diet consists of whole wheat-flour, unleavened bread (*chapattis*) lightly smeared with fresh butter, sprouted Bengal *gram* (legume), fresh raw carrots and cabbage ad libitum, unboiled whole milk, a small ration of raw meat with bones once a week, and abundance of water both for drinking and washing purposes.

During the past two and a quarter years there has been no case of illness in this community of albino rats, no deaths from natural causes in the adult stock, and, but for a few accidental deaths, no infantile mortality. During this period I have, myself, performed complete post-mortem examinations on 1189 of these rats, ranging in age from the new-born to 2 years. In none have I encountered any macroscopical evidence of disease with the exception of an occasional cyst in the liver, containing tapeworm larvæ. Both clinically and at post-mortem examination this stock has been shown to be remarkably free from disease. Disease and death have been excluded, almost completely, by minute attention to three environmental conditions: cleanliness, comfort, and food.

High Incidence of Disease in Ill-fed Animals.

I wish now to turn to my experimentation-rooms. Here are the same corrugated-iron huts, the same cages, the same scrupulous cleanliness. Here the animals are exposed in the same way to the sun's rays. But they live in separate cages—as do the controls for each experiment—isolated from their fellows; they are thus less contented than their more fortunate kith and kin in the stock animal rooms; and they are more exposed to the effects of chill, since they cannot be given straw-bedding, though each evening they are given bedding of clean cotton-waste. The main regard in which they differ from the stock animals is in their food, which is always faulty in some way or another. Further, as my business is to learn, as far as I can, how the foods eaten by the people of India are related to disease, synthetic diets are used comparatively rarely and then only for special purposes. The materials entering into the various faulty dietaries are usually those in use by the people of India; sometimes actual Indian dietaries are used.

During the last two and a quarter years I have examined 2243 of these improperly fed rats at post-mortem examination; that is to say, during the same period in which I failed to find disease in the community of stock rats. The morbid states encountered included all forms of diseases (1) of the lungs; (2) of the nose and accessory sinuses, including (3) otitis; (4) of the upper respiratory passages (adenoid growths); (5) of the eye; (6) gastro-intestinal diseases (cancer of the stomach in two cases only); (7) diseases of the urinary tract; (8) of the reproductive system (including death of the fœtus in utero and premature birth); (9) of the skin (including gangrene of the tail or feet); (10) of the blood; (11) of lymph and other glands; (12) of the endocrine system; (13) of the nervous system—nervous instability and polyneuritis; (14) of the heart; and (15) œdema. Not infrequently animals are found to be suffering from more than one of these diseases.

I say nothing of diseases of the bones and teeth, since the diets were not specially designed for their production, but mention might be made of crooked spines and distorted vertebræ and of imperfect teeth. The list includes only those morbid states which I have myself seen; it has been prepared from the post-mortem records of the 2243 imperfectly fed animals. It is an experiment on a large scale extending over two and a quarter years. As controls there is a community of hygienically housed rats, fed on a well-balanced diet composed of natural foodstuffs, as described, so combined as to provide in proper amount and proportion all elements and complexes necessary for normal nutrition. On the other side, there is a community of rats, also hygienically housed but fed on ill-balanced diets composed mainly of cereal grains or cereal products and vegetable fats with little or no milk, butter, and fresh vegetables. I claim for this experiment that it proves conclusively that one-sided diets which are disproportionately rich in cereals and poor in animal fats, milk, and *fresh* vegetables are capable of inducing in albino rats a large proportion of the diseases included in our calendar of human ailments; I may add that of all the faulty diets I have used, that composed of white bread, margarine, tea, sugar, jam, preserved meat, and scanty overcooked vegetables—a diet in common use by many people in this country—proved to be one of the worst and most likely to be associated in rats with many of the morbid states I have mentioned, especially diseases of the respiratory and gastro-intestinal tracts.

---

* Being an abstract of the first of two lectures delivered at the Royal College of Surgeons of England, May 18th and 20th, 1931.

Rats are not the only animals I use: guinea-pigs, rabbits, pigeons, and monkeys are also used. In them I have found many of the above-mentioned diseases and some others besides. Of the latter I may mention the following: prescorbutic states, scurvy, and duodenal ulcer in guinea-pigs; hyperplastic goitre in rabbits; epithelioma contagiosum, polyneuritis, and true beri-beri in pigeons; and ulcerative colitis in monkeys. Two conditions I have not, so far, encountered: gall-stones, observed by Fugimaki (1926), de Langen (1929), and others; and cataract, observed by Eckstein and Szily (1924).

In every species—pigeons, rats, guinea-pigs, rabbits, and monkeys—I have found the same thing: properly fed animals remain remarkably free from disease, improperly fed animals are remarkably subject to it. It is reasonable, therefore, to assume that the human species is no exception to this rule and that many of the ailments, to which man is erroneously supposed to be heir, are the outcome of his improper feeding, a general conclusion which I have been emphasising during the past 12 years. Some may hold that it is not possible directly to translate to human experience the results of an experiment such as that just described. This may be true if we seek to do so too rigidly and fail to take sufficient count of other environmental factors to which human beings may be exposed. But in general the results of an experiment of this kind do, in my opinion, apply to man, and point the way to a solution of many ætiological problems connected with his physical infirmities.

Vitamin A Deficiency.

In the above list of diseases there are many of interest to the surgeon. Sinusitis, adenoid growths, otitis media, gastro-duodenal ulcer, gynæcological ailments, certain types of goitre, and urinary calculus are some of them. At first sight it would appear that morbid states so dissimilar as adenoids and stone in the bladder had nothing in common; yet ætiologically they are not so far apart. All these surgical conditions were found to have this in common; they occurred in animals whose ill-balanced diets contained little or no vitamin A bearing food materials, such as raw milk, butter, cod-liver oil, carrots, and fresh green vegetables. In my hands these food materials, when suitably combined, have protected my animals from these diseases, and I do not doubt that in the hands of the surgeon they will go far to protect his human patients from them and facilitate their cure and non-recurrences after operation.

[The lecturer here pointed out that he laid stress on the food materials themselves rather than on any particular ingredient, believing that the elements and complexes of normal nutrition combined in Nature's laboratory in a way that cannot be satisfactorily imitated. In the materials on which his stock rats were fed, and on which, he said, some of the finest physical specimens of mankind were reared, he found that an insufficiency of vitamin A might occur and be responsible for the occurrence of surgical diseases. He showed a number of slides illustrating characteristic changes, and said that the sites in which these changes had been observed in experimental animals were the nares, larynx, trachea, bronchi, submaxillary glands, parotid gland, and the accessory salivary glands of the tongue and pharynx; the pancreatic duct, bladder, ureter, and pelvis of the kidney; the uterus and oviduct; the epididymis, prostate, and seminal vesicles; the conjunctiva, Meibomian gland ducts, cornea, lacrymal gland, Harderian gland, and the extra-orbital (lacrymal) gland; the thymus (Wolbeck and Howe, 1925); and the thyroid gland. He found the changes, he said, to occur more readily in growing animals and, though focal in distribution, to have no definite confines or localities. He observed that, since man's food is rarely or never wholly lacking in the factor, it is important to realise that the conditions could occur in animals fed on human dietaries containing insufficiency of vitamin A. The changes would be helped in their occurrence not only by all food faults, but by unfavourable environment, the interplay between nutritional and climatic or bacterial conditions being thus illustrated. He continued:—]

The varying occurrence and location of the changes due to vitamin A deficiency are among the most interesting things about them. Thus, in monkeys fed on a diet said to be complete in other regards, but lacking a sufficiency of vitamin A, eye changes, sinusitis, and mastoiditis, so common in rats, are, as E. B. Tilden and E. G. Miller (1930) have shown, conspicuous by their rarity. Twelve years ago (1919) I demonstrated that the colon was of all organs in monkeys the most sensitive to faulty nutrition; and the recent work of Tilden and Miller, while confirming this observation, re-emphasises the importance of vitamin A deficiency in causing the ulcerative colitis which is so conspicuous a feature in these animals. The monkey's colon is also very sensitive to deficiency of other vitamins (McCarrison, 1919); particularly of vitamin C "which causes a condition varying from local congestion and thickening of the mucous membrane to one indistinguishable from ulcerating sloughing dysentery" (F. P. Mackie and G. D. Chitre, 1928). In some of these respects man resembles the rat more than the monkey. Thus, he is very susceptible to the eye changes resulting from insufficiency of vitamin A bearing foodstuffs in his diet, if one may judge by the prevalence of keratomalacia in the Madras Presidency, and by its amenability to treatment by cod-liver oil (Wright). But I suspect that he resembles the monkey in the sensitiveness of his colon to food deficiency; the number of cases of ulcerative colitis of "unknown" cause (T. B. Menon. 1930) occurring in India is sufficient to justify this suspicion. But however the changes vary, either as to extent or location, they are always to be found in mammals of all species so far examined—rats, guinea-pigs, rabbits, and monkeys—and in man himself.

These changes are independent of infection, though infection is frequently superimposed upon them. Indeed, it is because of them that infection becomes possible, since they occur for the most part in "outside" coverings of the body: the respiratory passages, the urinary tract, the reproductive tract, the conjunctiva, the nasal passages, the ear, and the ducts of organs. They are breaches in the walls of the body's defences, through which the invading microbe may enter. In this sense vitamin A is "anti-infective"; but the "anti-infective" quality is shared with other vitamins—C, B, and D—though exhibited by them in other ways.

Two points of interest to the surgeon remain to be mentioned: (1) if rats, fed on a diet deficient in vitamin A, be artificially infected with a bacterium, such as the Breslau bacillus (paratyphoid), they usually die from the resultant infection. But some may live, and in them the infection persists in the lymph glands "for a very long time after the general infection has been overcome" (H. C. A. Lassen, 1930). It seems to me probable that chronic enlargement of lymph glands in childhood, due usually to infection of one kind or another, may often be due to such persistence of infection as a result of a vitamin A deficient diet. Further, it seems probable that the focal breakdown of the tissue defences induced by this deficiency may be concerned in the causation of those "septic foci" about which so much is heard of nowadays. (2) I have spoken above of breaches in the walls of defence against bacterial invasion consequent on the use of vitamin A deficient diets, and I have mentioned that other vitamins may also exercise an anti-infective action though exhibiting it in a different way. This way may not need the breaching of the walls but their scaling. I take the following from an unpublished manuscript which Dr. Lloyd Arnold, of the Department of Pathology and Bacteriology, Chicago, has recently sent me: "McCarrison has repeatedly called attention to the early appearance of digestive disturbances in vitamin deficiency studies. The pathological examination of the dead animals following avitaminosis experiments shows evidence of tissue changes due to infections of various kinds. We have found that one of the first demonstrable changes in avitaminosis is an alteration in the distribution of the bacterial life within the lumen of the intestinal tract. The bacteria ingested by the mouth are not destroyed in the usual manner, but remain viable for many hours within the contents of the whole length of the small intestine. The mixed bacterial flora of the large intestine ascend into the upper levels of the small intestine. There is a gradual and progressive loss of the power of the body-surface to control the microbic life existing in contact with it. These findings have been constant and hold for vitamin A, B, and D deficiencies. By the time the adult animals show a loss in body-weight or the young animals show a stationary weight curve, there is evidence of bacterial invasion of the mucosa of certain surfaces. These latter observations have been made by numerous investigators. We attribute the early inflammatory changes in the lining membranes of the eye, mouth, throat, alimentary tract, &c., to the loss of power of these body-surface coverings to regulate the bacterial flora in contact with their cells. This precedes evidence of invasion of the membrane by bacteria."

This statement, so amply demonstrated by Dr. Lloyd Arnold's investigations, calls to mind the contentions of Sir Arbuthnot Lane and Dr. Nathan Mutch in regard to infection of the upper reaches of the intestine consequent on chronic gastro-intestinal stasis, a condition which, as my own researches (1921) have shown, may be due to the consumption of faulty food from the "first bottle" onwards through life.

The function of vitamin A, so far as it is known at present, is thus to maintain the functional integrity of the cells covering body-surfaces, thereby preventing invasion of the organism by microbic agents. Here, however, I must re-emphasise the position which I reached more than ten years ago, and which all my subsequent work has but strengthened—that whatever the specific function of any vitamin may be, vitamins are but links in the chain of essential substances requisite for the maintenance and harmonious regulation of the chemical processes in the tissues, and their action must be considered in connexion with metabolism as a whole—i.e., in relation to balance of food ingredients in general, to organs of digestion, and assimilation and to endocrine regulation of metabolism. Their deficiency, like that of the other elements and complexes necessary for normal nutrition, leads to depreciation of cellular function: depreciation of cellular function is the foundation upon which disease is built (McCarrison, 1921).

Surgical Diseases and Faulty Nutrition.

[The lecturer said he would briefly mention some examples in surgical diseases associated with faulty nutrition.

Adenoids and Otitis Media.—Referring to slide demonstrations already made of adenoids in the trachea, he said that rats developed adenoid-like growths in the neighbourhood of the nasopharynx from faulty nutrition and asked if there was not here an analogy with growths in the nasopharynx of children. Of otitis media, he said that as a result of faulty food, deficient in vitamin A, pus might be found in the middle ear of 60 or even 70 per cent. of rats, and the frequency of the condition in rats when on faulty diet must recall the frequency of the condition among school-children in England and Wales, *improperly fed.]*

Otitis Media.—The probable nutritional factor in the causation of otitis media does not appear to me to have received the consideration it deserves. According to S. Hastings (1925) a high proportion of all cases occur before the fifth year and many before the first birthday. In 1923 no less than 46,000 children had ear trouble; while 90 per cent. of deafness in adults is due to preventable causes in childhood. Ponfick reported that of 100 autopsies in children under 4, who died from various diseases, 91 had evidence of middle-ear disease, and in only 10 of these was the trouble recognised during life. The causes giving rise to middle-ear disease interact with one another; they are squalid poverty—with its accompaniment of malnutrition—neglected catarrh, tonsils and adenoids, mouth-breathing and the after-effects of measles, scarlet fever, and diphtheria. My rats do not suffer from the three last; but my experience in these animals leads me to believe that the insufficient supply of vitamin A bearing foods may be responsible for middle-ear disease in children to an extent much greater than is generally believed.

Gastro-duodenal Ulcer.—Twelve years ago (1919) I recorded the occurrence of this condition in guinea-pigs fed on a scorbutic diet of crushed oats and autoclaved milk. Recently I have repeated this experiment with the same result; and in this later experience I have found duodenal ulceration at all stages of the process up to perforation (in one case), the resulting abscess being localised. Magee, Anderson, and M'Callum (1929) have observed similar conditions in calves fed on food deficient in certain essentials. Gastric and duodenal ulcer are extremely common in Southern India. An experiment was accordingly undertaken to test the influence of diet in the localities. Albino rats were used; and the experiment was continued for 675 days. Two diets were employed: one, resembling that eaten by the poorer class Madrassi and containing rice, red pepper (chillies), tamarind, a little fish, and *conjee* (rice water); the other, resembling that of the poorer class Travancorian and consisting largely of tapioca root, with rice, a little fish, red pepper, and rice water. Both these diets were very deficient not only in vitamins of the A, B, and C classes, but in other regards also. The diets were prepared and cooked as used. About this time I had occasion to examine at post mortem gangrene.[1] The discussion gave occasion for protests against such legal judgments as those to which Dujarier fell a victim, but it must be confessed that the attitude of medicine towards the law was reminiscent of that of the mice who, in solemn conclave, recommended belling the cat. Another subject to be discussed was that of motor-car accidents, and the numerous cases of abortion alleged to be due to such accidents. It was suggested that, in fatal road accidents, a post-mortem examination should in the future be just as obligatory as it is already in fatal criminal cases. Traumatic appendicitis also came in for discussion, as well as traumatic sarcoma and sudden death from inhibition coinciding with attempts at abortion. In connexion with the criticism of "death by inhibition" as being in such cases a nebulous and negative conception, Dr. Paul described a case of prolonged and profound syncope provoked solely by a simple hygienic vaginal douche in the absence of pregnancy.

RAINFALL AND INFECTIOUS DISEASE.

In a communication to the Académie de Médecine on April 21st, Dr. Paquet developed his thesis that the rainfall influences the evolution of certain infectious diseases, such as typhoid fever, scarlatina, measles, diphtheria, and tuberculosis. His studies referred to the department of the Oise in the 20-year period 1911–1930. The notifications of typhoid and paratyphoid fever showed marked differences from year to year, and when a graph showing the notifications month by month, was compared with a graph showing the rainfalls in the same periods during the 20 years under review, it became evident that the driest years were the worst typhoid years, and that the notifications tended to be most numerous a month or two after heavy rainfalls following a more or less prolonged drought. A rainy spring would be followed by much fewer notifications. The outbreaks of typhoid following heavy rainfalls after a drought were traced to pollution of wells due to a too sudden surface flushing with rain water. With regard to scarlatina, the annual notification again showed wide oscillations—from 556 in 1914, to 70 in 1918. A blunt peak lasting two or three years would be followed by a sudden fall which would either be continued in the following period, or would remain flattened out for some years. On certain occasions, sudden rises of the monthly notifications of scarlatina coincided with a period of exceptionally heavy rainfall. The annual variations in the notifications of measles showed even wider oscillations, with a maximum of 1500 in 1912, and a minimum of 95 in 1922. The tendency of measles to flare up every second or third year could be correlated with years with a heavy rainfall. Dr. Paquet also associated a high incidence of diphtheria in the autumn and winter months with heavy rainfall. Even in the case of such a chronic disease as tuberculosis, he has been able to establish a certain correlation between rainfall and mortality.

TINNED FOOD.

It is commonly believed that if tinned foods are adequately supplemented by vitamin-containing substances, all is well. This teaching was vigorously attacked by the explorer, Dr. J. B. Charcot in a communication to the Académie de Médecine on May 5th. He described a condition which begins among explorers with a slight œdema over the front of the tibia, whence it spreads to the rest of the limb, and later to the scrotum and abdomen. At the same time small red spots, like flea-bites, appear on different parts of the body. Large ecchymoses sometimes appear, notably over the large joints, and ulcers over the joints of the fingers, but ulceration of the gums is rare (Charcot has never seen such a case) and the patient's most pronounced symptom, is extreme lassitude, which ends in five to seven months in fatal cachexia. When, in such cases, the patient continues to eat preserved foods, even in small quantities, the administration of any number of vitamin-containing foods will not prevent the disease from pursuing its course inexorably. On the other hand, if the patient cuts preserved foods completely out of his menu, his symptoms will, even if severe, disappear in a few days, and he will be completely restored. Charcot related how during his second expedition in 1908–1910 he diagnosed scurvy in himself and a companion, and how they dosed themselves with lemon juice and ate fresh meat and adopted a general antiscorbutic régime without, however, dispensing altogether with preserved foods. Their symptoms became worse, and it was only when he was in dire straits, hardly able to walk, that Charcot reduced his dietary exclusively to fresh meat (seal). After what he described as a "débâcle urinaire formidable," his symptoms disappeared completely in four days, and he felt perfectly fit. His companion, who was put on the same régime, was cured in five days, the ulcers from which he was suffering disappearing without leaving the slightest scarring. Dr. Charcot is inclined to incriminate preserved fish as well as preserved meat in this disease which he describes as "la maladie des conserves."

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

AUTOMOBILE AND AEROPLANE ACCIDENTS.

SINCE it is impossible to determine the population exposed to risk in the automobile, we cannot say whether the air is yet safer than the roads. But it is evident that the trend is in that direction. During the 18 months ended Dec. 31st, 1930, there were more deaths from automobile accidents than were suffered by American forces during 18 months of the world war (50,900 to 50,510 respectively). The first quarter of 1931 has seen 6230 automobile deaths, according to records of the National Safety Council. Three specific violations of traffic regulations account for 68 per cent. of the 1930 accidents. They are: exceeding the speed limit, driving on the wrong side of the road, and failing to give right of way. About 90 per cent. of the killed and injured were victims of cars in good mechanical condition. Half of the fatalities occurred in collision with pedestrians. During the same year (1930) 400,000 passengers were carried in the air and 24 were killed. In the last four years the number of air passengers has increased 31 times, while the fatal air accidents have increased only four times.

BIRTH CONTROL.

The Public Health Relations Committee of the New York Academy of Medicine have been considering birth control in its relation to the medical profession. They find that the conservatism of the medical profession with reference to contraception has been justifiable, but that recent research in this field demands recognition. "The guidance of the public in sexual matters should be assumed by the medical profession wherever it naturally comes within the scope of their work." They regard the present importance of the work of the Birth Control Clinical Research Bureau as temporary. This bureau maintains a contraceptive clinic at which the attendance far outnumbers the total of patients attending the nine contraceptive clinics attached to hospitals in New York city. But the modern tendency is away from detached dispensaries. And in this case the association with a general hospital is all the more desirable since "lacerations, erosions, and displacements, calling for treatment or operation, are many and are frequently overlooked." A birth control clinic also offers opportunities for the detection of early cancer or communicable disease.

---

[1] See THE LANCET, April 4th, p. 774.

The Public Health Relations Committee recommends: (1) that the Academy concern itself solely with the medical and public health aspects of birth control and not with its economic aspects; (2) that present contraceptive clinics associated with hospitals be continued and others established as the need appears; (3) that where an extramural clinic exists to meet a temporary need it should be staffed with men who have an adequate knowledge of gynæcology and with consultants available; and (4) that instruction in modern contraceptive measures and in the indications therefor should be introduced into the curriculum of medical schools and that post-graduate instruction should become available to practising physicians.

THE PRACTICE OF MEDICINE IN MEXICO.

The department of public health of the United States of Mexico finds that many of the foreign "physicians" who enter Mexico to practise medicine have obtained their licences either from a "diploma mill" or by some other irregular means. On the advice of the public health department the Secretary of the Interior has issued instructions to the immigration authorities to the effect that foreign physicians will not be permitted to enter Mexico to practise medicine unless they have been previously authorised to do so by the Department of the Interior. It is said that the difficulty which Mexican physicians are experiencing in making a living adds to the demand to exclude foreign competitors.

MEDICAL MEN AS ARTISTS.

More than 250 examples of painting, drawing, photography, statuary, woodcarving, and metal work by medical men were on exhibition this spring at the New York Academy of Medicine. This was the fifth exhibition of the New York Physicians' Art Club which invites all members of the medical profession who wish to do so to exhibit their work in the plastic or graphic arts. "With a few exceptions," writes Stephen Bourgeois in the catalogue, "most of the doctor-artists are in fact more interested in technic, in skill, in methods of composition, or colour arrangement than in actual expression, although they probably believe the contrary." The artist-critic is strangely surprised to find that the doctors are "inveterate optimists."

NEW YORK STATE HEALTH COMMISSION REPORTS.

The distinguished commission appointed last May by Governor Roosevelt has presented its preliminary report. If no recommendations are made for change in the essential structure or policies of the State department, it is not because Dr. Farrand and his fellow commissioners have overlooked any detail of administration. They make comprehensive recommendations for improving the efficiency of local health administration, stressing especially the wastefulness of the present abundance of local boards of health of which there are no less than 1036 in the State. This system of many small health units, designed by law to meet the conditions of 1850, in the opinion of the Commission fails utterly to meet the needs of 1931. The units are too small to provide the services which modern public health demands. Advances which have resulted from research in the prevention of disease necessitate the employment of trained personnel who will devote their entire time to protecting community health. Moreover, better methods of communication by reason of the telephone, improved highways, and the automobile, make it easier to serve the larger territory of a county than it was to serve a single town a half century ago. Throughout the country the county with full-time personnel is recognised as the best possible unit for satisfactory local health administration. In 35 States there are more than 500 county health departments, some of which have been in successful operation nearly 20 years. The Commission feels that this is the most vital matter it has had to consider, and urges that legislation be enacted substituting the county as the unit of local health administration in place of the town and village. Other recommendations include the provision of more space for sanatorium care of the tuberculous, and provision for treatment by the county health departments of venereal disease, whether the patient be indigent or self-supporting, infectious or not.

SOCIETY FOR RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN.

THE annual general meeting of this society was held on May 13th, with Mr. V. Warren Low, the President, in the chair. It was reported that the total membership of the society at the end of the year was 285, made up of 160 life members, 124 ordinary members, and one honorary member. During the year six members died and seven new members were elected. On Dec. 31st, 51 widows and 12 orphans were in receipt of grants. One widow died during the year; since 1917, when she came on the fund, she had received £925 in grants, her husband having paid £31 10s. in subscriptions. The annual grant during 1930 was £75 to widows over 65 years of age, and £60 to those under 65. Each orphan under 16 years of age received £50. In addition a Christmas present of £10 was made to each widow and orphan. This present being dependent on the money available for distribution, was smaller than in recent years. A sum of £241 5s. was also paid to six orphans who had reached the age of 16, to enable them to continue their education at school or start on some professional or business career. The invested funds of the society now amount to £140,700, and the cost of administration was just under 6 per cent. of the total income.

The society is described as a "mutual provident benevolent association of medical men who at the time of their admission were resident within a radius of 20 miles from Charing Cross." Admitted under 40 years of age a member pays an annual subscription of two guineas. When three annual subscriptions have been paid his dependants become eligible for benefits. If under 30 years he may become a life member for a single payment of 20 guineas with immediate eligibility of his dependants for benefits. For his subscription of two guineas a newly married man obtains a guarantee that his wife and young children will, in the event of his early death, not be left unprovided for. Such an insurance on a commercial basis would, it is pointed out, involve very large premiums. Until success in practice enables a member to make provision for his dependants his subscriptions are of a potentially provident nature. When success in practice renders them ineligible for benefits his subscription becomes of a benevolent nature, safeguarding the fund for those less fortunate.

Further particulars and application forms for membership may be had from the Secretary of the Society, at 11 Chandos-street, Cavendish-square, W. 1.

THE DIFFICULT CHILD.

To the Editor of THE LANCET.

SIR,—In thanking you for your very appreciative notice last week (p. 1097) of the lectures of my colleagues and myself on the Difficult Child, may I take this early opportunity of dispelling an unfortunate impression left by one statement which it contains? The annotation states that "one of the peculiar features (of the method) . . . is that the home has become the peculiar province of the social worker, and the psychiatrist never sees the home and does not always see the parents." While the former statement with regard to the home is unfortunately true, the reports which the physician receives are usually very full indeed, and are deliberately detached in outlook. Any personal expression on the part of the social worker is eliminated, and where it creeps in it is usually rejected or treated as an interesting sidelight on the social worker's own temperament. This is by no means a negligible piece of oblique information. The statement that the psychiatrist does not always see the child is most misleading. Not only does he see the parents when they exist or are accessible, but he sees in addition as many members of the family as possible, sometimes uncles and aunts, who from time to time have played a part in the life of the child. Moreover, fully a third of the psychiatrist's time is spent in talks with the family. If this were not the case, the fears expressed in your annotation would indeed be justified.

All workers in this field are realising that the doctor must be the central exchange for the gathering in and interpreting of the data of each case. Failure to recognise this will leave the field ultimately for the social worker to interpret in terms of sociological categories which are still far from clear, and not in *biological terms which the broad medical standpoint* demands.—I am, Sir, yours faithfully,

EMANUEL MILLER.

Wimpole-street, W., May 18th, 1931.

DURACAINE IN SPINAL ANALGESIA.

To the Editor of THE LANCET.

SIR,—I believe the dose of novocain for spinal injections is not the most that a patient will recover from, but the least that will give effective analgesia. After quoting authorities who support my contention that from 150 to 200 mg. is a sufficient dose for a heavy-weight adult with a long spine, Dr. Falkner Hill says: "Yet this child of 6 received 200 mg. How is such a thing possible? The answer is that gliadin made it so." Why, this is just what I am complaining about! What evidence has ever been produced that gliadin delays absorption and prolongs analgesia? If this were the case I should have expected that an amount of novocain which by itself was formerly ineffective in the duration of analgesia, would with the help of gliadin now have become adequate. What are the facts? In order to justify the name Duracaine, the dose must apparently be increased beyond anything previously in use, and in most instances doubled.

If a 4 c.cm. ampoule were graduated in the middle, the top half labelled "planocaine" and the bottom half "duracaine," this would at least be logical and not misleading. Consider the small cross section and short length of the dura in a child 6 years of age. How much cerebro-spinal fluid bathes the thoracic nerve roots in this area? Probably much less than 10 c.cm., for this volume goes far to spread the roots of an adult woman with a short spine.

I will now display 200 mg. of novocain in a choice of strengths for Dr. Falkner Hill's inspection. It represents 5 c.cm. of 4 per cent.; $6\frac{2}{3}$ c.cm. of 3 per cent.; 10 c.cm. of 2 per cent.; $13\frac{1}{3}$ c.cm. of $1\frac{1}{2}$ per cent.; and 20 c.cm. of 1 per cent. What concentration of novocain would be required to give effective analgesia on the delicate nerve roots of a child of this age? Surely not nearly 7 c.cm. of 3 per cent.!

Dr. Falkner Hill cannot seriously suggest that a state of utter collapse to a pulseless condition is a good preliminary to a surgical operation. Or does he believe in the old time doctor's expedient "Ah Ma'am, you have got to be worse before you are better"? He states that duracaine is a very remarkable liquid, and with this I agree, for a close examination of the various conflicting rituals performed in the administration of these mixtures would lead anyone to suppose that they contained a kind of "ectoplasm" which reacts in a variable manner in the hands of different mediums. But there is a more credible solution.—I am, Sir, yours faithfully,

London, W., May 16th, 1931. W. HOWARD JONES.

SEASONAL VARIATION IN MAN.

To the Editor of THE LANCET.

SIR,—In the notice of my small book in your issue of May 9th (p. 1036), I observe that no mention is made of what is perhaps its salient feature, and as I cannot but think that this feature has significance perhaps you will grant me a few lines in which to explain it. Briefly, the hypothesis developed carries the implication, among others, that the group of phenomena following deficiency of fat-soluble factors (such as factors A and D) is to be thought of as resulting from the working of a normal functional process under abnormal conditions, the abnormal conditions which render this process morbid being the continuance of general functional activity—locomotion, digestion, excretion, &c. This aspect is unfamiliar at present. My point is that when it is entertained and reasoned upon, one begins for the first time to understand the type and sequence of the events characterising this group of disorders, and can even make successful predictions, of a specific kind, as to their nature; which, were the guiding idea without any truth, would be impossible. Predictions of this kind were made, while working out the thesis forming the subject of the book, years before the facts they required could be realised as such. I therefore have some confidence that this biological way of synthesising the morbid events in question will ultimately find favour, since it offers a possible interpretation where none now exists.

I am, Sir, yours faithfully,

Liverpool, May 10th, 1931. EDMUND HUGHES.

SYPHILIS AND YAWS.

To the Editor of THE LANCET.

SIR,—I feel that the myth about sibbens should be stamped out. Dr. Burke's expression in his letter of May 16th referring to sibbens, "I rather regard it as being an European type of yaws," is perhaps sufficiently damning in its faint praise of the idea that this disease, which occurred in Scotland and was described in 1765, was yaws. Anyone who will read the *whole* of the literature upon sibbens, and who is conversant with the accounts of the epidemics of non-venereal syphilis which occurred elsewhere (Mal de Sainte Euphemie, 1727; Pian de

Nerac, 1751; La Radezyge, 1758; Mal de la Baie de St. Paul, 1770; La Facaldina, 1786; Maladie de Fiume, 1800; Maladie de Chavanne Lure, 1829) and who has an up-to-date knowledge of yaws will, I am sure, be convinced without any doubt whatever that sibbens was not yaws and that it was syphilis.

I am afraid, too, that some of the arguments put forward by Dr. Burke in support of the duality of syphilis and yaws cannot be upheld as of any value. He states :—

> In contrast with syphilis the primary lesion of yaws is seldom genital, and it is usually preceded by marked constitutional symptoms. . . . In yaws there is little or no adenitis, the type of exanthem is single, there is great itching. . . . The one disease does not confer immunity against the other.

These statements need amendment. The primary lesion in syphilis among certain native communities may commonly be extra-genital; constitutional symptoms may or may not occur in yaws as in syphilis; adenitis may be quite common in yaws and itching absent. Many types of skin lesion have been described in yaws.

As regards immunity Dr. Burke would appear to be ignorant of the more recent experimental work on cross immunity.

I am, Sir, your faithfully,
HUGH S. STANNUS.

Wimpole-street, W., May 18th, 1931.

AERIS: A NEW NAME FOR LAUGHING GAS.

To the Editor of THE LANCET.

SIR,—I consider that a specific name of an attractive character has long been required for nitrous oxide and its admixtures with oxygen and small percentages of carbon dioxide. If we look carefully at its chemical composition, we find that only those elements which are present in the atmosphere are contained in it. I suggest, therefore, that the word *aeris*—i.e., "of air"—would be a scientific and euphonious designation for this most acceptable and beneficent anæsthetic. The word "gas" is a misleading generic term associated in the public mind with various unpleasant and irrespirable gases. Instead of the ideas "gassed in the war," "an escape of gas," "a gas oven case," "step on the gas," the new name would offer only that of breathing a refreshing and harmless air, which indeed well describes this pleasantest and safest of all inhalations for annulling pain.

I am, Sir, yours faithfully,
BELLAMY GARDNER.

Clarence Gate-gardens, N.W., May 9th, 1931.

APHTHOUS ULCERS.

To the Editor of THE LANCET.

SIR,—In your issue of April 4th (p. 777) Dr. F. A. Phillips asks for information about the treatment of aphthous ulcers of the mouth. At this institute we have found very successful an application of 8 per cent. zinc chloride solution to these areas, which have been previously dried with cotton or gauze; the solution is allowed to remain for a minute and followed with Talbot's solution of iodine. Usually one application will suffice. Occasionally a second application within 24 hours is necessary and in the most severe type a third treatment. Zinc chloride in this strength does not destroy the surrounding healthy tissue, as occurs with silver nitrate or other strong caustic. Talbot's solution is made up of zinc iodide 15 g., iodine crystals 25 g., glycerin 50 c.cm., and water 40 c.cm.

I am, Sir, yours faithfully,
JAMES E. AIGUIER, Ph.G., D.D.S.

The Thomas W. Evans Museum and Dental Institute,
School of Dentistry University of Pennsylvania,
Philadelphia, May 2nd, 1931.

SWEEPSTAKES FOR HOSPITALS.

To the Editor of THE LANCET.

SIR,—Perhaps it is the prospect of a deluge of sweepstakes that makes St. Thomas's Treasurer sceptical. It is doubtful if legislative sanction would be limited to hospitals alone. There are said to be 48,000 other charities. If but 5 per cent. of charities indulged in sweepstakes we should have 47 a week.

I am, Sir, yours faithfully,
RALPH B. CANNINGS,
Secretary, City of London Maternity Hospital.

May 18th, 1931.

WEST LONDON HOSPITAL.

AT the annual meeting Lord Phillimore pointed out that most of the hospital's previous records were broken last year. More than £73,000 was received for general purposes and the number of in-patients increased by 161. In the out-patient and casualty departments there were 58,000 more attendances than in 1929.

The seventy-fifth anniversary was the occasion of a festival dinner at the Guildhall on May 12th when more than 600 people attended. Prince Arthur of Connaught, the President, who took the chair, spoke of the opportunity of social service which was offered to the hospital in extending the benefits of its treatment to the "middle classes." For the past six years, he said, accommodation had been provided in private rooms for 26 paying patients, and experience had shown that there was a very real demand for such accommodation provided that the charges (including specialists' fees) could be kept moderate. The board had therefore decided that an additional 74 private rooms should be provided, bringing the total to 100. Hitherto, a charge of £3 5*s.* weekly had been made for a private room plus a further sum, varying in amount and assessed by the committee, for medical and surgical fees. When the new rooms were built a flat rate of weekly charges would be adopted. It would vary according to the patient's capacity to pay and would begin with a minimum of £7 7*s.* This would include operative and all other treatment, and once the charge had been assessed the patient need have no further anxieties about his bill. The private beds would be entirely self-supporting, said Prince Arthur, and any surplus derived from them would be devoted to the upkeep of the general wards. In view of the increase in the hospital practice, it was urgently necessary to find less cramped accommodation for the casualty, pathological, and radiological departments. The noise of the traffic in the Hammersmith-road made the wards no longer suitable for patients and these were to be transferred to the back of the hospital. At least £200,000 was needed to carry out alterations and extensions, which had been approved in principle by King Edward's Hospital Fund. Mr. Winston Churchill urgently pleaded the cause of the "black-coated man," who was, he said, least provided for in the giant scheme of national insurance in which this country led the world. The lack of intelligentsia—the man who could write a telegram and send it, the black-coated man—had in his opinion counted largely in the collapse of Russian armies. Sir Henry Simson and Mr. Justice McCardie also spoke. Later in the evening Sir William Wells, chairman of the board of management, was able to announce that £23,800 had already been raised.

ST. MARY'S HOSPITAL, PADDINGTON.—The King of the Belgians has become patron of this hospital in token of his gratitude for the services rendered to the Belgian army during the late war. Between 1914 and 1918 the hospital supplied Belgium with sufficient anti-typhoid vaccine to inoculate 840,000 people, and sufficient "antisepsis" vaccine for more than a million and a quarter persons.

OBITUARY

THOMAS R. GLYNN, M.D., F.R.C.P. Lond.,

EMERITUS PROFESSOR OF MEDICINE, LIVERPOOL UNIVERSITY.

WE recorded last week the death on May 12th of Prof. T. R. Glynn, who was for 40 years Professor of Medicine at the University of Liverpool. The event occurred at his house, Bryn Bella, Tremerchion, N. Wales, in his 91st year.

Thomas Robinson Glynn was born in 1841. He was the son of Dashpen Glynn, a well-known Liverpool shipowner, and received his early education in Liverpool and his medical training in London at St. Bartholomew's Hospital. He graduated in 1865 in medicine at the University of London and began his lifelong association with the city of his birth by election as demonstrator of anatomy at the Liverpool school of medicine, associated with the Royal Infirmary, and he was also elected assistant physician to the Childrens' Hospital and physician to the Northern Hospital. In 1871 he was elected to the medical staff of the Royal Infirmary, having taken the M.R.C.P.Lond. Just previously to this date, the beginning occurred of a remarkable development of Liverpool as a medical centre. The Royal Infirmary then contained some 250 beds, and students at the school attached were admitted to the practice of the hospital and also to the practice of the Liverpool Lock Hospital, attendance fitting them for entrance to the qualifying examinations. The movement to raise the status and improve the scope of the school, which was set on foot in 1869, was throughly successful owing to the exertions among others of the Bickersteths, Mitchell Banks, Reginald Harrison and Richard Caton, and with this energetic group Glynn became a valuable coöperator. As is well known the school formed part of the University College of Liverpool, founded in 1881, as a constituent body in the Victoria University. In Liverpool College Glynn received the chair of medicine. Eleven years later the powers and property of University College were transferred from the Victoria University to the new University of Liverpool, and Glynn succeeded to, or continued in, the chair of medicine in the new University, with the result that his tenure of the professorship lasted practically 40 years. During much of this time he lectured regularly on medicine in the medical school, being one of a band of notable teachers, several of whom have just been mentioned by name; while William Carter, Alexander Davidson, and Rushton Parker should be added to the list. Of Glynn, Prof. Hill Abram writes :—"His instruction in his lectures was largely based on bedside work, and to all of the students he was untiring in teaching the value of the correlation of the physical signs and pathological findings. Further, his instruction was so imparted that he was always to his students something more than the brilliant teacher; he was the congenial comrade, appreciative of a story and ready to cap it."

PROF. T. R. GLYNN.

[From a portrait by R. E. Morrison.

Prof. Glynn had a long and distinguished connexion with the Royal College of Physicians of London, where he was elected a Fellow in 1882. He served on the Council in 1907–1909, and delivered the Lumleian Lectures in 1903 and the Bradshaw Lecture in 1913. In the former he took as his subject infective endocarditis, and dealt mainly, almost entirely, with the clinical aspects of the condition, analysing the ætiology and going very thoroughly into post-mortem pathology, where his lessons were made clear to the audience by the handing round of drawings made by himself, exhibiting the lesions that had been discovered at autopsy. The University of Liverpool possesses an instructive series of Glynn's drawings of morbid conditions, notably of heart lesions, among which these illustrations are to be found. Ten years later he delivered the Bradshaw Lecture upon hysteria and discussed the alliance between hysteria and various groups of diseases, making distinctions between hysterical and neurasthenic cases. The teaching here, too, was closely associated with his long clinical experience at the Royal Infirmary. Glynn was elected Emeritus Professor in 1901, and in the same year he retired from the active staff of the infirmary, having reached the age limit, when he was elected consulting physician to the institution. Among the other of his numerous appointments, he was past president of the Liverpool Medical Institution and had held at different times the posts of chief medical officer at the Royal Insurance Company, medical officer to the Customs, consulting physician to the Woolton Convalescent and Hoylake Hospitals, the Liverpool Dental Hospital, and the Catholic Blind Asylum.

We have received the following appreciation from Dr. Charles Macalister :—"It is of the man himself and of the influences of his work and of his personality that I venture to add a few words of appreciation. It was not as a student of the school that I had the advantages of his teaching. As a young practitioner one soon realised that he was a master of clinical medicine, the dynamic power of whose teaching attracted those who were fortunate enough to be able to attend his clinic. Every man's life involves a history and, so far as our profession is concerned, it was the fact that Dr. Glynn was a great clinical observer and teacher which rendered his life so essentially valuable. He belonged to the days when specialism had not as yet split up the work of the physician. He taught general medicine, of which his knowledge was wide, on broad lines eminently educative not only in the way of impressing clinical facts but, importantly, in that of cultivating the principles of observing the meanings and associations of these facts.

"The value of his influence as a teacher is reflected by the circumstance that very many members of the hospital staffs were his pupils and they carry on the traditions of his work. To his immediate students, who were attracted in large numbers to his wards, he was an oracle whose word was beyond dispute. I recollect many years ago discussing a case with a young resident who had been one of his pupils. The house physician held very definite opinions about the case in question and, on inviting his reasons, his answer was 'Because Dr. Glynn thinks differently from most people about these cases,' or words to the same effect, which indicated that he meant to hold by the teaching of his master whatever others might think of the matter. I may give an instance of Prof. Glynn's quickness of perception illustrated by his noting an ill-looking boy in the out-patient department becoming distressed by a draught from an opening door. It at once occurred to him that the lad might be suffering from rabies which proved to be the case. When calling on Dr. Glynn last year I reminded him of the incident, which must have happened more than 40 years ago, and he was very interested to hear that I remembered it. His teaching was largely based on his knowledge of pathology and, at the Medical Institution and in his classrooms, his expositions were frequently illustrated by excellent water-colour paintings of specimens of fresh preparations and also of clinical conditions.

"Prof. Glynn's life was a busy one. A large consulting practice, added to his professorial and hospital work, afforded him little time for leisure. In the 'nineties it was thought hardly proper for any well-known citizen in a wide circle round Liverpool to die without being seen by Glynn or by another eminent contemporary physician. His temperament, however, was one of great activity and it would have been impossible for him to leave any time unoccupied, and busy as he was he found opportunities for cultivated studies. He was an artist of considerable merit, had a fine appreciation of colour, and produced many good landscapes which, in some respects, resembled those of Robert Fowler, R.I., a friend who was frequently his guest during the summer vacations. His work was at times exhibited at the Royal Liver Society meetings and the Liverpool Autumn Exhibitions. Further, he had a great love of music; he was an organist, he delighted in singing, and retained his singing voice even when he was over 80 years of age. His humour permeated both the professional and social sides of his life. He, Mitchell Banks, and Edgar Brown, were a never failing source of entertainment at social functions; at the Chester Medical Society's annual dinners, for example, the interchange of witty talk between these three was as much an annual event as the dinner.

"On the death of an old friend memories of the past crowd in to the mind, but it will be sufficient here to testify to the work of his long life, given to the establishment of indelible traditions; we mourn that we shall neither see nor hear again one who has been a devoted friend to, and a distinguished member of, our profession."

MEMORIAL TO A MEDICAL MAN.—The board room in the new block at the Boscombe branch of the Royal Victoria and West Hants Hospital is to be a memorial to the late Mr. Arthur Heygate Vernon who joined the surgical staff of Boscombe Cottage Hospital in 1890, and had been vice-president, chairman of the board, and chairman of the house committee of the Victoria Hospital. The new block will more than double the out-patients' departments and will provide about 40 private paying wards and accommodation for special departments. The cost will be £120,000, towards which £80,000 has already been obtained. Of the 4136 in-patients admitted last year, an increase of 34, there were 202 victims of motor accidents.

MEDICINE AND THE LAW.

Pay-beds at the Miller General Hospital.

ON May 15th Mr. Justice Farwell gave his decision on the application of the Miller General Hospital for South-East London to establish a scheme under which the number of pay-beds might be increased from 15. There had been an adjournment from the previous week in order that the court might be informed of the accounts for 1930. These accounts showed that the past year was exceptional owing to large windfalls in legacies and donations. Thanks to these and to income from the 15 pay-beds (at £7 a week each), which the 1929 scheme of the Charity Commissioners had sanctioned, there was a profit of over £2000 for 1930. The existence of a profit imperilled the success of the application to the court, because the court has no jurisdiction to interfere except in the case of an emergency involving the failure of the existing scheme. At the same time, though the hospital had not proved the emergency, the court would naturally not wish to wait till disaster occurred before taking action. Mr. Justice Farwell, after reasserting the expressed objects of the hospital "to provide free medical and surgical relief and assistance for and to the necessitous poor" of the district, and after emphasising the principle that these objects must not be interfered with, was willing to look at the average financial results over a period of five years. The average result was a considerable deficit and the court was satisfied that it was necessary to make some alteration of the scheme. The court sanctioned a temporary increase of the number of pay-beds from 15 to 20 for 12 months, with liberty for the management to apply afresh after that time. The beds would be in two wards, to be used primarily for paying patients only. The hospital had asked that where the doctors thought that paying cases required separate rooms the cases might occupy some of the eight separate rooms available for that purpose. This request also was sanctioned.

Fraud Charge against Psychologist Fails.

After several days' hearing before Mr. Justice Horridge and a special jury, allegations of fraudulent misrepresentation brought by a patient against a medical practitioner failed. The plaintiff's case was that, while she was undergoing psychological treatment by the defendant, he found out from her that she had over £3000 at her bank; he told her (it was alleged) that he was chairman of a certain company, falsely representing that the company had valuable sulphur deposits in the Eastern Mediterranean, that its prospects were wonderful, and that he himself had invested in it every penny he could spare. She said that, believing these representations to be true, she had invested £1000 in the company. The plaintiff also claimed damages for alleged negligence and for alleged breach of duty by the defendant as her medical adviser. On the other hand, the defendant denied all the charges and counterclaimed for his fees. His counsel described the action as a wicked and shocking conspiracy to draw a medical practitioner to the court on a charge of fraud in the belief that he would rather pay up than face a jury. Cross-examined by Sir Patrick Hastings, the defendant frankly agreed that the company had never paid a dividend, never earned a penny, and possessed no tangible assets. But he had done his best to explain the matter clearly to the plaintiff; he had done nothing underhand;

he had not tried to persuade her to put money into the company; on the contrary, he had mentioned the matter to her husband and had strongly advised against the investment. After evidence had been given on both sides, the judge summed up. He pointed out the serious nature of the charge of fraud; the case was "all or nothing." The jury found in favour of the defendant on all issues, but added an expression of opinion that the defendant was unwise in accepting from a patient money for a concern in which he was interested.

Allegations of Negligence against Surgeon Withdrawn.

On May 11th Mr. Justice McCardie approved the discontinuance of the action of Moore and wife *v.* Ligat, in which allegations of negligence were made against a surgeon. Mrs. Moore's claim arose from an accident which unfortunately caused her to lose the sight of one eye. She underwent an operation in 1927 for turbinectomy and a deflected nasal septum. She attributed her loss of sight to the use of undue force during the operation. The defence was that this was an occurrence which could not have been guarded against and was due to pre-existing disease. At a previous trial before Mr. Justice Horridge, lasted from March 31st to April 4th of last year, jury had disagreed. Plaintiff's counsel now stated that with a fuller knowledge of the facts than had been available in the earlier stages of the case, he had advised his client to accept an ex gratia payment (by which she would receive £75 clear) offered by the defence. The offer was in no sense an admission of the alleged negligence; counsel made it clear that all allegations of negligence were entirely withdrawn. Defendant's counsel explained that the surgeon's object naturally was to vindicate his professional reputation. That object had been attained and, as the defence was conducted by the Medical Defence Union, the defendant was not concerned in any matter of money. Mr. Justice McCardie assented with pleasure to the termination of the action; he was satisfied that all allegations had been withdrawn and he considered that the cheapest course had been followed. The result must certainly have been satisfactory to the defence. The hearing—it was stated—was likely to last four or five days. None of this expense, presumably, could have been recovered from the plaintiff, for whom leading and junior counsel were appearing under the Poor Persons Rules without fee.

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS.

REGISTRATION AND REGULATION OF OSTEOPATHY.

On May 12th in the House of Commons the Order for the second reading of the Registration and Regulation of Osteopathy Bill was read and discharged and the measure was withdrawn.

This Bill was introduced by Mr. W. M. Adamson, the Member for Cannock, and obtained a first reading in the House of Commons on Feb. 11th. It is understood that the Bill was not regarded with favour by the British Osteopathic Association, and Mr. Adamson was not prepared to proceed with the measure unless there was agreement among osteopaths themselves.

HOSPITAL LOTTERIES.

In the House of Commons on Tuesday, May 19th, Sir William Davison asked leave to introduce the Hospitals Lotteries Bill, a measure to authorise the raising of money by means of lotteries for the support of hospitals. He said that he had sent to the Home Secretary a memorial signed by 70 Members of the House belonging to all parties asking him to take this matter into consideration. He had also furnished Mr. Clynes with the results of a questionaire which was recently sent out by the Special Appeals Committee of St. Bartholomew's Hospital to some thousands of representative people, including supporters of the hospital. The result of that questionaire to date was that 3125 persons were stated to be in favour of a lottery for the hospital and only 61 were against. Meanwhile, nothing was being done and British hospitals were in the greatest need of funds for building, equipment, and maintenance. He was aware that a number of Members of the House of Commons considered that hospitals should be a charge upon the State. But even they must surely realise in view of the statements of the Chancellor of the Exchequer in presenting his Budget that it was not practical politics in present financial conditions to provide State money for hospitals. The chairman of a large hospital, in a letter to the *Times* a few weeks ago, pointed out that hospitals were being seriously prejudiced by reason of the uncertain state of the law in regard to this matter, and he added that they were losing subscriptions both from those in favour of lotteries and from those who were opposed to them. That supported the view that it was time that this uncertainty of the law should be ended, at any rate so far as hospitals were concerned. Immense sums have been raised in Dublin in aid of the Southern Irish Hospitals.

AN UNAMBITIOUS MEASURE.

The Bill which he was asking leave to introduce was an unambitious measure. It did not attempt to modify or remove the many anomalies relating to lotteries, raffles, and sweepstakes. It was a short permissive measure which left the law as it stood until such time as the Government were in a position to deal with it. The Bill provided that notwithstanding anything in the existing law a lottery might be held under regulations to be approved by the Home Secretary for the benefit of British hospitals something on the lines of the Irish Free State hospitals lottery, but with improved regulations as a result of experience gained in the conduct of that lottery. This Bill would not refer to Northern Ireland. There was nothing inherently vicious in the idea of a lottery. It was bad for the country that the law should be openly broken by all classes, and with general approval, as it was being to-day. This Bill would be of immense benefit to the hospitals and through them to the sick and suffering people of the country.

ARGUMENTS IN OPPOSITION.

Mr. Foot, who opposed the Bill, said that it prejudged inquiry and demanded from the House a verdict before the evidence had been given. The Bill could not be limited to hospitals. If it was right for hospitals, it was right for the blind, for orphanages, and for every beneficent enterprise, national and municipal. This was a charity lottery which would not achieve its purpose, but would dry up the resources of charity. The man who would buy a sweepstake ticket would be tempted to feel that he had discharged his responsibility. In the Dublin sweepstake of November, 1929, £798,433 was raised from the sale of tickets, and of that sum £249,000 went in expenses and organisation, and £417,000 in prizes. Out of the £798,000 the hospitals took only £131,000. Out of each 1*s.* ostensibly raised to help the sick, 2*d.* went to the avowed purpose of the scheme. A short time ago the Earl of Onslow, at one time chairman of the Voluntary Hospitals

Commission, wrote to the *Times* setting out his reasons for condemning the proposal as disastrous to the financial interests of the hospitals of this country. The same opinion was given by the chairman of the Royal London Ophthalmic Hospital, and by Sir Arthur Stanley, Treasurer of St. Thomas's Hospital. The *Manchester Guardian* sought the opinion of 13 prominent members of the Manchester Hospital boards. Two declared in favour of the proposal, one was neutral, and ten declared against it. The House Governor of the Charing Cross Hospital, Mr. Philip Inman, in an interview this month, said that he and the hospital would have neither part nor lot in any such schemes. Their reasons were not simply moral ones, although they weighed very considerably. Looking at the matter simply from a business standpoint, they believed that the gains would be outweighed by the losses. This proposal, Mr. Foot added, screened cupidity with a thin smear of charity. The Good Samaritan would have taken a very different place in history if he had sought to discharge his responsibility to his distressed neighbour by spending his 2*d*. on the purchase of a ticket in the Jericho Hospital Sweepstake. Speaking a few weeks ago, Sir Alan Anderson, chairman of the Hospital Saving Association, said: "Illness is not a gamble, and it would not accord with the principles on which the Hospital Saving Association appeals to its members to base the finance of healing on the unstable foundation of gambling." The hospitals of this country ought not to be built on the very shifting and uncertain sands of chance and cupidity.

Leave to introduce the Bill was refused by 181 votes to 58.

WORKMEN'S COMPENSATION BILL.

On May 19th, in the House of Lords, Lord NOEL-BUXTON moved the second reading of the Workmen's Compensation Bill (which has already passed through the House of Commons). The object of the Bill was, he said, to repeal Section 9 of the Workmen's Compensation Act, 1925, and to substitute for it a new subsection. This subsection provided that if a workman had so far recovered from his injury as to be fit for employment of a light character, but had failed to obtain it, and it appeared to the county court judge that his failure was a consequence, wholly or mainly of the continuing effects of the injury, the judge should order that the workmen's incapacity should be treated as total incapacity resulting from the injury, and therefore entitled to continuing compensation. The Bill was read a second time.

HOUSE OF COMMONS.

WEDNESDAY, MAY 13TH.

Road Traffic Act and Public Safety.

Mr. FREEMAN asked the Minister of Transport whether he could make any report on the working of the recent Road Traffic Act; and whether it was securing increased safety for the travelling public.—Mr. H. MORRISON replied: To the best of my knowledge the provisions of the Road Traffic Act are working satisfactorily, but some time must necessarily elapse before their full effect can be judged. As regards public safety, I understand that the record of accidents in the metropolitan police district and the City of London show a reduction for the first quarter of this year of 10 per cent. in the case of fatal accidents and of more than 10 per cent. in the case of non-fatal accidents compared with the corresponding period of last year. The corresponding figures for the remainder of the country are not yet available.

THURSDAY, MAY 14TH.

The Sandstone Silicosis Fund.

Mr. NEIL MACLEAN asked the Home Secretary the cost of administering the sandstone silicosis fund for the last complete year; and the amount paid out in compensation during the same period.—Mr. CLYNES replied: It appears from the revenue account of the fund for 1930 that the total administrative expenses incurred in that year in connexion with the collection of levies and payment of compensation claims amounted roughly to £2700. This figure does not include the cost of the medical board or of the local joint committees which determine claims. These expenses, which amounted roughly to £7600 can hardly, I think, be regarded as expenses of administering the fund. The amount paid out in compensation during the year was £5580, odd, and the amount collected in levies was £48,715.

Teachers and Physical Culture Training.

Sir WILLIAM JENKINS asked the President of the Board of Education what facilities there were in England and Wales for training men in physical culture, and whether there was a sufficient supply of teachers to meet the demand in the schools; also what grants were being made towards physical training.—Mr. LEES-SMITH replied: Physical training is included in the course of every ordinary student at a two-year training college, and of a large and increasing number of graduates who take a one-year course of training. All the colleges referred to are aided by grant.

Epileptic and Mentally Defective Children.

Mr. ALBERY asked the President of the Board of Education what accommodation in public institutions was available for epileptic children in England; and what accommodation was available in Kent.—Mr. LEES-SMITH replied: There are six residential special schools for epileptic children certified by the Board of Education, providing altogether accommodation for 600 children. None of these schools is situated in Kent, but most of them admit children from any area. Provision is also made in certain institutions for mentally defective children for cases in which mental defect is combined with epilepsy.

Mr. ALBERY: Is the right hon. gentleman aware that there is a considerable shortage in accommodation and a very long waiting-list of patients, and can anything be done to remedy this state of affairs?

Mr. LEES-SMITH: I have made inquiries and I find that that is the case. At present the Board offers a grant of 50 per cent. to any local authority or voluntary association establishing these schools, and I hope that the result of that grant will be an increase in accommodation.

Bovine Tuberculosis in Man.

Lieut.-Colonel FREMANTLE asked the Minister of Health if he would arrange for the Ministry of Health Memorandum on Bovine Tuberculosis in Man to be issued as a Parliamentary publication and included in the Pink Paper.—Mr. GREENWOOD replied: This memorandum has already been published as a non-Parliamentary Paper, and it is available to hon. Members on application to the Stationery Office on the usual green form.

Captain PETER MACDONALD asked the Minister of Health whether he proposed to introduce legislation regulating the production and sale of milk with a view to reducing the incidence of bovine tuberculosis in human beings.—Mr. GREENWOOD replied: I am considering this question in consultation with the Minister of Agriculture and Fisheries.

Infant Mortality in London.

Mr. WEST asked the Minister of Health which three London metropolitan boroughs had the highest infantile mortality-rates.—Mr. GREENWOOD replied: According to the most recent available returns (1926–30) Paddington Stepney, and Shoreditch are the metropolitan boroughs with the highest infantile mortality-rates.

Claims of Married Women and Health Insurance.

Sir KINGSLEY WOOD asked the Minister of Health if he could give, for the last convenient date, the percentage of claims or other material particulars concerning the claims of married women on the funds of approved societies under the National Insurance Act; and how these compared with the original estimate of the Government actuary and the basis upon which married women's contributions were calculated.—Mr. GREENWOOD replied: The claims of married women have not in recent years been separately tabulated, but in view of the facts brought out in the report of the Government actuary on an investigation into the experience of a representative sample of the insured population (C.M.D. 3548) arrangements have been made for the separate tabulation of these claims in the future. In reply to the second part of the question, the report referred to showed that in the year 1927 the sickness claims of married women were 130 per cent. of the provision made by the valuation standard, while those of unmarried women were 117 per cent. In regard to disablement benefit the respective percentages were 171 and 119. In the case of both benefits the relative increase in the claims of married women over the previous six years had been much more marked than in the case of the unmarried. For a due appreciation of these figures it should be added that the valuation standard itself provides for a considerably greater amount of claims from the married than from the unmarried.

MONDAY, MAY 18TH.

Experiments on Living Animals.

Mr. FREEMAN asked the Home Secretary whether in the performance of experiments on living animals, who decided whether the experiment was calculated to give pain; and if the performer was the only judge.—Mr. CLYNES replied: No. In the case of this Act, as of all others, people have to consider for themselves whether what they propose to do is in accordance with the law; but if they infringe the provisions of the Act they are liable to have legal proceedings taken against them and the Court decides whether the experiment is or is not calculated to cause pain. Experience shows that people who propose to perform experiments which might by any possibility be regarded as calculated to cause pain are anxious to comply with the requirements of the Act in order to be on the safe side.

Factory Inspection in India.

Mr. DAY asked the Secretary of State for India the number of whole-time or part-time factory inspectors employed in India; and how many were women.—Mr. WEDGWOOD BENN replied: At the beginning of this year the number was 47, including one woman inspector in Bombay.

TUESDAY, MAY 19TH.

Patent Medicines.

Mr. HAYDN JONES asked the Minister of Health whether he proposed to introduce legislation to give effect to the recommendations of the Select Committee on Patent Medicines, whose report was issued in 1914.—Miss LAWRENCE replied: My right hon. friend fears that owing to the present state of business the Government are unable to undertake to introduce legislation on this subject during the present session.

ECCLES AND PATRICROFT HOSPITAL.—There is said to be a danger that, for lack of means, this institution may shortly have to close many of its beds, although it has a waiting-list of 300. The difficulty is officially attributed to the "refusal of the Lancashire insurance committee and the approved societies of financial support for the treatment of their members who are patients"; 61 per cent. of the in-patients come under this head.

INTERNATIONAL POPULATION UNION.—The second general assembly of the International Union for the Scientific Investigation of Population Problems will take place under the presidency of Prof. Raymond Pearl, at the house of the Royal Society of Arts, John-street, Adelphi, London, from June 15th to 18th. The first three mornings will be given to the business of the Union, but the afternoons will be available for reports and papers. The afternoon on June 15th will be devoted to Population and Food Supply. On the 16th Prof. F. A. E. Crew and Mr. Eldon Moore will introduce a report on Differential Fertility. On the 17th the Vital Statistics of Primitive Races will be considered, and on the 18th both morning and afternoon will be free for individual communications. Among countries to be represented are the United States, Belgium, Denmark, France, Germany, Great Britain, Holland, Spain, Sweden. The organising committee of the general assembly is the British Population Society, whose chairman is Sir Bernard Mallet. Application for tickets may be made to the hon. secretary, Mr. Eldon Moore, at Eliot Vale House, Blackheath, Kent.

ROYAL MEDICAL BENEVOLENT FUND GUILD.—A garden party in aid of the educational work of this Guild will be held in the Royal Botanic Gardens, Regent's Park, London, N.W., on Tuesday, June 2nd, from 2.30 to 8.30 P.M. The Duchess of York, *patroness of the Guild*, has consented to be present. The band of the R.A.M.C. will play; there will be hospital side shows and other entertainments; and purses will be presented. Tickets of admission may be had from the Hon. Treasurer, Mrs. E. D. D. Davis, 46, Harley-street, W. 1. Prices are reduced if they are purchased in advance.

The Guild, or women's branch of the R.M.B.F., has its offices at Tavistock House, Tavistock-square, W.C. 1, and coöperates by giving help to those beneficiaries of the Fund who are recommended to it by the Fund case committee.

The education of children and the subsequent training of students to earn their own livelihood are the Guild's special care, and in addition to fees paid, schools and training centres are recommended, and holidays also are arranged when necessary. The Guild raises its own funds and depends entirely on voluntary subscriptions and donations.

Medical Diary

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

The Society's house and Library will be closed from Saturday, May 23rd, to Monday, May 25th, both days inclusive.

TUESDAY, May 26th.—5 P.M., MEDICINE. Election of Officers and Council.

WEDNESDAY.—5 P.M., COMPARATIVE MEDICINE. Election of Officers and Council. Paper: Dr. G. P. Male: Gland Grafting in Veterinary Practice.

THURSDAY.—8.30 P.M., UROLOGY. Election of Officers and Council. Paper: Mr. A. Ralph Thompson: Further Considerations, Relative to Congenital Deformities of the Lower Urinary Tract.

FRIDAY.—5 P.M., DISEASES IN CHILDREN. (Cases at 4.30 P.M.) Election of Officers and Council. Clinical Meeting: Cases will be shown. 8 P.M., EPIDEMIOLOGY AND STATE MEDICINE. Election of Officers and Council. Paper: Sir William Hamer: The Crux of Epidemiology.

SATURDAY.—THERAPEUTICS AND PHARMACOLOGY at the University, Cambridge. Election of Officers and Council. Short communications: F. B. Parsons: The Action of Avertin on the Liver. S. E. F. Gooding: The Action of Radon on Isolated Tissues. E. G. Holmes and C. A. Ashford: Cerebral Metabolism. J. Heller: Sensitisation of the Uterus. W. E. Dixon and J. Heller: Some New Observations on Intracranial Pressure. N. Myers: The Treatment of Toxæmia. J. C. Hoft: The Action of Histamine.

MEDICO-LEGAL SOCIETY.

THURSDAY, May 28th.—8.30 P.M. (at 11, Chandos-street, W.), Dr. Nathan Raw: Dangerous Drugs. To be followed by a discussion.

LIVERPOOL MEDICAL INSTITUTION.

THURSDAY, May 28th.—4.30 P.M., Mr. D. McCrae Aitken: Principles of Rest and Exercise in the Treatment of Joints. (Hugh Owen Thomas lecture.)

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

INTER-STATE POST-GRADUATE ASSEMBLY OF NORTH AMERICA.

(Lectures in the Barnes Hall, Royal Society of Medicine.)

TUESDAY, May 26th.—10 A.M., Sir Thomas Horder: Some Medical Hints. 11 A.M., Mr. Donald Armour: Some Points on the Treatment of Head Injuries. 12 noon, Dr. J. Strickland Goodall: The Myocardium, with Special Reference to the Right Ventricle.

WEDNESDAY.—10.15 A.M., Mr. A. Lawrence Abel: Cancer of the Rectum and Cinematograph Demonstration of the Abdomino-Perineal Operation. 11.30 A.M., Mr. Victor Bonney: A Gynæcological Talk. In the afternoon of both days visits will be made to London hospitals.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, London, W.

TUESDAY, May 26th, to SATURDAY, May 30th.—MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, M.R.C.P. Special evening lectures at 8.30 P.M. Tues., *Dr. W. J. Adie: Diseases of the Nervous System (II.).* Fri., Dr. W. J. Adie (III.).—CHELSEA HOSPITAL FOR WOMEN, Arthur-street, S.W. Fri. Gynæcological operations by Mr. L. C. Rivett at 2 P.M. No fee.—HAMPSTEAD GENERAL HOSPITAL, Bayham-street, Camden Town, N.W. Fri., 2 P.M., Dr. H. V. Morlock: Some Recent Advances in the Diagnosis and Treatment of Pulmonary Diseases. Cases. No fee.—Further particulars from the Fellowship of Medicine.

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith, W.

TUESDAY, May 26th.—Operations. 10 A.M., Medical Ward Visit, Dental Department. 11 A.M., Throat Operations. 11.30 A.M., Surgical Clinical Demonstration. 2 P.M., Medical, Surgical, Throat Out-patients, Operations, Medical Ward Visit.

WEDNESDAY.—Medical Ward Visit, Children's Medical Out-patients. 2 P.M., Medical, Surgical, and Eye Out-patients, Gynæcological Operations. 4.45 P.M., Venereal Diseases.

THURSDAY.—10 A.M., Neurological Department. 11.30 A.M., Treatment of Fractures. 2 P.M., Medical, Surgical, and Eye Out-patients, Genito-Urinary Department Operations.

FRIDAY.—10 A.M., Medical Ward Visit, Skin and Dental Departments. 12 noon, Medical Lecture. 2 P.M., Medical, Surgical, and Throat Out-patients. Operations.

SATURDAY.—9 A.M., Throat Operations. 10 A.M., Medical Ward Visit, Surgical and Children's Medical Out-patients.

NATIONAL HOSPITAL, Queen-square, London, W.C.

TUESDAY, May 26th.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Dr. Critchley: Cerebral Vascular Disease (4).

WEDNESDAY.—2 P.M., Dr. Martin: Out-patient Clinic.

THURSDAY.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Dr. Critchley: Cerebral Vascular Disease (5).

FRIDAY.—2 P.M., Dr. Adie: Out-patient Clinic. 3.30 P.M., Mr. Julian Taylor: Trigeminal Neuralgia.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION, St. James's Hospital, Ouseley-road, Balham, S.W.

WEDNESDAY, May 27th.—4 P.M., Sir John Collie: Backache.

TIONAL COUNCIL FOR MENTAL HYGIENE.

COMMONWEALTH FUND FELLOWSHIPS.—Among recipients of Fellowships granted by the Commonwealth Fund to enable British graduates to study in American universities for the two years beginning next September is J. H. Biggart, M.B., of Queen's University, Belfast, who is going to Johns Hopkins University.

MEDICAL NEWS

Royal College of Physicians of London.

At a meeting of the College on May 14th, with Lord Dawson, the President, in the chair, the following lectureships were announced: Lumleian (1932), Dr. C. E. Lakin; Goulstonian (1932), Dr. L. J. Witts; FitzPatrick (1932), Dr. James Collier; and Croonian (1933), Dr. W. E. Dixon.

A diploma in gynæcology and obstetrics was granted, jointly with the Royal College of Surgeons, to Wallace Freeborn, M.B. Sydney.

The College will be closed on Saturday, May 23rd and Monday, May 25th.

Royal College of Surgeons of England.

A meeting of the council was held on May 14th, with Lord Moynihan, the President, in the chair. The honorary gold medal of the College was conferred on Mr. G. Buckston Browne in recognition of his valuable contributions to the surgery of the genito-urinary system, and of his great liberality in the endowment of an institution for surgical research.

A diploma of Fellowship was granted to Alfred Richard Denis Pattison, of Durham University. A diploma in gynæcology and obstetrics was granted jointly with the Royal College of Physicians to Wallace Freeborn, M.B., Sydney. Diplomas of membership were granted to 161 of the 164 candidates whose names were given in our issues of May 9th and 16th (pp. 1059 and 1113) as recipients of the L.R.C.P. (excepting Inez E. Banner, W. Dodd, and Margaret M. White). In our previous list the names of S. G. Cimmering, G. I. Culank, and Lena Finkelstein should have been given as now printed.

The President reported that a vacancy on the Court of Examiners, caused by the retirement of Mr. L. Bathe Rawling, would be filled up at the meeting of the council on June 11th.

The Huddersfield Royal Infirmary was added to the list of hospitals recognised for the 12 months' surgical practice required of non-members before admission to the Final Fellowship Examination.

Royal College of Surgeons of Edinburgh.

At the last meeting of the College, with Dr. J. H. Ferguson, the President, in the chair, the following 23 candidates (out of 83 entered) who passed the requisite examinations between Jan. 5th and 13th were admitted to the Fellowship.

William Alistair D'Arcy Adamson, M.B. Edin.; Sundar Singh Ahluwalia, M.B. Punjab; George Lionel Alexander, M.B. Edin.; Alec Letts Dawkins, M.B. Adelaide; Harold Edmund Emmett, M.B. Manch.; Eric Leslie Farquharson, M.B. Edin.; Gerard Joseph Hanley, M.B. N.U.I.; Robert William Hendry, M.B. Aberd.; Richard William Johnson, M.D. Melb.; Isaiah Kallmeyer, M.B. Witwatersrand; Charles Herbert Leedman, M.B. Melb.; James Fraser Macdonald, M.B. Edin.; Leonard George McQueen, M.B. N.Z.; Bruce Toomba Mayes, M.B. Sydney; *Stanley James Granville Nairn*, M.B. Edin.; Belinda Elizabeth Nesbitt, M.B. Belf.; Papatla Pattabhiramaiya, M.B. Madras; Alan Alexander Pullar, M.B. N.Z.; Ian Monro Robertson, M.B. Edin.; Kenneth George Ward Saunders, M.R.C.S. *Eng.*; *William* George Eric Shand, M.B. N.Z.; George Drury Shaw, M.R.C.S. Eng.; Wilfred Charles Wickremesinghe, L.M.S. Ceylon.

The Bathgate memorial prize, consisting of bronze medal and set of books, was after a competitive examination in materia medica awarded to Norman Walter Nisbet.

Glasgow University Club, London.

This club is to hold its annual summer dinner at the Café Royal, Regent-street, at 7.30 P.M., on Friday, June 12th. Prof. Gilbert Murray is to preside. Any Glasgow University men who, though *not* members of the club, would like to attend are requested to communicate with the hon. secretaries, 62 Harley House, N.W. 1.

Committee on Welfare of the Blind.

In view of the continued development in work among the blind, owing to the operation of the Blind Persons Act, 1920, and the Local Government Act, 1929, and the new problems constantly arising in *connexion with this* service, the Minister of Health has reappointed the Advisory Committee on the Welfare of the Blind for a further period of office. The Committee has been *constituted* so as to afford representation to the local authorities concerned with the working of the Blind Persons Act, 1920, and to voluntary associations for the blind, as well as to organised blind workers. The Chairman is Lord Blanesburgh, and the members include Dr. Alfred Eichholz, Dr. S. J. C. Golden, and Dr. J. Middleton Martin. The Committee will advise the Minister on matters relating to the care and supervision of the blind, including any question *that* may be specially referred to them by the *Minister*. Mr. F. M. Chapman, of the Ministry of Health, will act as secretary.

University of London.

The Goldsmiths' Company has decided to offer, subj to the consent of the *Charity Commissioners*, which probably have to take the form of a scheme under Charitable Trusts Acts *confirmed* by Parliament, subject to certain other conditions, a sum not exceed £50,000 towards the cost of erecting and equipping library building of the new headquarters of the Univer in Bloomsbury. The University library, at present hou in the Imperial Institute, South Kensington, contains 260,000 volumes and pamphlets.

Congress of Comparative Pathology.

The second international congress of comparative pat logy will be held at the Paris Faculty of Medicine Oct. 14th to 18th, under the presidency of Prof. C. Acha Membership is open to doctors, veterinarians, and phy pathologists, and national committees have been constitu in participating countries.

Liverpool Medical Institution.

The fourth Hugh Owen Thomas memorial lecture will given in the Medical Institution at 4.30 P.M., on Thurs May 28th, by Mr. D. McCrae Aitken. His subject will "Principles of Rest and Exercise in the Treatment Joints."

University of Belfast.

It has been decided that the honorary degree of D. shall be conferred on Dame Louise McIlroy, professor obstetrics and gynæcology in the University of Lond Mr. Joseph Barcroft, F.R.S., professor of physiology in University of Cambridge, Maj.-General J. W. D. Meg director-general of the Indian Medical Service, and Hugh Hampton Young, professor of urology in Joh Hopkins Hospital, Baltimore.

Sweepstakes for Hospitals.

The governors of the Royal London Ophthalmic Hospi City-road, have ascertained the opinion upon the desirabi of sweepstakes for hospitals of those who contributed to i funds last year. Of those who answered, 59 per cen were opposed and 41 per cent. were in favour. Many o the latter based their assent on the ground that abnorm times justify abnormal methods; others agreed conditi ally that no loss of ordinary contributions would involved.

Hospital Out-patients.

The conclusions and recommendations of the Counc discussed on April 28th at a special meeting of th St. Pancras Division of the British Medical Associatio (see THE LANCET, May 2nd, p. 1001), were carried 14 votes to 9 at the annual general meeting of the divisi on May 12th.

Ladies' Medical Golfing Society.

The spring meeting was held on May 14th at Northwood Golf Club, Middlesex. The results were as *follows*:— Canny Ryall Challenge Cup: Mrs. Gordon Holm 90–19=71. Scratch prize: Miss M. Lett, 86. Handi prizes: First Division, 1st, Mrs. de Paula; 2nd, Mrs Ritchie. Second Division, 1st, Miss A. Bristow; 2nd, Mrs J. Gibson. Third Division, 1st, Miss S. Dudgeon; 2nd, Mrs Perry. Flag Medal Foursomes: 1st, Mrs. Gordon Holm and Mrs. Russell-Smith (beyond 20th hole); 2nd, Mrs Oldershaw and Mrs. Burn (19th hole).

University of Dublin.

The usual three weeks' post-graduate course for general practitioners will be given this year in the School of Physic Trinity College, and at certain clinical hospitals in Dublin from Sept. 14th to Oct. 3rd. Sir Edward Sharpey-Schafe will give the first John Mallet Purser lecture on June [illegible] in the medical school and has chosen for *his subject* The New Physiology. This lectureship was founded by Miss Sarah Purser in memory of her brother who held the chair of physiology in Trinity College and *was later* Regius professor of physic in the University. The lecture will be open to all medical practitioners and medical students. Among those who are to receive honorary degrees at the summer commencements, to be held on July 3rd, is Prof. Ariens Kappers, director of the Brain Research Institute at Amsterdam. Dr. Kappers has promised to give three lectures when he comes to Dublin for the ceremony, Sir John Rose Bradford, F.R.S., ex-President of the Royal College of Physicians of London, is to receive an honorary degree on the same day.

NOTES, COMMENTS, AND ABSTRACTS

EUGENIC STERILISATION.

EXPERIENCE IN CALIFORNIA.

THE fact is well known in this country that it is in alifornia that the experiment of eugenic sterilisation s been carried to the fullest lengths. A semi-opular book entitled Sterilisation for Human etterment,[1] describing the experiences of various merican States, was published in 1929 and briefly viewed[2] in our columns at the time. The original pers from which this summary was made have been llected in a single volume and are now available.[3] Up to Jan. 1st, 1930, a total of 10,877 operations r eugenic sterilisation had been performed in merica. Of these, 6787—nearly two-thirds of the tal and more than ten times as many as in any her State—were done in California. In several ates sterilisation laws have been passed and for rious reasons repealed. Of these reasons the mmonest has been that when compulsorily applied e measure is incompatible with the principles of dividual liberty which are laid down as the right every American citizen. There was in fact some certainty as to whether laws passed by separate ates might not be superseded by the Federal laws. 1927 however the question was settled in a anner satisfactory to advocates of eugenic steri-ation by a case from the State of Virginia which s carried through the Circuit Court to the Supreme urt of the United States, where the judgment of the rginian Court was confirmed by Mr. Justice Holmes.

THE QUESTION OF PROMISCUITY.

It has frequently been urged in opposition to the inciple of eugenic sterilisation that such a measure ould lead to an increase of promiscuity and to a ssemination of venereal disease. The results of the lifornian experiment indicate that this expectation not borne out when sterilisation is combined with thorough programme of parole and social after-care. questionaire relating to the effects of sterilisation on xual behaviour was sent to parole and probation ficers of the State and to the secretaries of associated arity organisations. These yielded 22 replies vering a total of 2154 women who had been observed om periods ranging up to 14 years, some of the ses being duplicated. In this series there were only lf a dozen instances in which the operation was ought to have contributed to sexual misbehaviour. o instances were observed amongst 3000 sterilised ales. The findings as a whole, it is claimed, compare vourably with those of other investigations of roled patients who have not been sterilised. The nclusions of the investigation are summarised in e following words:

> Under the conditions in which sterilised feeble-minded tients have been paroled in California, such parole does not nd to increase the amount of promiscuity in the popula-on, but greatly decreases it. The possibility of the spread venereal disease is decreased to a corresponding degree.

his contention is substantiated by a further claim that arriage without the responsibilities of parenthood exerts a stabilising influence upon defectives. Referring to a series of 124 marriages of defective girls whose course has been observed, the following statement is made:

> Had these girls not been sterilised, and had they promptly become mothers after marriage, it is not likely that so large a percentage of successes would have been recorded. Many of them who have the capacity to fulfil such responsibilities as wifehood involved in this social stratum would lack the capacity to take care of a steadily increasing number of children even if the husband were able to support the family. Unquestionably many of them, in view of their mental and emotional equipment, are not well qualified to bring up children successfully. On the other hand, freedom from childbearing enables these deficient girls to work outside the home with at least two useful results:—
>
> (1) They add to the family income, so that even if both husband and wife are economically not very efficient their joint earnings are adequate to support them comfortably; *and*
>
> (2) They are kept busy and out of mischief.
>
> Sterilisation, then, seems definitely to be a factor in the success of these marriages.

Stress is laid throughout on the importance of combining the system of parole and after-care with one of eugenic sterilisation.

RESULTS OF MATING.

The mean size of families of persons sterilised in Californian State Hospitals for the Insane is, for married men 1·64 living children, and for married women 2·03; for all men, including unmarried, 0·61 children, and for all women 1·85 children. The following conclusion is added: "In general, no large group of institutional insane in California will produce enough children wholly to reproduce itself even if it were not sterilised, the complete family being only two or three children. (Higher figures have been reported elsewhere.)"

An important conclusion of the recent Mental Deficiency Committee, which in 1929 reported upon the incidence of mental deficiency in this country, was that high-grade defectives were for the most part born of low-grade families which exhibited various forms of anti-social behaviour. The Californian investigation has resulted in a different finding, the discrepancy being probably accounted for by the very different social conditions which prevail in the two places. In the American investigation of the family status of the parents of defectives, no distinction was made between those which gave rise to primary and secondary aments. The *following* conclusion embraces both types:

> The fact stands out prominently that the institution is not kept filled by the progeny of the down-and-outers, the poor-house group, or even the unskilled labourers. It represents all grades of the population.

The following is a conclusion of an analysis of 126 marriages of 28 months' average duration after eugenic sterilisation.

> There was found to be no significant relation between the length of time that elapsed between the girl's first commitment and marriage, and her success in matrimony. This length of time represents the period when she was subject to control and discipline, was learning good habits or unlearning bad ones; it might be supposed that the longer this period of apprenticeship, the better would be her subsequent achievement. But the fact is not so.

The husbands of defective girls were classified in terms of the grade of the occupations of the husbands and a correlation was made between the grade of the occupation of the husband and the grade of defectiveness of his wife. It was concluded that "there is no tendency on the part of the superior husbands—i.e., those of higher Barr rating—to select more intelligent girls who were better behaved prior to commitment."

EFFECT ON INDIVIDUALS.

Histories obtained from 65 normal men who had undergone vasectomy voluntarily, and whose subjective testimony was deemed reliable, showed that the operation resulted in no significant change in their ability to control the duration of coitus or in the frequency or pleasure derived from the act, or in any unusual sense of fullness or discomfort in the scrotum, or in any feeling of distension or lack of complete relief from the orgasm. In 13 of the cases both cut ends of the vas were ligated; in 50 the lower end was left patent, and in two the records are incomplete on this point. Rejuvenating effects claimed by Steinach to occur after the operation were not observed.

The volume contains many other observations of interest and the material is subjected to very thorough statistical analysis. That many of the sociological conclusions are inapplicable to this country is to be expected from the geographically unstable character of the population of California.

AID TO INVALID CHILDREN.

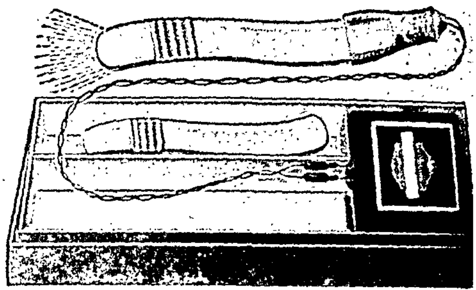
ADDRESSING the annual meeting of the Invalid Children's Aid Association, held at Londonderry House on May 5th, Sir Humphry Rolleston spoke of the value of the Association's work from the point of view of physicians and surgeons. Any doctor who had worked in an out-patient department would admit the difficulty of ascertaining why a particular child was jumpy, why [illegible] could not sleep, what was the cause of its ailing condition. The medical officer of an out-patient department could not go into the homes of his patients and find out the conditions there, but a wise visitor could give him much useful information which would help him in diagnosis and treatment. Social service in connexion with hospital practice had not been sufficiently utilised in this country, and the after-care given by I.C.A.A. workers in the homes was invaluable from the medical point of view. Lord Burnham, who presided, mentioned the satisfactory record of 1930. During the year new cases referred to the Association amounted to 16,023, while old and new cases helped had reached a total of 24,134, more than 7000 children having been sent away to convalescent homes. The Dean of Westminster emphasised the value of the voluntary spirit in work of this nature, and asked for offers of personal service. Mr. Hugh Walpole pleaded for the new areas growing up around London, for the dwellers in rows and rows of little houses all alike, all having about the same amount of means, and far removed from hospital facilities. The I.C.A.A. wanted to extend its work to places of that kind. Mr. Mitchiner went further, and said that families who had gone to live in the new districts had been driven back to London, in order to get the necessary help for crippled or invalid children. A plea for financial support was ably put forward by Dame May Whitty, and the usual resolutions, adopting the report and accounts, electing the council and executive committee for the ensuing year, and pledging the meeting to obtain the necessary financial support, were carried.

NON-STEAMING SPECTACLE GLASSES.

WE have received a pencil of "Clarocit," the function of which is to prevent condensation forming on spectacles. The pencil is to be rubbed with a circular motion on both sides of the lens which is then polished with a handkerchief, when it is claimed that the glasses will remain clear in any atmosphere for a period of at least 24 hours. The makers have testimony from medical men of its value when operating in hot theatres, which we can confirm from other sources. The pencils are made by The Clarocit Co., Ltd., 110, Gt. Portland-street, London, W.

THE "BRILITE" TONGUE SPATULÆ.

AN old method of illuminating microscopic object by means of a bent glass rod which, by internal reflecti conveyed the light from a dark chamber contai a lamp, has now been ingeniously applied t tongue depressor which has been put on the ma



by the Holborn Surgical Instrument Company, 26, Thavies-inn, London, E.C. In this case source of light is a small electric bulb, which concealed in a metal socket into which the gl tongue depressors are inserted. The light is conve along the blade of the spatula and out through end of it, giving a brilliant illumination. Spat can be kept ready sterilised, and a fresh one used each patient. The outfit shown in the illustra which is British made, consists of [illegible] spatulæ, and children's size, respectively, with lamp soc cords,—and battery in box [illegible] ral J. W is ma [illegible] Medical Servic

Births, Marriages, and Deaths

BIRTHS.

BELLAMY.—On May 18th, at Welbeck-street, W., the wife of Dr. W. A. Bellamy, of a daughter.

INNES.—On May 17th, in London, the wife of L. Walrond Innes, F.R.C.S., of Windsor-villas, Lockyer-street, Plymouth, of a son.

McNAIR.—On May 13th, at Welbeck-street, W., the wife of Arthur J. McNair, F.R.C.S., of a daughter.

O'KEEFFE.—On May 16th, at Merstone, Tring, the wife of Dr. C. E. O'Keeffe, of a son.

ROOKE.—On May 12th, at Grove House, Runcorn, to Dr. and Mrs. Rooke—twin boys.

WOOKEY.—On May 13th, at Station-road, Hendon, the wife of Eric E. Wookey, L.D.S. R.C.S., of a daughter.

MARRIAGES.

EVANS—YARDLEY.—On May 14th, at Holy Trinity Church, Brompton, Thomas Charles Jameson Evans, M.A., B.Chir. Camb., to Mary Elizabeth, younger daughter of the late Frank Yardley, M.A., and of Mrs. Yardley, Solihull, Warwickshire.

ORMEROD—MARTIN.—On May 16th, at All Saints' Church, Woodford Wells, Essex, Thomas Laurence Ormerod, M.B., to Margaret Muriel Challis, second daughter of and Mrs. H. C. Martin, of Elm View, Woodford Green.

DEATHS.

BLAKESLEY.—On May 16th, suddenly, Henry John Blakesley, F.R.C.S. Eng., of Severn-street, Leicester, in the of his age.

CLOWES.—On May 10th, at Belsize Park-gardens, Hampstead, Dr. Herbert Alfred Clowes, aged 75.

DOBSON.—On April 29th, 1931, at Burley, Leeds, Dobson, M.D. Lond., aged 85.

GILLIS.—On May 14th, after an operation, Max David Gillis, L.D.S., D.D.S., formerly of South Africa.

GLYNN.—On May 12th, at Bryn Bella, St. Asaph, Robinson Glynn, M.D., F.R.C.P., Emeritus of Medicine, the University of Liverpool, aged

HIGGINSON.—On May 12th, after a very short illness, George Higginson, M.R.C.S., L.R.C.P., R.A.M.C.T., and Hon. Captain, Serbian Army, St. Sava and of the Serbian Red Cross, of Church Stretton, aged 63.

MACCONKEY.—On May 17th, at Lyndhurst, Blindley Heath, Surrey, Alfred Theodore MacConkey, M.B., D.Ch.

MILNER.—On May 12th, suddenly, at Reading, Milner, late of Bere Alston, Devon.

WALLACE.—On May 11th, at Pirbright, Surrey, Robertson Wallace, M.B., C.M. Edin.

N.B.—A fee of 7s. 6d. is charged for the insertion of Births, Marriages and Deaths.

TERNAL DISABLEMENT.*

IR BELL, B.S., M.D. LOND., F.R.C.S. ENG., P.C.O.G., HON. F.A.C.S.,
L AND GYNÆCOLOGICAL SURGEON, ROYAL INFIRMARY, ; AND PROFESSOR OF OBSTETRICS AND GYNÆCOLOGY IN THE UNIVERSITY OF LIVERPOOL.

LECTURE I.

OUGH for many years the obstetrical world ose boards and government departments which ncerned with the health of civilised nations roduced statistics, reports and memoranda to maternal mortality, isolated remarks only ound publicity regarding maternal disablement. at over 3000 women die annually in England and Wales, and that they die in similar or in even ster numbers in other countries, as the result of ations associated with childbearing is a distressing, it seems, that other eventualities otten, or are relegated to the background as lesser importance. It is generally believed aternal deaths are largely preventible, and be prevented. How much truth there is in sertion it is not my task to analyse to-day; may, perhaps, say that, since those deaths are where there should be rejoicing in the tion of a natural event, it comes about at even though the mother escape with her life ter grave difficulties have arisen, this happy issue liable to obscure subsequent disabilities which rsist, sometimes to "dog her footsteps" for life, metimes causing little immediate discomfort, yet ading to her death many years later. It is the gent, the dramatic, that affects: the long-drawn-out too often regarded as inevitable—a pleasing ternative to "something worse." So it is that each ar at least 60,000† women—that is, 10 per cent. of l mothers—are more or less crippled (for this is hat "maternal disablement" means) as the result childbearing.

It has seemed well, therefore, to explore as far as is t present possible this further burden of our women-ind—chronic ill-health, continued suffering, and, erhaps at some remote time that separates it from e immediate cause, death—in the hope that if ttention be focused on this pathological aspect of aternity some serious consideration may be devoted o organised prevention and treatment. With the ssistance of my gynæcological friends, I have had vestigations made—necessarily of a limited number f cases—to discover, so far as possible, the proportion f all parous women presenting themselves for reatment of lesions due to pregnancy and parturition r exacerbated thereby, in comparison with those uffering with other gynæcological disorders. Out of 275 consecutive parous women recently examined n the gynæcological out-patient department at the Royal Infirmary, Liverpool, no less than 775—that s, 34 per cent.—had lesions, constitutional or local, which were directly attributable to pregnancy and parturition and caused disablement. I am much indebted to my house surgeon, Mr. Arthur Bell, who collected these figures and made a full analysis of them. Unfortunately space forbids inclusion of the complete statistics here.

Such figures do not, of course, give an exact estimate of the damage that results from the exercise of the natural functions of reproduction. On the one hand, they represent only the more serious for which women seek advice; and, on the other, until we have standardised records of a number of pregnancies and labours of all kinds, with postnatal details—such as might be possible under an efficient national scheme—we shall never be able to obtain exact records of disablement, especially of that type of which the patient is ignorant or which she tolerates, for example, laceration of the cervix, a lesion that in the long run may be of vital importance.

It cannot be too clearly emphasised, as I have insisted elsewhere,[4] that the reproductive functions and processes are dependent on a woman's individual metabolism, and therefore are associated with her physical and mental functions. So it comes about that pre-existing pathological conditions may be accentuated, or lesions may be initiated by gestation, parturition and the puerperium.

It will be convenient first to group our remarks under these two heads, although there must obviously be some overlapping, and then briefly to touch upon the sociological aspects of motherhood, in so far as they affect maternal disablement, and on some of the general principles of prevention and treatment. Last of all, I shall venture to suggest an efficient organisation for the avoidance and alleviation of these disabilities, as well as for the reduction of maternal mortality.

In order to avoid repetition in regard to those lesions which may not only be pre-existent and adversely influenced by pregnancy, parturition, and the puerperium, but may also be brought into existence by these natural functions, it will be better to consider them at one and the same time.

Conditions made Worse or Initiated by Maternal Functions.

NERVOUS DISORDERS.

I shall make no attempt to separate the neuroses from the psychoses, for no doubt some of the former are partly dependent on loss of higher control—for example, chorea.

The most important true psychical disturbances are mental shock and puerperal insanity. The causal factors of these two conditions seem to be entirely different.

Mental shock is traumatic in origin, and resembles the state sometimes produced by a severe surgical operation. Crile and Lower[5] have shown that changes in the cells of the higher centres in the brain are visibly affected by severe trauma, when histologically examined, and that recovery may be slow. This condition is somewhat rare owing, no doubt, to the natural adjustments of the maternal mentality to the ordinary and inevitable unpleasantness and pain of parturition. It is only to be expected, however, that with the evolution of the human mind, and the apparently increasing difficulty of parturition, the mental resilience should occasionally be overwhelmed. Indeed, we should be glad, even though surprised, that this is not commoner. When the disaster occurs, it is seen, almost invariably, after the first confinement, and the condition may lead to serious consequences. The patient loses her *joie-de-vivre* and becomes apathetic. Towards her husband she becomes indifferent, and though she often has the normal maternal love for her child, she definitely

† No exact figure can be given, but the statistics obtainable, and the yearly proportion of primigravida (1 1 : 4), make 60,000 a moderate figure in this connexion.

5622

Y

avoids, if she can, further conception. Her bodily health may be quite satisfactory.

This condition is, I think, rarely seen when the pains of labour have been adequately controlled by anæsthesia. It almost always follows prolonged labour with severe pain borne, perhaps, with fortitude by a woman of high mental development. It is clear that if this tragic event were of more common occurrence the case for anæsthesia, at any rate in primigravidæ, would be made even stronger than it is at present.‡

Whereas mental shock may occur in an apparently healthy woman with no psychopathic family history, it is otherwise with *puerperal insanity*, for it is found that in about half of all such cases the patient has an hereditary psychical taint. Yet it is believed, almost universally, that there is always a determining factor of a toxæmic nature, such as that produced by a bacterial infection or chemical auto-intoxication, with which eclampsia may have been associated.

Puerperal insanity is not uncommon, for it has been found in one case in every 616 labours by H. J. Berkley,[5] and in one in every 1100 labours by R. Jones.[16] The disturbance, accompanied as it often is by homicidal and suicidal tendencies, is well worthy of more attention than is usually given to it, especially when we remember that some 30 per cent. of the patients fail to make a complete recovery, and that 15 per cent. die. Since this condition usually supervenes on a toxæmia in women with a psychopathic family record, it is of great importance that the psychological history should always be included in the antenatal history.

Of the neuroses we need only consider here *chorea gravidarum*. In this serious disturbance a past history of rheumatism, with or without chorea, in childhood is obtained in a majority of the patients, according to French and Hicks.[10] Wall and Andrews[23] concluded that strain and worry play a large part in the causation. The onset in half the cases is during the first three months of pregnancy, and the commonest age appears to be between 19 years to 24 years.[7] As Fletcher Shaw[22] states, chorea, which is probably of toxic origin, occurs in girls and young women at age-periods of irritability and instability. In patients in whom a maniacal psychosis develops death generally supervenes.

CARDIAC, VASCULAR, AND HÆMATOLOGICAL LESIONS.

Pre-existing lesions in this sytem are nearly all adversely affected to a greater or lesser degree by pregnancy and parturition.

The subject of *heart disease* in pregnancy and parturition is one which has received much attention at the hands of cardiologists since Mackenzie[18] first so carefully studied this question. The most recent contributions to the subject in this country are those of John Hay and of Crighton Bramwell. In 1928 Hay and Hunt[14] published a paper on Pregnancy and Parturition in Patients with Crippled Hearts, in which they described an investigation of 50 consecutive cases. Of these five died: all had mitral stenosis, two with slight aortic regurgitation, and in one there was auricular fibrillation and a "large white kidney." These authors call attention to the gravity of associated renal damage. Crighton Bramwell[6] recently based a paper on the study of 82 cases in which heart disease was associated with pregnancy. These were derived from 3000 antenatal patients, and three who had been sent as emergencies—that is, about 2·7 per cent. of all cases of pregnancy attending an antenatal clinic. Of the 82 patients five died. Bramwell was able to follow 66 of the women who got over the confinement safely, and found that in three at least the cardiac condition had been made much worse by pregnancy and parturition. Consequently about 10 per cent. of these patients lost their lives or were permanently disabled.

Leyland Robinson[20] has published an account of 18 cases of heart disease with auricular fibrillation, of which as many as 13 proved fatal as the direct result of parturition. These cases did not receive adequate, if any, antenatal care.

Arising out of this brief summary of recent work on heart affections and pregnancy, coupled with my own experience, I think it is clear that mitral stenosis, with and without aortic regurgitation, and especially when associated with auricular fibrillation, is a very grave disease in pregnancy. I myself have been impressed by the liability to a very sudden break in compensation during gestation without any warning—and this even though the patient be in bed and in hospital. Moreover, it is obvious from such figures as those of Robinson that uncared-for cases with fibrillation have but a small chance of surviving parturition. Renal complications add to the danger, and these may be due to a toxæmia of pregnancy. The greatest antenatal care with rest and good nursing seems to afford the best chance for these patients. The question of the artificial termination of pregnancy by induction or Cæsarean section may require consideration in many cases, but each must be judged on its merits. One advantage Cæsarean section with spinal anæsthesia offers over induction of labour is the opportunity for sterilisation. Whether any patient seriously crippled in this way, and further crippled by pregnancy and labour, should be allowed to face another conception in her disabled state is not difficult to determine.

Vascular lesions to which pregnancy may be assigned as an aggravative and also a causal factor are arterio-sclerosis following renal disease, pre-existing or the result of pregnancy toxæmias, and varicose veins of the lower extremities, the vulva and rectum. The former may, after the patient has passed a life of invalidism lead to death, and the latter may prevent a working woman from carrying out her duties.

Hæmatological disturbances, apart from secondary anæmia from excessive loss during parturition, need no consideration here. Stress must, however, be laid on the serious ill-health that may be associated with secondary anæmia in mothers, especially those of the working classes.

RENAL AFFECTIONS OF TOXIC ORIGIN.

Renal affections, whether due to a pre-existing nephritis or to a toxæmia of pregnancy, with or without the supervention of eclamptic seizures, are a very grave complication of pregnancy, not only in respect of the first gestation, but also because recurrence in subsequent pregnancies is likely; and, as we have seen, lesions of the kidneys militate against the chances of the mother when associated with cardiac abnormalities.

James Young[28] has found that severe toxæmias, with albuminuria and eclampsia, recur in 31·9 per cent. of subsequent pregnancies with added risks; and that if recurrent toxic albuminuria without eclampsia be superimposed the percentage of similar disability in subsequent pregnancy is raised to 57 More recent unpublished figures with which Dr mes Young and Dr. Elsie Crowe have kindly pplied me, show that the incidence of toxæmia 7790 patients examined in routine antenatal inics in Edinburgh is 6 per cent. of unselected cases that is, excluding those which are specially referred r this condition—and that about 40 per cent. of ese require admission to hospital. Further, they ve found that of 96 cases of pre-eclampsia and cases of hypertension, watched for an average me of eight months following childbirth, apparent covery took place in 40 per cent., and there was bsequent impairment in 60 per cent., and that the latter in 37·5 per cent. their health was shattered." In recurrent toxæmia there was impaired ealth in 73·5 per cent. of all patients, including shattered" health in 58 per cent.—a very high isability-rate. When eclampsia supervened there as subsequent impairment of health in 63 per cent. f the patients, including "shattered" health in 4 per cent.

---

‡ I shall not refer here to the important condition known as obstetrical shock, which has recently been ably discussed by Miles Phillips, for this resembles ordinary surgical shock and is usually followed by death or recovery, and not by disablement.

A general average of all forms of disability due to xæmic causes, including associated accidental æmorrhage, in a total of 151 patients showed that 0 per cent. of all patients suffered with impaired ealth, a figure which included 31 per cent. with shattered" health.

Greenhill[13] found that 43 per cent. of a series of omen who had suffered with eclampsia were again fflicted with a similar condition in a later gestation. ibberd[11] noted that in 28 cases of albuminuria here was a toxæmia subsequently in 68 per cent. f those who conceived. Moreover, Gibberd states hat chronic nephritis may arise *de novo* as a sequel albuminuria of pregnancy. The frequency with hich this permanent damage occurs is stated to be 7 per cent. of all cases of albuminuria of toxæmic rigin. It is only to be expected, therefore, that the oman who already has chronic nephritis comes to regnancy damaged, and is likely to suffer further amage, with cardiorenal embarrassment, as the esult of additional stress produced by this function, f nothing more tragic occurs.

Prof. F. J. Browne, also, has been good enough to urnish me with some interesting and instructive igures on this subject. Of 38 patients suffering with clampsia or pre-eclampsia, 16 have subsequently hown evidence of chronic nephritis—that is, 42 er cent. Of 60 patients with albuminuria of regnancy eight had chronic nephritis—that is, 13 er cent. But of ten cases of accidental hæmorrhage, n none was chronic nephritis subsequently found. An insufficient number of Prof. Browne's cases have ubsequently become pregnant to allow conclusions o be drawn concerning the frequency of the recurrence f toxæmia in this series. We have, however, once nore evidence of the serious renal damage which is aused by severe toxæmias of pregnancy.

HORMONOPOIETIC SYSTEM.

Since there appears to be what I have described[2] as a "genital system of ductless glands" on which are dependent all the sexual functions, it is easy to nderstand that pregnancy may initiate derangements or influence pre-existing lesions in any member of this system. The chief organs with which we are concerned in this connexion are the thyroid and the pituitary. Concerning the other organs of internal secretion which may also be involved, for example, the ovaries and suprarenals, we have no evidence that they are directly and alone affected.

The Thyroid.—The clinical types of lesions of the thyroid with which all are familiar, are the toxic, including the exophthalmic goitre, the hyperplastic, and the hypoplastic. There is a certain degree of normal enlargement of the thyroid during pregnancy. This appears to be due to hyperplasia and increase in the colloid secretion. Sometimes the enlargement is considerably in excess of the normal and Bignami—quoted by Whitridge Williams[27]—has recorded a case in which this occurred in a first pregnancy, after which retrogression took place. In her second pregnancy the condition recurred, and the patient died of suffocation. I have recently seen a patient in whom exophthalmic goitre originated during pregnancy, but was greatly relieved by treatment with X rays, although a neurosis has persisted.

There is no difference of opinion concerning the exacerbation that may occur in goitres of toxic nature during pregnancy. Clifford White,[24] in 1911, in a critical review concerning exophthalmic goitre and pregnancy, labour and the puerperium, concluded that:—

> "Pregnancy is an important factor in the ætiology of the disease, and on the whole makes it worse. The patients may pull up lost ground towards the end of pregnancy, but are again made worse by the labour in a good many instances. Improvement during the puerperium is usual, and occasionally even a cure may take place. Relapses during subsequent pregnancies are to be expected."

White says nothing about fatal issues which have not been uncommon; but he calls attention to the liability to postpartum hæmorrhage. Seitz[21] in 1913 collected 112 cases of exophthalmic goitre of various grades, and noted aggravation in 60 per cent., and a fatal issue in seven patients.

Atrophy of the ovaries with superinvolution of the uterus has been noted in cases of thyroid disturbance, but may occur independently of recognisable lesions in that organ: I have seen a certain number of cases of this kind, and two are to be found among our 775 cases of maternal disablement. The condition is sometimes described as "lactation atrophy," and has, therefore, been observed when lactation has been unduly prolonged, as is sometimes practised in the poorer classes in the hope—often falsified—that conception may thereby be prevented.

The *pituitary*, as has long been known, shows great activity in the anterior lobe in pregnancy.[3] This may lead to symptoms and signs of acromegaly with glucosuria, and be followed by sterility and by a permanent change in the appearance of the woman.

Pancreas.—Although glycosuria occurs in the last few weeks of pregnancy as the result of the formation of lactose for mammary excretion, this should not be mistaken for glucosuria, which is seen only with disturbances of the pituitary and pancreas. I have already referred to the pituitary, and there should be no difficulty about the diagnosis of true diabetes.

Pancreatic diabetes is usually held to be a most serious complication of pregnancy. Williams[26] states that of 66 cases which he had collected from the literature, 27 per cent. of the mothers died at the time of labour or within two weeks afterwards, while a further 23 per cent. were dead within two years of the confinement. There is, moreover, the greater predisposition to infection[17]—a liability borne by all diabetics. Modern treatment with insulin and by dieting has to some extent reduced the danger of diabetes in pregnancy, but it is still one of the most serious constitutional complications.

BACTERIAL INFECTIONS.

Although pregnancy, parturition, and the puerperium are all responsible for the aggravation of chronic bacterial conditions, and may even determine adversely the outcome of acute infections, such as pneumonia and infective endocarditis, the local infections that may appear in the puerperium are nearly always due to the artificial introduction of organisms. In a few cases, however, the local lesions may be associated with septic infections of the ears, teeth, and elsewhere: this is known as auto-infection. These local infections we shall consider later. Infection from the vagina should not be regarded as auto-infection.

In the category which we are now studying I shall mention only chronic infections of the teeth, including caries, tuberculous lesions of the lungs (phthisis), and those of the urinary tract.

Dental lesions are of great importance, and a proper examination and hygienic treatment of the mouth is most necessary in practically every case during the antenatal period. As I have just stated, untreated dental infections may lead to puerperal sepsis, and, short of this, the mother may subsequently suffer the loss of teeth no longer amenable to conservative treatment.

Apart from infections, or superadded thereon, is the very common type of caries that is associated with gestation. This appears to be chiefly due to a disturbance of the calcium metabolism, which, in a sense, is normal to pregnancy. Throughout the whole nine months of gestation calcium is urgently required by the mother as an alkaline base to prevent acidosis, for cardiac and nervous stability, and for the integrity of her skeletal—including dental—structures. Too rapid and too great depletion may, and not infrequently does, lead to serious consequences in all these respects.

Depletion from the maternal tissues is due to the demands of the developing fœtus. Since the child obtains from the maternal blood about 70 g. of calcium in all, it appears that the mother must part with an average amount of 0·25 g. per diem throughout gestation, but probably as much as 0·6 or 0·7 g. per day during the last eight weeks, and less than 0·25 g. in the early weeks of pregnancy.

Dental caries must be considered both as to prevention by an ample supply of calcium to the expectant mother in milk or in other vehicles, and to treatment by temporary fillings, for it is a very common and most important antenatal disorder. Disregard of this condition leads to much subsequent ill-health, and sometimes to the mutilation of good looks.

Pyelitis and Cystitis.—According to Williams, Murray and Wallace,[25] between 25 and 42 per cent. of all gynæcological patients harbour in their urine colon bacillus; and no doubt a few have *Streptococcus fæcalis* also. In normal circumstances, that is to say, when the patient is in good health, these organisms cause no symptom. Whether in these circumstances they produce toxins or not, or how, if toxins be produced, they are neutralised is unknown. When, however, the patient is in ill-health, or when there is local irritation of the urinary organs, cystitis and pyelitis may supervene. Consequently, pregnancy may be associated with pre-existing bacilluria, with or without cystitis and pyelitis, and may aggravate these conditions or initiate them, by mechanical pressure, which may be very considerable with a retroverted gravid uterus, or by a lowering of the general resistance of the patient.

Pyelitis, the graver lesion, is far more common in pregnancy than is generally appreciated; but it is a complication of, rather than specifically associated with, pregnancy. It is more accurate, I believe, to speak of "pyelitis *in* pregnancy," than "pyelitis *of* pregnancy."

Prof. F. J. Browne has kindly sent to me the following particulars concerning 77 pregnant and puerperal patients suffering with pyelitis who were carefully investigated and followed; 41 were discovered in the antenatal period, and 36 in the postnatal. Of the antenatal patients 19 were cured—that is, there was no pus in their urines, and no growths were obtained on culture. Of the rest, 22 in number, 14 continued to have pus in the urine and organisms on culture. The remainder had organisms only. Six of the 41 cases have had subsequent pregnancies, and of these four have shown no evidence of pyelitis. Two have had pyelitis, but in them the condition had persisted between the pregnancies. Of the 36 patients in whom the lesion was discovered in the postnatal period, 20 were cured, and 16 were not cured in the sense given above.

In patients in whom there is persistent bacilluria, subsequent pregnancy, no doubt, as already indicated, may precipitate another attack of pyelitis. However, persistent bacilluria must be regarded in the light already given—namely, that it is present in many women even during pregnancy without producing symptoms, but should be regarded as a source of pyelitis in those whose immunity to the organism is lowered. Immunisation, therefore, should be practised to raise the patient's resistance.

Parturition, during which there may be prolonged pressure on the base of the bladder in the second stage, may so injure the tissues that cystitis supervenes, with or without a fistula forming. It must, nevertheless, be remembered that infection of the urinary tract not infrequently results from impure catheterisation, and that this is most likely to happen in the early days of the puerperium.

It is clear from these few remarks that infections of the urinary tract are often preventible, or may be amenable to prompt treatment.

Phthisis.—The effects of pregnancy and the puerperium on tuberculous lesions of the lungs have received a considerable amount of attention in recent times. In a discussion at the Royal Society of Medicine[10] this year attention was called to the statement of Rist, who recorded 52 cases of tuberculous (pulmonary) women who became pregnant. Of these 85 per cent. were made worse by pregnancy, and 50 per cent. had died within two years. Many other statistics were quoted by the speakers. These figures show that taking a large number of cases of the various types, deterioration occurs in about 45 per cent. of all the patients. It seems that when the disease is in an incipient or active phase pregnancy and the puerperium are dangerous periods; whereas when the disease is in a quiescent or healed condition little anxiety need be felt, provided the patient is well nursed, and is suitably fed in a healthy environment. In most cases, however, lactation should be forbidden, for this function leads to a continuation of the withdrawal of large quantities of calcium salts from the maternal economy—salts which are specially employed in reparative processes in connexion with infective lesions.

NEOPLASMS.

Pre-existing neoplasms, whether in the genitalia or elsewhere, may be considerably affected by pregnancy and parturition.

Malignant Disease.—It is commonly believed, in a somewhat general and vague way, that the growth of cancer is augmented by pregnancy, and this is the view of most clinicians. Although there are many contradictory statements to be found in the literature,[9] there can be no doubt that the matter has never been adequately investigated with proper biological perception. If, as I believe, the tissues of a malignant neoplasm show reversion to the chorion-epithelial type, we should expect that during the early weeks of pregnancy there would be acceleration, to be followed by stasis in the later months, with subsequent reawakening of active growth after parturition. This would correspond with the parental reaction to chorionic invasion; and, in my experience, this is what seems to happen.

We must all have observed the stimulation of a recurrence of mammary cancer by pregnancy—it is a phenomenon surgeons so dread that pregnancy is usually forbidden after operation or abortion effected. It is common to see, also, a great access of growth in a primary malignant tumour early in pregnancy to be followed later by quiescence, and after pregnancy by fresh neoplastic energy.

Innocent tumours, unless they be situated in the genitalia, are unaffected by pregnancy or parturition. Not so those in the genital organs and tract. These may be subjected to mechanical injury during pregnancy and labour, as a result of which sloughing may occur in them. I cannot here deal with the surgical treatment of these conditions; it is designed to prevent such serious consequences.

Degenerations, too, are common in fibromyomata, and may necessitate surgical treatment during or after gestation.

Creation of Local Lesions.

In this group we find the largest number of freshly created lesions due to parturition.

TRAUMATIC AND INFECTIVE LESIONS.

It is difficult to separate trauma from infection, for the latter so often follows lacerations.

At the Royal Samaritan Hospital, Glasgow, ætiological factors are recorded in the annual reports, and we find that in 1928 and 1929 63 per cent. of all the gynæcological lesions observed were due to parturition, and that 69 per cent. of all operations were performed for the lesions attributed to parturitional trauma and its results, and to infection. As, however, in a number of patients—roughly estimative from the difference between the total number of cases and the number of lesions treated—there was more than one abnormal condition present, we may correct the figures to read that about 48 per cent. of all lesions were due to infection and trauma, and that these were included in 51 per cent. of all operations performed—figures not very different from others which are mentioned below.

I am indebted to Dr. R. Newton, resident surgical officer, and to the honorary staff of St. Mary's Hospital, Manchester, for an analysis of the conditions found in 431 parous women presenting themselves in the out-patient clinic. In 185—that is, 43 per cent.—there were lesions attributable to pregnancy and parturition. Of these 185 lesions, 70 per cent. were due to trauma and infections. There were also 19 patients suffering with carcinoma cervicis.

Dr. G. H. Henderson, gynæcological registrar to the General Hospital, Birmingham, has been good enough, at the request of Prof. Beckwith Whitehouse and Mr. A. B. Danby, to send me the result of an examination of the case-cards of 500 parous women attending the out-patient gynæcological clinic at that hospital. From the records he has given me it appears that 157—that is, 31 per cent.—had lesions made worse or freshly created by pregnancy and parturition. Of these 72 per cent. were suffering with lesions due to trauma and infection. There were 11 also with carcinoma cervicis.

At the Royal Infirmary, Liverpool, I find that during the last six years 47·3 per cent. of all gynæcological operations have been concerned with the relief of local injuries and infections. Moreover, of the 775 disablements found in 2275 consecutive parous women (34 per cent.) seen in the out-patient department, suffering with disablement due to pregnancy and parturition, no less than 80·8 per cent. had traumatic or infected lesions. Among the remaining 148, out of the total of 775 cases of maternal disablement and its sequelæ, were 112 cases of carcinoma cervicis, leaving only 36 due to other causes.

These figures are summarised in Table I.

TABLE I.

Hospital clinic.	1	2		3		4	
	Parous women whose case-cards were examined.	With lesions created or aggravated by pregnancy and parturition.		With disability due to trauma and infection.		With cancer of the cervix.	
	Total.	Cases	Per cent. of total.	Cases	Per cent. of cases in Col. 2.	Cases	Per cent. of cases in Col. 2.
St. Mary's, Manchester	431	185	43	130	70	19	10
General, Birmingham	500	157	31	114	72	11	7
Royal Infirmary, Liverpool	2275	775	34	627	81	112	14·5
Total cases and percentages ..	3206	1117	34·5	871	78	142	12·5

Of the 1117 cases of trauma and infection shown in the above Table, only 169 cases—15 per cent.—were recorded as infections apart from cervicitis following laceration.

Disregarding the large number of acute infections, and taking into consideration only those found as subacute and chronic lesions in the pelvis in the postnatal periods, and putting aside infections of the breast and urinary tract, we have obtained the figures shown in Table II. from the total number of 775 cases of maternal disablement:—

TABLE II.

Cervix:	Chronic cervicitis	34
Body of uterus:	Chronic endometritis	2
	Abscess in uterine wall	1
Fallopian tubes:	Chronic salpingoöphoritis ..	74
	Subacute salpingoöphoritis ..	10
	,, pyosalpinx	16
	,, tube ovarian abscess	2
	,, ovarian abscess ..	3
Pelvic cellulitis	.. ..	15
,, ,,	with abscess	1
Pelvic peritonitis	.. ..	2
Thrombosis of pelvic veins	.. ..	2
		162

With regard to the 34 cases of chronic cervicitis shown in this Table, in them this was the only lesion recorded. As already indicated a large majority of all lacerations become in some degree infected, and are associated with other lesions, especially displacements of the uterus and vagina.

It is interesting to contrast with these British figures statistics which Prof. Essen-Möller has been kind enough to send me from Sweden. Out of 1000 consecutive cases confined in 1929, only three have subsequently sought relief for parturitional trauma, that is, 0·3 per cent. Again, out of 1000 consecutive parous out-patients there were but nine cases of trauma and four cases of infection due to parturition, that is, 1·3 per cent. It is true that retroversions and simple lacerations of the cervix are not included in these figures; nevertheless they bear out remarks I shall have to make later concerning obstetrics in Sweden.

Of the local lesions those resulting from trauma are, then, of the greatest frequency and importance. They may be encountered at the time of injury, or at a remote period, when the results of injury and often of subsequent infection become evident. These lesions concern the uterus and cervix, the vagina and adjacent organs—the bladder, ureters and rectum—and the perineum.

Rupture of the body of the uterus, as the result of manipulative interference, is not uncommon, but this catastrophe is related to the maternal mortality rather than to maternal disablement.

Not so, however, with lacerations of the cervix. Here we have an open wound which may become infected at once and cellulitis follow. More often we have the train of symptoms associated with chronic cervicitis, and in some cases the long-continued disablement pictured by James Young,[29] although such a serious state as a result of cervicitis alone is not, I believe, very common. Rather is it the ultimate result that may be serious—namely, cancer of the cervix.

Out of the 2275 parous women examined in my clinic, 139—6 per cent. of all the parous women investigated—had *bad* lacerations of the cervix, often, of course, associated with other lesions, and most of these cervices were infected, but it is probable that there were many more. Of 500 parous women examined in Birmingham, 43 are recorded as having badly lacerated cervices, but probably similar injury occurred in many of the cases of prolapse, but are not recorded. In Dr. Young's clinic in Edinburgh, out of a total of 1214 gynæcological cases, chronic cervicitis with and without other lesions, such as prolapse, occurred in 13 per cent. of parous women.

Still, we have no means of knowing how common are lacerations, especially the minor grades, of this part. It is believed that most primipara have some degree of cervical injury.

CARCINOMA CERVICIS.

In England and Wales about 4000 women die annually of cancer of the cervix alone, of whom at least 3800—that is, 95 per cent.—have borne children. It seems, therefore, that parturition, with cervical laceration and infection, is a very definite predisposing factor of malignant disease in this site—and it is the immediate effect of a single parturition rather than the result of repeated childbearing.[15] §

This annual death-roll should be added to the toll of maternity.

We have interesting and significant evidence of the value of the surgical treatment of the lacerated cervix in the figures published by Prof. W. P. Graves,[12] of Harvard University, and given below.

Cancer of the Cervix in Parous Women.

Number examined	488
Number in which repair of the cervix had been performed	9*

After-history of Cases in which Cervical Repair had been Practised.

Number examined	4815
Number in which cancer had developed subsequently	4†

* Operations performed many years previously and probably with poor technique.

† In two of these four cases there was evidence that the operation had been badly performed.

Strictly speaking, to complete the comparison we require to know also in how many untreated lacerations of the cervix malignant disease does not develop. Such figures have never been obtained and probably never will be, for the patients would require watching for the rest of their lives. Yet I hope the time will come when few lacerated cervices will escape treatment. I called attention to the importance of this over 20 years ago.[1]

As already stated, the large majority of all cases of cervical injury in which surgical intervention is practised are associated with lesions of the vagina and levatores ani, with various types of prolapse, or with puerperal retroversion. These conditions are most crippling, but fortunately are amenable to skilled gynæcological surgery. Fistulæ between the bladder and vagina and rectum and vagina, and complete lacerations of the perineum, also, are not uncommon.

Sociological Considerations.

I shall but briefly touch on the sociological aspect, for it is concerned largely with economic difficulties and with the evils attaching to poverty and ignorance. It is obvious that such conditions are more apparent in large towns than in country districts. Crowded homes, poor feeding, indiscriminate sexual intercourse, especially late in pregnancy, and the absence of personal hygiene and cleanliness are matters for serious consideration.

It goes without saying that the pregnant and puerperal woman needs good fresh food, with fresh air and sunshine. The development of our knowledge of the action of vitamins in relation especially to the anti-infective action of vitamin A, and the influence of vitamin D on the calcium metabolism make it imperative that pregnant women in the antenatal period should be provided with foodstuffs rich in these substances, and also receive daily at least one quart of milk which contains 1·0 g. of calcium in an available form; *this should give an adequate supply* of this essential element. All this is now well known and to some extent applied in connexion with antenatal work; but very often in the antenatal period it is too late to deal effectually with antecedent affections in early life which have seriously handicapped a woman's reproductive capacity.

Prevention and Treatment of Maternal Disablement.

The prevention and treatment of many of the constitutional and local conditions responsible for maternal disablement are difficult matters for, as I have just stated, the causal factors—for example, rheumatism and rickets—often go back to the early life of the woman concerned. In the ideal national health scheme the individual will be watched from the neonatal period through childhood to adolescence; rickets due to unhealthy environment, lack of sunshine, and bad feeding will disappear, and with it a considerable proportion of cases of contracted pelvis; imperfect pelvic development, too, will receive attention; orthopædic lesions of the lower extremities and back will be so managed as to obviate distortion of the bony canal; cardiac lesions will be prevented or treated early, and infections, which may produce permanent constitutional, such as renal, and local pelvic lesions unfitting women for maternity, will also be taken into account from this point of view.

No doubt much else can be done, but these are examples which indicate the necessity of long-continued care in the case of all women, for no one knows which will become mothers, all of whom should be in group A1, not in group C3, in a health classification. I believe that the fact that in Sweden most mothers are sound and healthy accounts almost tirely for the low rate of mortality and disablement that country.

---

§ I am indebted to Sir George Newman for information on this subject.

I hold such considerations to be a most important art of any national maternity scheme, for, as I have ready said, antenatal observation is only of relative lue—great as that is—and postnatal investigations little more than enable us to discover and to repair me of the damage caused by pregnancy and rturition.

With regard to constitutional lesions discovered the antenatal period, there should always be rangements whereby experts can be consulted; many of the conditions are merely associated with egnancy, although adversely influenced thereby. lose coöperation in these matters can be secured ly in a perfectly organised scheme, and in relation large consultative centres. With these matters shall deal in my next lecture.

The prevention of the local injuries and infections, hich constitute at least 75 per cent. of all causes of aternal disablement, at present lies in the hands of te obstetrician and the nurse-midwife. Much can e done by careful antenatal anticipation, but even ore will be accomplished by ensuring the production a healthy maternal population. Meanwhile, good nd up-to-date midwifery must play an important ile. Such disregard as is shown by some of the equency of contraction of the outlet in otherwise ormal pelves, which leads to a large proportion of complete lacerations of the perineum, and such ck of knowledge or appreciation by most of the alue of efficient and proper massage and purification the vagina to prevent laceration and infection in fficult cases, and of *skilled* radiography, are clear dications that even the obstetrician himself may ave mental obfuscations concerning additions to our nowledge. No one of us is free from blame in this spect, and we must realise it in all humility before e attempt to apportion the responsibility for the rrible rôle of disablement that follows in the wake f motherhood.

Summary.

1. While 3000 women die annually in England and ales from the direct results of maternity, probably, t a most conservative estimate, 5000 die from the late sults of childbearing, including cancer of the cervix. hat is to say, more than 8000 women are lost nnually.

2. At least 60,000 parous women, also, are crippled nnually, many gravely, others, though less seriously jured, enough to cause ill-health and disablement.

3. Constitutional disorders form an appreciable percentage of all cases; and *they are more immediately* erious than local lesions, apart from acute sepsis.

4. Trauma and infection are often associated, nd comprise about 75 per cent. of all causes of isablement. In the present conditions with proper reventive obstetrics and by skilled reparative urgery the disablement from trauma and infection ould be much reduced.

5. To mitigate such a state of affairs as that escribed we must go further back than the antetal period, and ensure a supply of healthy mothers y watching women from the neonatal period of life o maturity.

STUDIES ON NUTRITION IN RELATION TO IMMUNITY.*

A PRELIMINARY COMMUNICATION.

BY J. B. ORR, *D.S.O.*, *M.C.*, M.B., D.SC. GLASG.,
DIRECTOR OF THE ROWETT INSTITUTE FOR RESEARCH IN ANIMAL NUTRITION, ABERDEEN;

J. J. R. MACLEOD, M.B., LL.D. ABERD., F.R.S.,
REGIUS PROFESSOR OF PHYSIOLOGY IN THE UNIVERSITY OF ABERDEEN;

AND

T. J. MACKIE, M.D. GLASG.,
IRVINE PROFESSOR OF BACTERIOLOGY IN THE UNIVERSITY OF EDINBURGH.

FROM the earliest times it has been commonly believed that susceptibility to disease is affected by the quantity and quality of the food, and considerable justification for this belief has been afforded by the appalling increases in disease which followed many of the not infrequent famines throughout the ages. Modern work on nutrition with groups of animals on controlled diets is supplying more definite information. It has repeatedly been noted that susceptibility to infections, especially of the respiratory system and intestinal tract, is greater among animals on a deficient than on a complete diet, and such data as are available suggest that a similar connexion between diet and susceptibility to infection exists in human populations.

In studies on experimental animals it has been found that, when the diet is so deficient as to lead to the development of nutritional disease, changes occur in the tissues and body fluids which may be so marked that they can be detected by microscopic examination or chemical analysis. A well-known example is the abnormal level of serum calcium and blood inorganic phosphorus in rickets. These changes, when compared with observations on the incidence of disease in experimental animals on restricted diets, and on human populations under abnormal dietary conditions, afford evidence that the resulting perverted metabolism is accompanied by derangement of the defence mechanisms and reduced powers of resistance to infection.

---

* This investigation was carried out under the supervision of a subcommittee of the Imperial Advisory Council, formerly the Civil Research Council. This subcommittee was appointed by the late Lord Balfour in 1926. On its recommendation a grant-in-aid for the work was obtained from the Empire Marketing Board. A number of workers have been engaged on the different aspects of the investigation. The chief part of the work on the investigation in Kenya was done by the late Dr. J. M. Henderson and Dr. J. W. Foster; the early work on sheep by Major Walter Elliot, chairman of the above subcommittee, and Mr. A. Crichton. Since 1929 the main workers have been Dr. A. H. H. Fraser and Mr. G. J. Jamieson, organisation of sheep experiments and clinical observations; Mr. D. W. Auchinachie, biochemical work; Miss E. J. M. Anderson, serology; Mr. W. A. Carr Fraser, of the Council of Scientific and Industrial Research, Australia, hæmatocytology; and Mr. W. Godden, chemistry of pastures.

Within the last ten years several attempts have been made to put this hypothesis to experimental test, and to ascertain whether derangement of metabolism, due to known defects in the diet, can be correlated with measurable changes in the defence mechanisms. The results of this work show that resistance to induced infection may be lowered on defective diets. So far, however, there is doubt whether deficiencies in the diet affect the antibody forming mechanisms in such a way as can be measured by our present methods.

The present position is thus as follows: it is generally believed that the nature of the diet is a factor in determining susceptibility to disease, and this has been confirmed in animals fed on deficient diets and subjected to incidental or experimentally induced infections. There is, however, as yet little definite information on the relative influence of different dietary constituents or factors in affecting susceptibility. Similarly, little is known regarding changes in the composition of the tissues or fluids of the body or of the normal metabolic processes accompanying lowered resistance. These questions are obviously of the utmost importance in both human and veterinary preventive medicine. Systematic research has little more than begun. There is likely to be in the immediate future a great increase in the volume of work on the many diverse problems being raised, and there is justification to expect that their solution will throw new light on the causation, prevention, and treatment of disease.

Present Investigations.

At the Rowett Institute feeding experiments are carried out with groups of farm animals. It has been noted that the increased susceptibility to infections, especially of the respiratory tract, which seem to develop in small laboratory animals on defective diets, occurs also in larger animals under similar dietary conditions. Such information as could be obtained regarding the incidence of disease in farm animals, on different rationing systems, or on pastures of different composition, have suggested that a similar relationship exists under ordinary farming conditions.

In 1926 arrangements were made for carrying out some large scale observations on this subject on both human beings and animals under field conditions. These observations were accompanied by studies particularly with reference to experimental animals under controlled conditions on the influence of diet on the state of health, on the chemical composition of the blood, and on immunological reactions. The survey on human beings, as originally planned, has been completed. An account of it is to appear in one of the special reports of the Medical Research Council. Hence only a very brief reference to this part of the work is given here. The investigation on farm animals is being continued and developed, and as it progresses papers dealing with its different aspects will be published from time to time. The present preliminary communication is intended to give a general account of the investigation as a whole, with an indication of the nature of results being obtained.

Observations on Human Beings.

A survey was made of the nature of the diet and of the incidence of disease in two East African tribes with very different dietary habits. The diet of one of the tribes consisted chiefly of cereals. The calcium intake was low. The vitamin content of the diet was not determined, but it is probable that there may have been a deficiency of one or more of the vitamins. The diet of the other tribe, consisting largely of milk, meat, and raw blood, though defective in other respects, was rich in those nutrients which were deficient in the diet of the former tribe. Table I. shows the probable average daily intake of the most important food constituents in the diets of the two tribes. It will be noted that the diet of the women is somewhat different from that of the men, and, in the cereal-eating tribe, appreciably better.

TABLE I.

—	Cereal-eating tribe.		Meat-eating tribe.	
	Males.	Females.	Males.	Females.
	g.	g.	g.	g.
Protein	99	140	300	165
Fat	22	20	160	95
Carbohydrates ..	390	400	100	245
Ca	0·28	0·46	2·94	2·63
P	3·0	4·4	4·36	5·19
Na	0·48	0·88	1·80	0·94

g. = grammes.

Samples of blood were obtained from members of the cereal-eating tribe, but owing to a tribal taboo it was impossible to get samples from the flesh-eating tribe on their natural diet. The average calcium content of the blood-serum in 90 natives was 9·4 mg. per 100 c.cm., as compared with 11·4 mg. in 13 Europeans living in the same district. It was found that the addition of calcium salts to the food resulted in a rise in average serum calcium from 9·2 to 10·0 mg. in the case of seven experimental subjects. There was thus evidence that a restricted calcium intake was correlated with a low calcium level in the blood-serum.

A survey of the incidence of disease taken in the native reserves showed that in the tribe with the cereal diet pulmonary conditions, bronchitis, and pneumonia accounted for 31 per cent. of all cases of sickness, tropical ulcers for 33 per cent., and phthisis for 6 per cent., compared with 4, 3, and 1 per cent. respectively in the tribe with the meat, milk, and raw blood diet. In this tribe the chief disease was rheumatoid arthritis, associated with chronic constipation.

The cereal-eating tribe suffered generally from heavy infestation with intestinal parasites. The diet of the women was, on the whole, less deficient than that of the men. It was therefore thought that, if defective diet favoured infestation, a difference might be found in the incidence of parasites as between men and women. An examination of the post-mortem records of 104 serial, unselected cases, showed that infestation was nearly twice as frequent in men as in women, and records of examinations of fæces at the Medical Laboratory showed 74 per cent. of men infected as against only 49 per cent. of women. It is recognised that these observations do not carry the same weight as the results of carefully controlled experiments, but they are in line with veterinary data collected elsewhere.

Owing to the death of the chief investigator in East Africa, the part of the investigation dealing with African natives has been suspended. This pioneer work has given results which warrant further inquiry. The poor physique, high incidence of disease, and the rather rigid nature of the diet in many of the African tribes make them a field of great potential value for the study of the subject.

Investigation on Sheep.

It was decided to carry out the main part of the investigation on sheep. The chief disadvantage in using this animal is the difficulty and expense involved in testing susceptibility to disease by the direct experimental method of induced infection. On the other hand, this animal offers many concrete advantages for the purposes of a research of this nature. Its size and docility allow blood to be drawn rapidly and in large quantity. This is very necessary where a number of biochemical and serological tests are being performed concurrently on the same individual. Further, sheep of standard breed and age are easily obtained, expert practical management is available, and epizoötic diseases do not introduce serious complications as in laboratory animals. Sheep are available in sufficiently large numbers to render statistical data (such as mortality percentages) of value, and at the same time are sufficiently large to admit of correlation between the clinical condition of any particular individual, and the biochemical and serological properties of its blood. On any large scale experiment on sheep, the basal diet must of necessity be pasture. An extensive investigation on the chemical composition of pastures, carried out jointly by the Nutrition Institute at Cambridge and the Rowett Institute, has now been completed.

In using sheep, therefore, the present research becomes a natural sequel to that recently concluded, the focus of interest being merely shifted from natural pastures to the naturally grazing animal. Knowledge obtained is of direct application to an animal of economic importance.

FIELD OBSERVATIONS.

An attempt was made to collect information with regard to the mortality of sheep in districts with pasture of different nutritive value. It was found difficult to get reliable data. Such information as could be obtained showed that mortality was higher on poor hill grazings where the pastures had an abnormally low content of inorganic salts, especially calcium and probably, of course, with deficiencies in other respects. It was recognised that there are other factors affecting mortality besides the probable influence of the amount and composition of the food.

During the years 1926 to 1928 tests were done on various hill farms to ascertain whether the supplementary feeding of substances thought to be deficient in the pastures would be followed by improved nutrition and decreased mortality. Groups of sheep were given from ½ to 1 oz. per head per day of a mixture containing mineral salts, cod-liver oil, and a protein-rich foodstuff. These tests were complicated by the handling of the sheep for commercial purposes, and the data were largely statements by shepherds which could not be checked. Results seemed to indicate, however, that in areas where mortality was high, improved nutrition accompanied decrease in mortality following the supplementary feeding.

OBSERVATIONS UNDER CONTROLLED CONDITIONS.

By 1929 the results were considered sufficiently promising to warrant making provision for work under more exact conditions. A sheep farm, on which the nutritive value of the pasture was low and the mortality high, was taken over, along with the existing stock, so that the workers might have complete and continuous control of the animals.

Clinical.—Clinical observations, including weighings, chemical analyses of the blood for calcium and inorganic phosphorus and various other constituents, certain serological tests, and determinations of the cell and hæmoglobin content of the blood, were made concurrently at intervals throughout the year on sheep under natural conditions on the farm. Similar observations were also made on young sheep which had been removed from the farm to Aberdeen in the autumn, and grazed during the winter on pasture of better composition.

It was found that there was a remarkable progressive decrease in weight during the winter in the young sheep—*i.e.*, those born in the previous spring. Table II. shows the changes in weight in young sheep on poor grazing, compared with those wintered on relatively good grazing.

TABLE II.

Group.	—	Body-weight in lbs.						
		Oct. 5th	Nov. 3rd	29th	Dec. 25th	Jan. 30th	Feb. 13th	Mar. 3rd
A.	Hill pasture	49	49	48	45	39	39	35
B.	Cultivated pasture ..	48	51	54	54	54	52	50

These figures refer to ewe hoggs. Group A were wintered at the experimental hill farm without supplementary feeding. Group B were wintered on arable ground at Aberdeen. Only pasture was fed.

As will be seen below, an interesting parallelism with these changes was observed in certain of the biochemical and serological properties of the blood.

Biochemical.—Chemical examination of the blood showed that in hill sheep on mineral deficient pasture the blood calcium reaches a maximum (11·8 mg.) in summer (July), shows a progressive fall throughout the winter months, to reach a minimum value of 8·2 mg. in the following spring (April).

The calcium content of the pasture showed a similar seasonal variation. The values found on analysis were 0·30 mg. calcium per cent. of dry matter in summer compared with 0·16 mg. in the winter months. This progressive fall in the level of the blood calcium accompanying a progressive reduction of body-weight in animals under ordinary farming conditions is a finding of both scientific interest and economic importance. Experiments at present in progress suggest that both under-nutrition due to lack of food, and malnutrition due to deficiencies of special dietary factors, are involved.

Workers in South Africa have found that in cattle grazing on phosphorus-deficient veldt the inorganic blood phosphorus may be less than 50 per cent. of the normal value. It is obvious that the calcium and inorganic phosphorus content of the blood is not so constant as has been supposed, but that it is directly affected by, and is to some extent a reflection of, the nature of the diet.

Serological.—In this study is was decided, as a first step, to carry out systematic observations on the natural immunity reactions of the blood-serum. The natural lytic, agglutinating, and complement-fixing antibodies of various animals for bacteria were made the subject of detailed inquiry in the Bacteriology

Department of Edinburgh University, and certain serum reactions dependent on these principles were selected in virtue of their known occurrence in measurable degree with sheep serum. The tests were strictly quantitative.

The reactions selected were as follows: (1) hæmolytic action of serum towards rabbit's erythrocytes, which depends on a natural lytic antibody acting along with serum-complement; (2) bacteriolytic effects of serum towards (*a*) *Bacillus coli* (a typical strain), (*b*) *Bacillus suipestifer*, which also depends on natural antibodies acting along with complement; (3) agglutinating effects of serum towards (*a*) *B. abortus* (Hg), (*b*) *B. paratyphosus* B, which are due to natural agglutinating antibodies acting independently of complement. Owing to an initial difficulty in obtaining a suitable hæmolytic system for testing sheep's complement independently of any natural hæmolytic antibody present in the serum, the preliminary observations do not include a direct measure of complement activity.

The serological tests on the hill sheep referred to above elicited most interesting results. In the month of May when, according to clinical observations, the state of nutrition was at its worst, and the calcium level of the blood at its lowest, all the serum reactions were markedly weaker than in sheep of the same breed, age, and sex grazing on a cultivated pasture at Aberdeen. Further, the seasonal changes (from May, 1930, to March, 1931) in certain serum reactions—e.g., hæmolysis—ran parallel to those in body-weight and blood-calcium, and in animals transferred in October from the hill farm to Aberdeen these reactions showed an augmentation in value corresponding to the increase in body-weight and blood-calcium. In view of our limited knowledge of the significance of these reactions, and also of the probable intercurrence of uncontrolled factors other than nutritional which affect them, these findings which are stated here in general terms must be interpreted with the greatest caution. The results indicate, however, that the natural immunity reactions of blood-serum may be markedly influenced by nutritional factors which also affect the chemical composition of the blood.

Hæmocytological—These tests showed great differences among individuals under similar dietary and other environmental conditions, and this must be allowed for in evaluating the data. The figures in Table III. show the averages of 40 sheep taken at random in spring when the condition of the animals was worst, and in summer when the condition was improved.

TABLE III.

—	Mean red cell content per mm.^{3} × 10^6	Mean white cell content per mm.^{3} × 10^3	Mean percentage of hæmoglobin.	Mean percentage volume of packed cells.
May, 1930	7·39±2·02	7·19	64±11·95	25·7±6·2
July ,,	10·23±1·96	8·47	92±11·81	30·8±6·3

So far as the results can be considered as significant, they show that anæmia is one of the features of the malnutrition noted in spring. The study of sheep throughout the year on grazings recognised to be of low nutritional value shows a parallel seasonal variation in the chemical composition of the pasture, the general clinical condition of the animals, and certain constituents and properties of their blood. As yet, however, the data are insufficient to allow definite conclusions to be drawn.

INFLUENCE OF DIFFERENT DIETARY FACTORS UNDER EXPERIMENTAL CONDITIONS.

The pasture on the experimental farm to which the above observations refer is relatively poor in protein and in inorganic constituents, especially calcium. An experiment was done on sheep kept in confinement to ascertain the influence of the addition of calcium, cod-liver oil, and protein, both singly and in combination, when added to a basal diet roughly corresponding to hill pasture in chemical composition.

Eighty castrated male sheep were used, which were about seven months old—i.e., about half grown—at the beginning of the experiment. They were taken from the Institute stock, and had a uniform pre-experimental nutritional history. They were divided into 16 groups of five each, eight groups being kept indoors and the other half in outdoor pens.

At intervals of about a month clinical notes were made; samples of blood were analysed for calcium, inorganic phosphorus, non-protein nitrogen, urea nitrogen, and at longer intervals for fibrinogen, albumin, globulin, cholesterol, and cystine. Serological tests and blood counts were also carried out as described above. The results briefly were as follows.

CLINICAL.

The animals in the indoor basal group after about four months stopped growing and became weak and emaciated. The addition of protein (in the form of cotton-seed meal) apparently led to a prolongation of the growth period, but later signs of bone deformity and debility appeared and growth stopped.

The addition to the basal diet of either calcium or cod-liver oil prevented these results. Growth was most rapid in the groups receiving cod-liver oil. No such clinical differences were obvious in the outdoor groups until a much later date, and even then they never became so pronounced as in the indoor sheep.

In July the animals in basal and basal-plus protein groups indoors were so debilitated that the experiment had to be terminated. These groups, together with all poorly conditioned sheep from other groups, were then transferred to good grazing. This was followed by a remarkably rapid improvement in their condition.

BIOCHEMICAL.

The only biochemical data considered here are those referring to the calcium and inorganic phosphorus of the blood.

The pre-experimental average figures were calcium 11·45 mg. and inorganic phosphorus 5·11 mg. Table IV. illustrates the marked extent to which blood-calcium and phosphorus may be influenced by dietary factors. The figures refer to the outdoor groups in March, when no clinical differences were as yet appreciable.

TABLE IV.—*Blood-calcium and Inorganic Phosphorus.*

mg. per 100 c.cm.

	Calcium.	Phosphorus
Basal	7·06	10·53
,, + protein	6·46	11·32
,, + calcium	9·90	6·84
,, + C.L.O.	10·06	7·99
,, + protein + calcium	8·80	7·83
,, + protein + C.L.O.	9·35	7·78
,, + calcium + C.L.O.	9·66	6·72
,, + protein + calcium + C.L.O.	9·54	6·93

The figures show that there was a marked fall in the calcium in the basal group, accompanied by a marked rise in inorganic phosphorus. The addition of either calcium or cod-liver oil tended to maintain the normal levels of calcium and phosphorus in the blood.

In the indoor groups the general trend of the figures was similar as regards calcium, but the reciprocal rise in phosphorus was not observed.

Table V. illustrates the regulatory effect of cod-liver oil or lime in maintaining normal blood-calcium and phosphorus levels in the outdoor groups.

TABLE V.

mg. per 100 c.cm. blood.

—	Calcium.		Inorganic phosphorus.	
	January.	March.	January.	March.

Animals, from other groups receiving either calcium or C.L.O. or both	10·9	9·5	5·3	6·9

SEROLOGICAL.

In this preliminary communication only those data which seem of most interest need be referred to. Individual animals, as might be expected, showed quantitative variation in their reactions, and the values for the animals in each group were therefore averaged. The number of animals in a group was small, and any differences, unless pronounced, were not regarded as significant. It is noteworthy, nevertheless, that these averages in the pre-experimental stage were on the whole remarkably uniform.

During the course of the experiment significant variations in the average values for certain of the reactions were observed. These were related to: (1) the time of the year, (2) environment—according to whether the animals were kept indoors or outdoors, (3) the nutritional groups, (4) transfer to grass towards the end of the experiment.

Seasonal Variations.—To estimate this the average values of all the animals were taken. The bacteriolytic effect towards *B. coli* rose to a maximum in March, and fell progressively in May and September. A similar curve was noted in the hæmolytic reaction and in the agglutination of *B. abortus*. In the case of *B. paratyphosus* B agglutination the seasonal curve was different: rising to a maximum in January, and then falling progressively in March and May, but rising again to a second maximum in September. Such seasonal fluctuations are of great interest from a physiological standpoint, and require a good deal of detailed investigation before any interpretation can be placed on them. It is obvious that they introduce a factor which must be allowed for in any study of serum reactions in relation to nutrition. It should be noted also that these seasonal changes do not show any parallelism with the general condition of the animals or the results of chemical examination of the blood, though such seasonal parallelism was observed among animals on the hill pasture.

Environment.—A marked difference was elicited between the indoor and outdoor animals in their bacteriolytic reactions towards *B. coli*. In January the average for the indoor animals was about twice that of the outdoor groups; this difference became greatly accentuated in March. In May and September, the divergence was less. A somewhat similar, although less marked, difference in March was noted as regards the hæmolytic reaction. On the other hand, in the agglutination of *B. abortus* the outdoor animals showed a higher average value throughout.

Nutritional Groups.—In certain reactions distinct group differences were noticeable at particular periods; in other cases differences were insignificant.

Bacteriolytic Action towards *B. coli*. Groups 4 and 8—i.e., animals receiving added calcium and cod-liver oil in their rations—exhibited the highest averages in the early part of the year; after this there were no significant differences.

Hæmolysis. In January and March, Group 8 showed the highest values. Among the outdoor animals, in January the average values of the groups deficient in protein (1 to 4) were noticeably higher than those receiving protein in their rations (5 to 8). In March, however, the position was reversed: the values for Groups 6 to 8, and especially 8, had risen, whereas in Groups 1 to 4 there was a conspicuous fall.

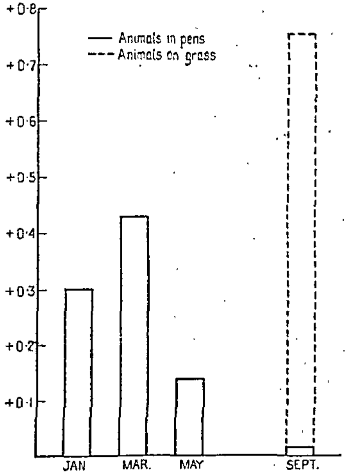

Chart showing comparative bacteriolytic activity of the blood-serum of sheep in pens and on grass.

Agglutination of *B. abortus*. The differences in September among the outdoor groups were striking, Group 1 (the animals in worst general condition) being highest, Group 8 (the best conditioned) lowest; Group 4 was the lowest of the protein-deficient animals (1 to 4), Group 1 the highest; Group 8 was the lowest of the animals receiving additional protein (5 to 8), Group 5 the highest. Taken together, the protein-deficient animals gave much higher average values than those receiving additional protein. This was practically the reverse of the hæmolytic results in March.

Transfer to Grass.—A comparison was made of the reactions in sheep transferred to grass towards the end of the experiment with those in animals kept in pens and rationed as previously. The average values for all animals in these two categories respectively were calculated, and remarkable differences were elicited.

Among the animals on grass a great increase was observed in the bacteriolytic activity towards *B. coli*, amounting to 29 times that of the animals on rations in pens (see Figure). An analogous result was obtained with another strain of *B. coli*. A similar difference, Department of Edinburgh University, and certain serum reactions dependent on these principles were selected in virtue of their known occurrence in measurable degree with sheep serum. The tests were strictly quantitative.

The reactions selected were as follows: (1) hæmolytic action of serum towards rabbit's erythrocytes, which depends on a natural lytic antibody acting along with serum-complement; (2) bacteriolytic effects of serum towards (*a*) *Bacillus coli* (a typical strain), (*b*) *Bacillus suipestifer*, which also depends on natural antibodies acting along with complement; (3) agglutinating effects of serum towards (*a*) *B. abortus* (Hg), (*b*) *B. paratyphosus* B, which are due to natural agglutinating antibodies acting independently of complement. Owing to an initial difficulty in obtaining a suitable hæmolytic system for testing sheep's complement independently of any natural hæmolytic antibody present in the serum, the preliminary observations do not include a direct measure of complement activity.

The serological tests on the hill sheep referred to above elicited most interesting results. In the month of May when, according to clinical observations, the state of nutrition was at its worst, and the calcium level of the blood at its lowest, all the serum reactions were markedly weaker than in sheep of the same breed, age, and sex grazing on a cultivated pasture at Aberdeen. Further, the seasonal changes (from May, 1930, to March, 1931) in certain serum reactions —e.g., hæmolysis—ran parallel to those in body-weight and blood-calcium, and in animals transferred in October from the hill farm to Aberdeen these reactions showed an augmentation in value corresponding to the increase in body-weight and blood-calcium. In view of our limited knowledge of the significance of these reactions, and also of the probable intercurrence of uncontrolled factors other than nutritional which affect them, these findings which are stated here in general terms must be interpreted with the greatest caution. The results indicate, however, that the natural immunity reactions of blood-serum may be markedly influenced by nutritional factors which also affect the chemical composition of the blood.

Hæmocytological—These tests showed great differences among individuals under similar dietary and other environmental conditions, and this must be allowed for in evaluating the data. The figures in Table III. show the averages of 40 sheep taken at random in spring when the condition of the animals was worst, and in summer when the condition was improved.

TABLE III.

—	Mean red cell content per mm.³ × 10⁶	Mean white cell content per mm.³ × 10³	Mean percentage of hæmoglobin.	Mean percentage volume of packed cells.
May, 1930	7·39±2·02	7·19	64±11·95	25·7±6·2
July ,,	10·23±1·96	8·47	92±11·81	30·8±6·3

So far as the results can be considered as significant, they show that anæmia is one of the features of the malnutrition noted in spring. The study of sheep throughout the year on grazings recognised to be of low nutritional value shows a parallel seasonal variation in the chemical composition of the pasture, the general clinical condition of the animals, and certain constituents and properties of their blood. As yet, however, the data are insufficient to allow definite conclusions to be drawn.

INFLUENCE OF DIFFERENT DIETARY FACTORS UNDER EXPERIMENTAL CONDITIONS.

The pasture on the experimental farm to the above observations refer is relatively poor in protein and in inorganic constituents, especially calcium. An experiment was done on sheep kept in confinement to ascertain the influence of the addition of calcium, cod-liver oil, and protein, both singly in combination, when added to a basal diet roughly corresponding to hill pasture in chemical composition.

Eighty castrated male sheep were used, which about seven months old—i.e., about half grown—at the beginning of the experiment. They were taken from the Institute stock, and had a uniform pre-experimental nutritional history. They were divided into 16 groups of five each, eight groups being kept indoors and the other half in outdoor pens.

At intervals of about a month clinical notes were made; samples of blood were analysed for calcium, inorganic phosphorus, non-protein nitrogen, urea nitrogen, and at longer intervals for fibrinogen, albumin, globulin, cholesterol, and cystine. Serological tests and blood counts were also carried out as described above. The results briefly were as follows.

CLINICAL.

The animals in the indoor basal group after about four months stopped growing and became weak and emaciated. The addition of protein (in the form of cotton-seed meal) apparently led to a prolongation of the growth period, but later signs of bone deformity and debility appeared and growth stopped.

The addition to the basal diet of either calcium or cod-liver oil prevented these results. Growth was most rapid in the groups receiving cod-liver oil. No such clinical differences were obvious in the outdoor groups until a much later date, and even then they never became so pronounced as in the indoor sheep.

In July the animals in basal and basal-plus protein groups indoors were so debilitated that the experiment had to be terminated. These groups, together with all poorly conditioned sheep from other groups, were then transferred to good grazing. This was followed by a remarkably rapid improvement in their condition.

BIOCHEMICAL.

The only biochemical data considered here are those referring to the calcium and inorganic phosphorus of the blood.

The pre-experimental average figures were calcium 11·45 mg. and inorganic phosphorus 5·11 mg. Table IV. illustrates the marked extent to which blood-calcium and phosphorus may be influenced by dietary factors. The figures refer to the outdoor groups in March, when *no* clinical differences were as yet appreciable.

TABLE IV.—*Blood-calcium and Inorganic Phosphorus.*

mg. per 100 c.cm.

	Calcium.	Phosphorus.
Basal	7·06	10·53
,, + protein	6·46	11·32
,, + calcium	9·90	6·54
,, + C.L.O.	10·06	[illegible]
,, + protein + calcium	8·80	[illegible]
,, + protein + C.L.O.	9·35	7·75
,, + calcium + C.L.O.	9·66	[illegible]
,, + protein + calcium + C.L.O.	9·54	6·93

The figures show that there was a *marked fall* in the calcium in the basal group, accompanied by a marked rise in inorganic phosphorus. The addition of either calcium or cod-liver oil tended *to maintain* the normal levels of calcium and phosphorus in the blood.

supplied at a nominal charge. The urine of each patient is tested before the course is commenced, and the temperature at each visit previous to undressing. Weights are recorded weekly.

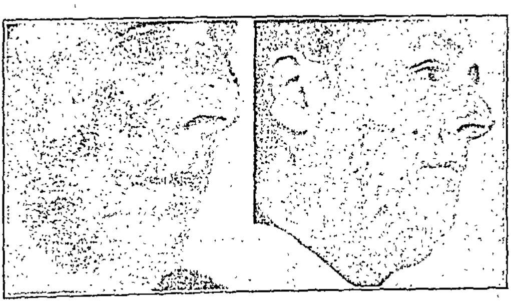
The treatment-room has through and wide ventilation, together with an electric fan, thus ensuring a constant circulation of air. Siemen's "snow-white" carbons have been used, as they were found to be cleaner and to give off less fumes than others tried. The initial dose, of 15 minutes back and front at three feet distance, is increased at weekly intervals by half an hour to a maximum of two and a half hours. This method is to be preferred to the shorter exposure of patients to more powerful cored carbons. The saving in time is counterbalanced by the risk of "lighting up" dormant lesions, and the very close medical supervision that is necessary. In attempting to combat a condition of extreme chronicity a rapid and transient stimulation appears unsuitable. Moreover, Leonard Hill and Eidinow[3] have shown, by exposing shaved rabbits to a "Beam" gas fire, which is rich in short infra-red rays, that their resistance to a general staphylococcal infection is increased. It would thus appear that the red and infra-red (heat) rays are of importance.

As the method of minimal stimuli gradually increased is perfectly safe, preliminary skin tests have not been found necessary. The majority of patients pigment well and profess a feeling of wellbeing. The carbon-arc lamps have been used for as many cases as possible, but general exposure to the Jesionek mercury-vapour lamp has sometimes been used. With this lamp, exposures at three feet distance are at first one minute back and front, increasing by two minutes weekly to a maximum exposure of 20 minutes. The results have not been found so satisfactory as with the carbon-arc lamps.

LUPUS.

As Reyn[4] has pointed out, lupus can be improved by light baths alone, but a real cure will not occur without the application of concentrated light. This has been obtained by the use of the water-cooled mercury-vapour (Kromayer) lamp with exposures long enough to obtain a blister (5–20 minutes), care being taken, by pressure of the lens, to render the part as bloodless as possible.

FIG. 1.



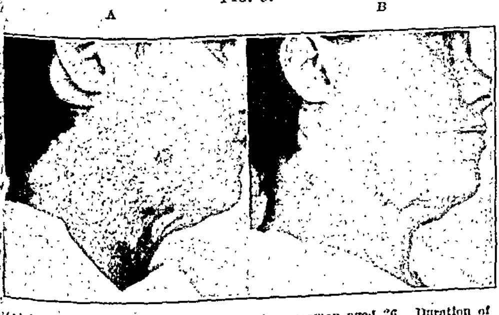
(A) Lupus of 33 years' duration in a woman aged 40. Previously treated with Finsen light at a skin hospital for five years and "snow." No treatment for last 19 years.
(B) Same patient after 14 months' treatment with general carbon-arc and local mercury-vapour Kromayer lamps. Pigmentation: deep. Weight: lost ½ lb.

In the treatment of extensive thick or warty lupus, especially on the trunk or limbs, a preliminary energetic treatment with creosote and salicylic acid plaster has proved very useful, as has "spiking" of isolated nodules with acid nitrate of mercury. A number of long-standing cases of widespread lupus have been treated at Eccles; many of them have had previous X ray treatment elsewhere. These cases have often proved intractable and tedious, with a tendency towards malignancy. They require more care and watchfulness than those not previously treated.

TUBERCULOUS ADENITIS.

Apart from lupus and scrofulous conditions of the skin, the next largest group treated has been tuberculous glands with softening, and frequently skin involvement. In these cases local treatment of the glandular condition is essential, by aspiration if possible, or by incision when the skin cannot be saved. The results in these cases have usually been good. More intractable is adenitis without softening. Local treatment with the Jesionek lamp in addition to general exposure to carbon-arc or mercury-vapour lamps has been found useful. It results in either (*a*) softening, when the local exposure should cease and aspiration be done; or (*b*) hardening and shrinking of the glands. The end-result is frequently the presence of small hard glands, which are apparently quiescent.

FIG. 3.



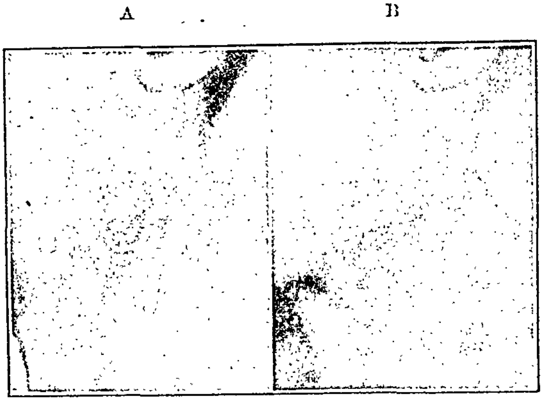
(A) Enlarged glands and scrofuloderma in a woman aged 26. Duration of disease before light treatment commenced, 19 years. Previous treatment: several operations.
(B) Condition after five months' treatment with carbon-arc and Jesionek (General) lamps. Pigmentation: deep. Weight: gained 10½ lb.

OTHER TUBERCULOUS CONDITIONS.

Other conditions—e.g., tuberculosis of bones, joints, and abdomen—will be referred to later. No cases of pulmonary tuberculosis have been treated.

It must be emphasised that light treatment has been used as a caustic or a stimulus, and has been combined with other forms of treatment—e.g., local caustics, aspiration and incision of superficial abscesses, and division of keloid bands. Attention to the general hygiene of the patient must not be overlooked; in some cases of under-nourishment milk has been provided with apparent benefit.

FIG. 4.



(A) Cervical adenitis with sinus in a boy aged 9. Duration of disease before light treatment commenced: four years. Previous treatment: operations.
(B) Condition after three months' treatment with carbon-arc and Jesionek (local) lamps. Pigmentation: medium. Weight: gained 3 lb.

Results.

The present paper deals with the three years 1928–30, during which period 273 cases have been treated (Table I.).

TABLE I.

—	Adults.	Children.	Total.
Lupus and scrofulous skin conditions..	75	31	106
Adenitis with softening ..	45	48	93
Adenitis without softening ..	15	21	36
Bones and joints	21	3	24
Abdomen	3	5	8
Others	4	2	6
Total	163	110	273

Of this number 63 ceased treatment for one or other of the following reasons: (*a*) admitted to a residential institution, (*b*) removal from district, (*c*) unwilling or unable to continue treatment on account of work or domestic circumstances. The 63 consisted of 45 adults and 18 children, and be subdivided as follows: lupus, 21; adenitis softening, 19; adenitis without softening, 11; bones and joints, 8; abdomen, 1; others, 3. At the end of 1930, 152 patients had been discharged as quiescent, leaving 53 still under treatment. Particulars of the patients discharged, together with the average duration of treatment, are shown in Table II. The average duration of all the 152 cases was seven and three-quarter months. The results are adversely affected by the existence of many cases of extensive lupus of long standing. Thus, four adult lupus cases have attended for over two years, and one of them has only made 70 attendances.

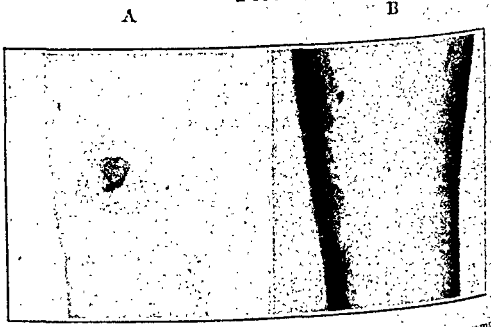
FIG. 5.



(A) Bazin's disease, of three to four years' duration, in a woman aged 21. Previous treatment: attended a skin hospital for ointment and medicine.
(B) Condition after four months' treatment with carbon-arc and eusol dressing. Pigmentation: deep. Weight: gained 4½ lb.

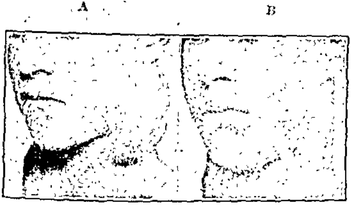
Table III. shows the degree of pigmentation of the 152 cases discharged as quiescent.

Thus in 90 the pigmentation was deep and in 51 medium, and improvement appears to be definitely associated with a good degree of pigmentation. As the ultra-violet rays cannot penetrate pigmented skin, early deep pigmentation is undesirable. With very deep pigmentation the carbon-arc baths have sometimes been temporarily suspended or replaced by exposure to the Jesionek lamp, local treatment being continued. The five cases without pigmentation received local treatment only.

WEIGHT OF QUIESCENT CASES.

Of 152 quiescent cases, 112 gained weight, 33 lost weight, and in 7 no change occurred (Table IV.).

FIG. 6.



A) Adenitis in a boy aged 16. Disease began ten years previously. *Previous treatment*: two operations at a general hospital eight years ago.
B) Condition after four months' treatment with general carbon-arc and local mercury-vapour Jesionek lamps. Also aspiration. Pigmentation: deep. Weight: gained 14½ lb.

The appearance of typical cases before and after reatment is shown in the accompanying plates, and ssential particulars are given in the corresponding egends.

RELAPSES.

All patients since discharge have been inspected at egular intervals; 23 patients have shown some egree of relapse, and further treatment has been iven. These cases were as follows: lupus, 16; denitis with skin involvement, 4; adenitis without kin involvement, 3.

Finance.

Lissant Cox[5] has dealt fully with the financial spect of light treatment at dispensaries, and has hown that a considerable saving has been effected s a result of not sending patients to residential nstitutions and out-patient departments of hospitals. he cost, which includes carbons and current as well s all standing charges—e.g., proportion of time of edical and nursing staff, rent and rates, fuel, light, leaning, repairs, renewals, and depreciation—naturlly varies with the number of patients treated. At ccles the numbers under treatment at the end of 928, 1929, and 1930 were 73, 60, and 53 respectively. n 1929 the total cost per patient per week was 4*s*. 6*d*., hich is about the same as the average for the dministrative county of Lancaster (403 patients nder treatment at 12 centres at the end of 1929).

Conclusions.

1. Artificial light treatment can be successfully ven at tuberculosis dispensaries under the control f local authorities.

2. It is especially useful in cases of lupus and allied kin conditions, adenitis with and without softening, nd other superficial conditions.

3. It is much less effective in the treatment of berculous disease of the larger joints and bones, hich should be sent to special residential institutions.

4. In the treatment of lupus a combination of eneral light therapy with local treatment—e.g., Kromayer lamp—is usually necessary, and the carbon-arc bath is to be preferred to the mercury-vapour lamp for general irradiation.

5. Prolonged exposure to weak carbons is preferable to brief exposure to strong-cored carbons. It is efficacious, safe, and particularly suitable for use by tuberculosis officers who have other duties to perform outside their dispensaries.

6. To obtain the best results, actinotherapy needs frequently to be combined with various forms of local treatment—e.g., the use of suitable caustics in lupus, and the aspiration or incision of abscesses. Painstaking attention to detail on the part of the doctor and nurse, and the regular attendance of the patient, are essential for success.

PORENCEPHALY.

A BRIEF REVIEW, WITH DESCRIPTION OF A CASE.

BY R. STROM-OLSEN, M.B. WALES, D.P.M.,
SENIOR ASSISTANT MEDICAL OFFICER, BOROUGH MENTAL HOSPITAL, ROWDITCH, DERBY.

TRUE porencephaly is a rare condition and will always be of interest, partly owing to the striking disproportion between the great anatomical defect in the brain and the mild degree of physical symptoms, partly on account of the controversy over its ætiology.

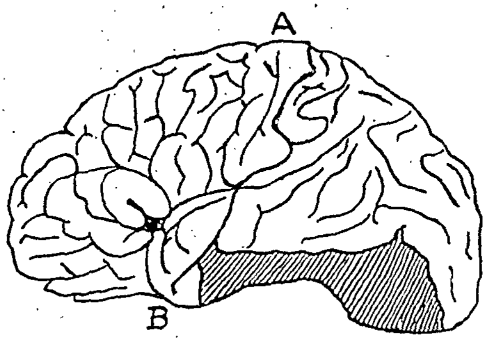
Heschl, who in 1859 first described this condition under its present name, assumed that the loss of brain substance was due to faulty development, analogous to other congenital malformations. Later he changed his view in favour of circulatory disturbances. Kundrat, in 1882, studied 12 cases and came to the conclusion that most of the porencephalic defects were congenital and due to vascular disturbances, hydrocephalus, anæmia, or psychic disturbance in the mother during pregnancy. He extended the use of the term to include any cerebral defect roofed over by the arachnoid. Schultze was the first to suggest that porencephaly might be due to infectious encephalitis and based his view on microscopic evidence of inflammatory changes. The existence of prenatal encephalitis was proved possible by Virchow and this ætiological theory has been supported by Strümpell, Limbeck, and recently by Globus. The histological investigations of the latter in a typical case afforded evidence of a meningo-encephalitis which led to strangulation of the blood-vessels producing anæmic necrosis, glial proliferation, and finally sclerosis and cavity formation. Very recently, Jaffé has emphasised the importance of trauma, which may occur in utero, during birth, in infancy, or in later life. He holds trauma at birth to be the commonest cause, citing the frequency of prematurity, prolonged labour, and instrumental delivery in the history of these cases, and suggests that, in addition to the direct action of the trauma on the brain, circulatory disturbances in the large veins from a damming-back of the blood in the sinuses are of great importance. In refuting the inflammatory theory he argues that inflammation may well be superimposed on a brain with an existing porencephalic defect, the latter acting as a locus minoris resistentiæ.

The following is an illustrative case of the traumatic group.

A female, aged 32, was admitted to Derby Mental Hospital in March, 1929, as a case of imbecility with epilepsy.

History.—Since infancy she had suffered from occasional epileptiform convulsions. In August, 1927, she had a serious fit and was comatose for two days. Her fits were not frequent, numbering about three or four a year. She had always had slight difficulty in walking, and had also suffered from a squint since infancy. Mental backwardness showed itself early, and at the age of 14 she had only reached Standard IV. She had never been able to earn her own living and was subject to frequent attacks of headache.

Her birth was abnormal. A fortnight before term her mother had a bad fall which brought about a premature labour; this was prolonged, but not instrumental. The patient was the twelfth child. No obvious abnormality was discovered after the birth. The fits began about a year later.



On admission she was an under-developed, but well-nourished female. No stigmata of degeneration were present, but there was a mild degree of right-sided pes cavus. In the heart, lungs, and alimentary system no abnormality was detected. The urine contained no albumin or sugar. The Kahn reaction of the blood was negative.

The pupils were equal and regular in outline and reacted to light and accommodation. There was right external strabismus. Marked nystagmus was present, most noticeable when the patient looked to the left. The sight of the right eye was greatly impaired, though probably the condition was a right-sided homonymous hemianopia as, owing to her mental state, very little coöperation could be obtained from her. The tendon reflexes were abnormally brisk in the right lower limb, which was slightly spastic and showed a certain loss of coördination. The right upper limb was normal in all respects except for a rather weakened grip. A Babinski sign was obtainable on the right side at times. No anæsthesia could be detected.

The patient was hesitating and slurring in speech, dull and retarded in thought, and had little educated intelligence. Her memory was impaired and she was unable to do the simplest calculations. She could give no connected account of herself and was childish in her ways.

During her stay in hospital she had only one fit, which was of an epileptiform nature. She was able to get about the ward and did some useful light work. In December, 1929, she developed pulmonary tuberculosis, and she died in June, 1930.

Autopsy findings.—The calvarium showed increased thickness in its left posterior quadrant. The meninges and vessels appeared normal. The brain weighed 32¼ oz. The right hemisphere appeared normal and weighed 16 oz. The left hemisphere was the seat of a large porencephalic cyst in its posterior half and weighed only 10 oz.

In the diagram the porencephalic area is represented as situated to the right of the line A–B, and the shaded area represents the porus covered with membrane.

The cavity was found to be in direct continuity with the lateral ventricle and to contain cerebro-spinal fluid. It measured 8½ cm. × 6½ cm. × 3½ cm. and extended from the occipital pole almost to the apex of the temporal lobe, undermining the central white matter beneath the Rolandic area. The lining of the cavity was smooth. The unaffected cortex at the edges gradually thinned out to form the cyst wall. This thinned cortex had lost its normal configuration, and no definite gyri or sulci could be identified. It had a uniform thickness of 2–3 mm. except on the medial surface, where it measured 11–12 mm. with the configuration retained. Inferiorly the thinned cortex merged into the membrane roofing over the gap. This membrane consisted of two layers, the outer layer being continuous with the pia-arachnoid, the inner with the lining of the cyst and the lateral ventricle. A curious feature presented itself; an offshoot of the choroid plexus was attached to the inner surface of the membrane and formed a conspicuous band of choroid tissue stretching across the cavity.

On section the corpus callosum was found to be greatly thinned, especially in its posterior half. The internal capsule, too, was much wasted, though the basal ganglia appeared normal, and in the medulla a marked diminution in the size of the pyramid was evident on the left side.

Microscopic section of the pre- and post-central gyri showed paucity in the number of pyramidal cells and disturbance of lamination, with exaggerated gliosis, especially towards the surface. No trace of any inflammatory exudate or perivascular round-celled infiltration could be seen. The thinned cortical cyst wall consisted of a dense network of neuroglia and degenerated nerve fibres with total absence of nerve cells. The membrane consisted of an outer layer of pia-arachnoid carrying blood-vessels and an inner composed of flat or low cubical epithelium, identical in structure with ependyma; interposed between the two were strands of neuroglia fibres.

Porencephaly may be suspected, but cannot often be diagnosed during life for, as Tredgold says, the hemiplegia in some cases of pronounced porencephaly discovered post mortem is often astonishingly insignificant. This can only be explained by the faculty of the contra-lateral hemisphere to undergo relative compensatory hypertrophy and thus to assume functions of the atrophied half. Diagnostically, besides the history, the only suggestive features are the occurrence in a mental defective of epileptiform convulsions, headache, hemiplegia, and a flattening of one side of the skull. The latter sign, however, is frequently absent, as in the case related above. Here the history of a difficult premature labour following an injury to the mother again illustrates the importance of trauma at birth in the ætiology of this rare condition.

I am indebted to Dr. J. Bain, medical superintendent, for permission to publish this case.

PROLONGED ADMINISTRATION OF ARTIFICIAL RESPIRATION.

BY PHILIP DRINKER, S.B., CH.E.,
ASSOCIATE PROFESSOR OF INDUSTRIAL HYGIENE, HARVARD SCHOOL OF PUBLIC HEALTH, BOSTON, MASS.

IN a series of papers published elsewhere there have been presented physiological[1] and clinical[2] data obtained by the use of a mechanically operated device for administering artificial respiration over long periods.

The device used is known as a respirator and consists of a sheet metal tank equipped with a comfortable bed and mattress (Fig. 1). The patient's head protrudes through a flat soft rubber diaphragm or collar attached to the body of the respirator, the rubber collar making an air-tight seal about the patient's neck. The diameter of the collar is adjustable, and thus excessive tension on the neck of the patient is avoided.

By means of electrically driven blowers and an appropriate valve arrangement, the air pressure within the tank is changed alternately from a few centimetre of water negative pressure to normal atmospheric pressure. The negative pressure induces inspiration—the chest and diaphragm of the patient expand and air is inhaled. The return to atmospheric pressure allows the recoil of the thorax and the respiratory muscles, together with the elasticity of the lungs, to cause expiration. Both the depth and the rate of breathing are under the control of the attendant and can be measured (or recorded) by means of a suitable U-tube manometer, filled with coloured water and connected by rubber tubing to the body of the respirator.

In general, a negative pressure of about 12 to 18 cm. of water suffices to maintain adequate ventilation in an adult or child with complete respiratory paralysis. In the case of new-born babies in which respiration does not begin within a few minutes after birth, smaller negative pressures (from 8 to 10 cm.) have been found adequate.[3] Our experience indicates that the negative pressure used should just be sufficient to prevent cyanosis or obvious respiratory distress; nothing is gained by using excessive negative pressures for long periods, while we have reason to believe that such pressures actually do harm to the lung tissue, particularly in the case of infants whose lungs may be atelectatic.[4]

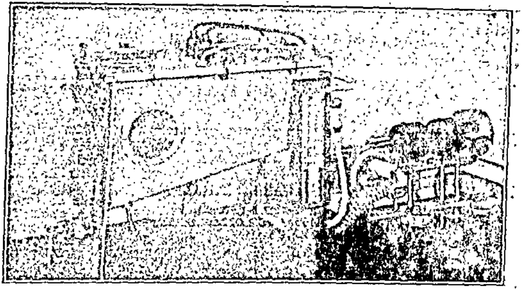
Without having the pump stopped, the patients can eat, drink, and sleep while in the respirator. A bed-pan can be passed through one of the portholes, enemas can be given, and rectal drips can be administered in deglutition cases. The noise of the machinery, although not excessive, is sufficient to prevent the use of a stethoscope in chest and heart examinations. We have taken rontgenograms of patients' chests both while the respirator was running and when the bed was pulled out and the pump stopped.

FIG. 1.

Respirator (for adults) showing patient in the apparatus. (Photographs by courtesy of Messrs. Siebe, Gorman and Co.)

Of possible interest to physiologists is the fact that such slight negative pressures—equivalent to 12 to 18 cm. of water—are sufficient to induce inspiration in a person whose respiration has ceased, and that it has been found unnecessary to use positive pressures inside the respirator. In the case of an animal deeply anæsthetised or curarised still smaller negative pressures suffice. The method offers the advantage, over intratracheal insufflation, that it imitates normal breathing fairly accurately.

FIG. 2.



Respirator for infants. The chamber is heated, when necessary, by two electric bulbs on the inside.

Severe apnœa can be produced on normal humans by intentional over-ventilation of the subject. In clinical practice the severely paralysed patient may be over-ventilated by increasing the depth of the respirations just prior to being withdrawn from the apparatus for a few minutes, in order that he may be bathed and changed. Without such over-ventilation he may become cyanotic too quickly to permit reasonable nursing care or medication.

This apparatus has had two years' trial in the United States and Canada and has been used in some 100 cases of respiratory failure from acute poliomyelitis, over 50 cases of unusually severe carbon monoxide poisoning, about 10 cases of alcoholic coma, 7 of drowning, 1 of post-diphtheritic paralysis, and over 30 of asphyxia of the new-born. In general the intercostal paralysis of poliomyelitis can be treated with immediate relief and comfort to the patient, the length of treatment varying from a few hours to several months, according to the severity of the disease. Cases of gas-poisoning, alcoholic coma, and drug poisoning seldom require more than 24 hours' treatment, while new-born babies rarely require over one to two hours' continuous treatment.

With the exception of those with poliomyelitis the patients usually recover completely. Numerous cases of both children and adults with severe intercostal paralysis from poliomyelitis have made gratifying recoveries, although we have several who have recovered the use of their intercostals but are otherwise crippled.

In view of the fact that over 70 of the adult machines and 12 of the infant size (Fig. 2) are in successful use in America, the manufacturing details have been entrusted to Messrs. Siebe, Gorman and Co., of London, and the apparatus will be made here as desired by the medical profession. No profits will accrue to any person in any way concerned with the development or sale of the apparatus in America.

This apparatus was developed and subsequently made available through the generosity of the Consolidated Gas Co., of New York City, who gave the funds to the Harvard School of Public Health to cover the expenses of the original research, and later bought and presented 14 adult-sized respirators to various hospitals in New York City.

CLINICAL AND LABORATORY NOTES

A CASE OF APLASTIC ANÆMIA.

By W. J. Fenton, M.D. Camb., F.R.C.P. Lond.,
CONSULTING PHYSICIAN TO CHARING CROSS HOSPITAL; PHYSICIAN TO THE HOSPITAL FOR CONSUMPTION, BROMPTON;

AND

A. Turner, M.D. Durh.

A MAN, aged 52, complained of acute pain in the epigastrium, mainly dependent upon the taking of food and frequently appearing during the night. It had first been noticed some six months previously. Pallor and dyspnœa appeared three months later. There was nothing noteworthy in his previous medical history and no history of venereal disease. He had noticed a tendency to "bleed" from small wounds, and four years before had had an attack of epistaxis, for which his nostrils had been plugged. He thought that his family, especially on the male side, was more than usually liable to bleed.

He was very abstemious and smoked little. His normal weight was 14 st. 7 lb.; when first seen it was 14 st. His appetite was good, but he suffered from considerable pain and discomfort after meals, with occasional pyrosis. The bowels were regular, and no blood had been noticed in the motions. Vomiting had not occurred. The urine contained a trace of albumin but nothing otherwise noteworthy. On physical examination he was remarkably anæmic but without a lemon tint. A few purpuric spots were noticed on the mucous surfaces of the lips, but not elsewhere. The pulse-rate was 92 and the pulse was regular and of medium force; the radial wall was healthy. The systolic blood pressure was 146 and the diastolic 66 mm. Hg. There was nothing discoverable in the viscera of the chest or abdomen except such as might be directly associated with the anæmia. The teeth were poor and the tongue slightly furred. There was no œdema, no history of sweating, and no evidence suggesting associated disease of the central nervous system. The diagnosis appeared to lie between duodenal ulcer, gastric neoplasm, and pernicious anæmia.

An X ray examination after an opaque meal was made by Dr. Stanley Melville and the conclusion reached that, although the behaviour of the stomach was not typical of duodenal irritation, a definite residue at two and six hours made it impossible to exclude ulceration in this region. The result was thus inconclusive as regards the presence of ulceration but appeared to negative malignant disease. Examination of the stools for occult blood showed that this was present in moderate amount. The blood count made at the time was as follows: white blood corpuscles, 3200 per c.mm.; red blood corpuscles, 2,500,000 per c.mm.; hæmoglobin, 22 per cent.; colour-index, 0·44; polymorphonuclear leucocytes, 63·0 per cent.; eosinophils, 1·5 per cent.; basophils, 0·5 per cent. large hyalines, 6·0 per cent.; small lymphocytes, 29·0 per cent.; poikilocytosis, anisocytosis, and polychromatophilia were present, but no nucleated red cells were seen. The coagulation time was not altered. The result of the blood examination was thus not specially indicative of pernicious anæmia, but rather suggested an anæmia secondary to hæmorrhage from duodenal ulceration. The patient was accordingly put to bed and treated upon this supposition. No improvement was obtained; the occult blood persisted in spite of all forms of treatment, including injections of horse serum, and no marked change was noticed in the general condition.

A consultation was held with Mr. G. Gordon Taylor and, while the difficulties of the case were fully appreciated, it was felt that, with the history of gastric symptoms already detailed, the persistence of occult blood in the stools and the absence of any other form of bleeding, together with the obviously serious condition of the patient, it would be advisable to open the abdomen and search for ulceration. This was accordingly done, but nothing was found to throw light upon the symptoms. The patient made a successful recovery from the operation, no special tendency to bleed having been noted, and his general condition remained in statu quo. The teeth meanwhile had received attention. A course of treatment by liver was tried and he was subsequently transfused, but without success.

Blood examinations were made from time to time and, while some of the counts had features suggestive of pernicious anæmia, none was typical, and nucleated red cells were never found. It now became apparent that the case was a true blood disease to which the anæmia and hæmorrhages were secondary, and the diagnosis of aplastic anæmia was made. The patient returned home and died about nine months after our first consultation, all forms of treatment having proved unavailing. The final count made three months before his death was as follows: white blood corpuscles, 6200 per c.mm. red blood corpuscles, 1,750,000 per c.mm.; hæmoglobin, 25 per cent.; colour-index, 0·7; polymorphonuclears, 62·5 per cent.; eosinophils, 0 per cent.; lymphocytes, 30·5 per cent.; mononuclears, 6 per cent. The stained film showed marked poikilocytosis and anisocytosis was very evident; there was a considerable number of megalocytes. A few cells showed polychromasia, but there were no nucleated forms. The report added the suggestion that despite the low colour-index, this count had several of the features of a true pernicious anæmia.

POST-MORTEM EXAMINATION.

The body was that of a well-nourished middle-aged man with pronounced pallor of the skin. Post-mortem staining was absent. There was a comparatively thick layer of yellow subcutaneous fat and the pericardial fat was increased. There was extensive and advanced fatty degeneration of the myocardium with fatty striation of the musculature of the walls of both ventricles as well as of the papillary muscles. There was an excessive deposit of fat in the omentum and mesentery, but no enlargement of the mesenteric glands. The intestines were normal; ulceration and neoplasm were both absent. The liver was enlarged and very soft, rusty brown in colour with deeper coloured areas suggestive of chronic passive congestion. The macroscopic appearances were consistent with widespread fatty change and some atrophy. The ferrocyanide reaction was only very slight. The spleen was a little enlarged, its pulp soft, and the normal markings lost. The cut surface presented a uniform appearance which might have been due to post-mortem changes. The kidneys were pale and apparently fatty, but showed nothing otherwise noteworthy. No special changes were observed in the pancreas and suprarenals. The bone-marrow of the femur was very pale and appeared to be mostly fatty, with the exception of a pinkish streak about 5 mm. in diameter. It was evident that erythrogenetic activity was inconsiderable.

HISTOLOGICAL REPORT.

Liver.—No changes of special importance beyond passive congestion and areas of central atrophy and fatty degeneration.

Lungs.—Œdematous.

Spleen.—The most striking feature was the comparative absence of red corpuscles. The Malpighian corpuscles were very poorly represented and appeared to be inactive. The reticulum cells were also apparently diminished in number and the connective tissue reticulum of the organ was very evident, although no new formation of fibrous tissue had occurred. A very fine fatty infiltration of the reticulum was present. The ferrocyanide reaction was negative.

Kidneys.—Chronic interstitial nephritis was present, with a considerable amount of fat in the epithelial cells.

Heart.—There was well-marked fatty degeneration.

Pancreas.—No special change.

Bone-marrow.—The section was taken through the reddish streak previously mentioned as being the most likely area to show evidence of the presence of regeneration. Many cells were found with basophil cytoplasm containing larger or smaller masses of hæmoglobin. In some cells there were definitely one or more mature red blood corpuscles, which suggested that some erythrocyte destruction was in progress. No typical nucleated red blood corpuscles could be found. Of the white cells the most prominent were eosinophil granular leucocytes of the myelocyte type, but typical polymorphonuclear leucocytes were not common. Cells of the lymphocyte series were fairly numerous.

We are indebted to Dr. H. W. Vines, of the Charing Cross Hospital Institute of Pathology, for the post-mortem report.

Thus, while the gross changes in the viscera were similar to those in pernicious anæmia of the ordinary type, there were also important differences in that the bone-marrow showed an absence of new red cell formation and nucleated red cells were entirely absent. The ferrocyanide reaction in the liver and spleen was also absent or inconsiderable.

Apart from the extreme pallor and the gastro-intestinal symptoms, the latter of which ultimately yielded to treatment, the most noteworthy clinical features were the presence of occult blood in the stools which proved quite uncontrollable, resisting all forms of treatment, and a blood count resembling in some respects pernicious anæmia yet seriously differing from it and at first suggesting a secondary anæmia for which the persistent intestinal bleeding offered a primary cause. A further complicating factor was the suggested history of "bleeding" in the family confidently put forward by the patient. This led to an examination of his blood coagulation time, which nevertheless was found to be unaltered. It is unfortunate that the platelets were not specially noted in the blood examination.

There had been no free hæmorrhage either from the stomach or bowel, but a persistent oozing arising from the gastro-intestinal mucosa. The absence of nucleated red cells from the blood counts did not perhaps receive sufficient weight in the earlier stages of the patient's illness, but the serious general condition, the history of gastric pain and pyrosis, and the persistent loss of blood seemed to suggest the possibility of a gross gastro-intestinal lesion which it was advisable to deal with or exclude. It was accordingly dealt with, but not without much misgiving.

DIFFERENTIAL DIAGNOSIS.

The case had all the appearances of an anæmia dependent upon persistent loss of blood, the main feature being a progressive fall in the number of red cells, accompanied in a general way by comparable changes in those characters usually associated with severe anæmia. A small apparent rise in polymorphonuclear cells may have been due to some septic complication; on the other hand, there was a small excess of lymphocytes. Thus intestinal hæmorrhage for which no gross lesion could be found, associated with a grave and uncontrollable anæmia, was the main clinical characteristic.

Post mortem the main change was found in the bone-marrow, which had the appearances consistent with failure of its normal erythrogenetic activities. Evidence of abnormal blood destruction in the liver and spleen was not found, as shown by the absence of the ferrocyanide reaction.

The clinical diagnosis between aplastic and pernicious anæmia depends upon a progressive fall in the red cell count and in the absence of any appearance of blood regeneration, together with complete resistance to all forms of treatment. It is of interest to note that even in an anæmia of such severity normal recovery from operative interference occurs. It was suggested in one of the blood counts already detailed that some of the characteristics of pernicious anæmia were present, and it may be a matter of some difficulty to decide between these two conditions upon blood examination alone. That there should be a certain amount of overlapping between aplastic and pernicious anæmia might perhaps be expected, for it is highly improbable that the erythrogenetic properties in the marrow of all the bones should be equally affected or should entirely fail, for the end would come when blood regeneration fell short of bodily requirements—when the balance between red cell production and destruction was so far disturbed as to be incompatible with life. Meanwhile, it is conceivable that the cells formed by the failing bone-marrow would be less resistant than normal to ordinary destructive influences and that a certain clinical resemblance to pernicious anæmia might be produced in this way.

Aplastic and pernicious anæmia appear to be blood diseases probably unconnected with each other except in so far as they occur at different phases in the life-history of the red cell. The former is a failure of red cell production; the latter an excess of red cell destruction.

Glossitis, achlorhydria, and degenerative changes in the central nervous system are absent. The colour-index of the blood and the hæmoglobin content of the red cells are variable and may be unreliable for differential diagnosis, which must be based upon the presence of a wholly intractable anæmia, with or without hæmorrhage from the mucosæ, along with a blood picture characterised by great reduction in the number of red cells and an entire absence of the features commonly associated with red cell formation. The duration of the disease varies through narrow limits and is almost invariably fatal.

A CASE OF MENINGITIS CAUSED BY STAPHYLOCOCCUS AUREUS.

BY ROBERT SWYER, M.R.C.S. ENG., D.P.H.,
SENIOR ASSISTANT MEDICAL OFFICER, NORTH-WESTERN HOSPITAL, LONDON COUNTY COUNCIL.

MENINGITIS caused by the *Staphylococcus aureus* is rare enough to make the following case worthy of note.

The patient was a female, aged 11 years, and was admitted to the North-Western Hospital on Feb. 18th, 1931, certified as suffering from cerebro-spinal meningitis, with a history of headache, vomiting, and constipation dating from Feb. 12th; there was also a history of intermittent vaginal discharge during the preceding 18 months. Retraction of the head was noticed on Feb. 17th.

On admission the temperature was 101·6° F., the pulse-rate 112, and the respiration-rate 22. There was marked head retraction and arching of the back, with increased knee-jerks and a marked Kernig's sign. The pupils were equal and reacted normally, and the mental condition was perfectly rational. Vomiting occurred twice on the day after admission but was not a marked feature, being absent until March 4th, when it became very persistent and remained so until the end. Headache was only slight, but head retraction and arching of the back steadily increased until finally both were present in an extreme degree. The patient slept well and remained moderately quiet until Feb. 24th, when a generalised serum urticaria, accompanied by great restlessness and shouting, supervened. A brownish vaginal discharge was noted on this date. On the following day she was more drowsy, and speech became slow and slurring. Dysphagia appeared on Feb. 27th, increasing in severity until, on March 1st, nasal feeding became necessary. Shouting and restlessness reappeared on Feb. 27th and continued until exhaustion supervened. Death took place on March 6th. Pyrexia was not marked, the temperature never exceeding 102° F. until immediately preceding death. For the first week it fluctuated between 99° and 102° F., then remained roughly normal for three days, when it again rose and remained elevated until death occurred.

TREATMENT.

Lumbar puncture was performed on admission, under general anæsthesia, when 30 c.cm. of turbid fluid escaped under increased pressure and, in view of the appearance of the fluid and the certified disease, 15 c.cm. of Lister's antimeningococcal concentrated serum was given intrathecally. This procedure was repeated on Feb. 19th, 20th, 21st, 23rd, and 25th, when turbid fluid varying from 36 c.cm. on the 19th to 15 c.cm. on the 25th escaped. On the latter date the fluid was thick and purulent, and there was no increase of pressure. At this point it was thought probable that a blockage had occurred in the spinal canal which was preventing proper drainage by lumbar puncture; accordingly, on Feb. 26th, a puncture of the cisterna magna was performed, 32 c.cm. of turbid fluid escaping under pressure and 10 c.cm of Lister's serum being injected; lumbar puncture on the same occasion yielded only 3 c.cm. of purulent fluid. Cisternal and lumbar puncture were repeated on Feb. 27th and 28th, March 2nd and 3rd, but as bacteriological reports had all been negative as regards the meningococcus the administration of serum was discontinued. On March 3rd an attempt was made to wash out the spinal canal with distilled water through the needle in the cisterna magna to the lumbar puncture needle which had been left in situ. The procedure was unsuccessful, no fluid escaping from the lumbar puncture; the fluid was therefore allowed to escape again from the cisternal puncture needle.

The only drug treatment was the administration of a sedative mixture and of a single dose of morphia on the day preceding death.

PATHOLOGICAL INVESTIGATIONS.

These were mostly carried out at the Council's laboratory at the North-Eastern Hospital, where seven specimens of cerebro-spinal fluid were examined and reported upon. Four had been obtained by lumbar puncture and three by cisternal puncture. A pure culture of *Staphylococcus aureus* was obtained in all but the first lumbar puncture specimen, from which a few colonies of a Gram-negative diplococcus were grown. This organism, however, proved not to be the meningococcus.

Cell counts showed a marked polymorphonuclear leucocytosis ranging from 10,000 per c.mm. in the first lumbar puncture specimen to 300 per c.mm. in the cisternal puncture specimen obtained on March 2nd. Reducing sugar was absent in all the lumbar puncture specimens and present in moderate amount in all cisternal specimens.

When it was definitely established that the *Staphylococcus aureus* was the infecting organism, search was made for a septic focus. Examination of a smear and culture from the cervix uteri showed only a Gram-negative coliform bacillus. Examination of the ears was negative but a blood culture made on Feb. 27th gave a pure culture of *Staphylococcus aureus*; there were about 50 colonies per c.cm. of blood.

AUTOPSY.

A post-mortem examination was carried out on March 7th.

Head.—The meninges and brain appeared normal except for some engorgement of the occipital region, probably due to hypostasis. Both middle and internal ears were opened and the left middle ear was found to contain thick yellow pus. A culture tube was inoculated from this pus and a pure culture of *S. aureus* obtained.

Spinal Canal.—On exposing the spinal canal the theca appeared normal externally but on incision the spinal cord was found to be surrounded with thick yellow pus. This was most profuse in the lumbar region and extended, though in diminishing amount, as far upwards as the upper dorsal region. Sections were made of the cervical, dorsal, and lumbar regions. The cervical region showed congestion of the blood-vessels and a definite, though not marked meningitis. The large motor cells showed marked degenerative changes—i.e., disappearance of granules and breaking up of nuclei. The dorsal region showed similar congestion and degenerative changes in the larger nerve-cells. In the lumbar region the meninges showed much more definite meningitis with abundant polymorphonuclear cells and fibrin on the meninges and around the nerve roots. Masses of staphylococci were present. The larger nerve-cells showed the degenerative changes described above.

Thorax.—The pleura, pericardium, and heart were normal. In the lower part of the upper lobe of the left lung about half a dozen small nodules were found; on section these showed changes varying from acute œdema through broncho-pneumonia to definite abscess formation.

Abdomen.—Nothing abnormal was found in the abdomen except that the liver was dark on section and engorged with blood; the Fallopian tubes were a little congested; the cervix uteri was a little patulous and the endometrium was slightly discoloured with altered blood towards the cornua.

DISCUSSION.

This appears, from the bacteriological and post-mortem findings, to have been a case of staphylococcal meningitis which had its origin in the middle ear. The otitis media was followed by a septicæmia with metastatic abscesses in the lungs, but whether the septicæmia or the meningitis occurred first is a matter of some doubt. Certainly there was no evidence of direct spread from the ear to the meninges. There was no septic focus in the uterus or vagina, and the post-mortem appearances and history of intermittent vaginal discharge were consistent with an abnormally early onset of menstruation.

Increase of Out-patients.—It was stated at the annual meeting recently of the Royal National Orthopædic Hospital, Great Portland-street, that, whereas 20 years ago there were 22,000 out-patients' attendances, last year there were 111,000. Although the cost of maintenance in both departments has been reduced, there is still a debt of £40,000.

New Sussex Hospital for Women and Children.—Princess Mary visited Brighton on May 8th to open the new John Howard wing of this hospital. The trustees of the late Sir John Howard had generously allocated £5000 for building and £20,000 for endowment of this extension, which comprises a ward of cubicles containing 12 beds for poorer patients and six bedrooms for private patients. Miss L. Martindale, M.D., the senior surgeon, made particular mention of the work that is being done at this hospital for the treatment of cancer. In conjunction with three London hospitals the N.S.H. has the use of £12,000 worth of radium. Facilities for encouraging patients to seek early advice was emphasised as one of the aims to be achieved in enlarging the out-patients' department. In connexion with the official opening a public luncheon was held at the Dome with Mr. A. O. Jennings in the chair. Countess Buxton responded to the toast of the hospital and the Sir John Howard Trust. Dame Louise McIlroy, M.D., strongly urged the continuance of the voluntary system, and Miss Irene Vanbrugh made an appeal emphasising the ever-growing requirements of the out-patients' department of the hospital. Over £200 was collected and later presented to Princess Mary.

MEDICAL SOCIETIES

CHELSEA CLINICAL SOCIETY.

At a meeting of this society held on May 19th, Mr. F. J. McCann, the President, being in the chair, a discussion on

Treatment Before and After Operation

was opened by Mr. Lawrence Abel. The art of surgery, he said, was as old as mankind, but the science of surgery, as known to-day, had its seed sown by Joseph Lister. The greatest pre-operative discovery of all time was that of general anæsthesia, for it robbed operations of their outstanding terror—namely, pain. But before this discovery surgeons did not omit provision for lessening the emotional state of the patient before an operation, in illustration of which Mr. Abel read an abstract from the pre-operative injunctions of Sir Astley Cooper before proceeding to operate; "a very elaborate ritual," he remarked. Even now there remained a dread of operations, and even Lister's work did not ban many mediæval practices.

BEFORE.

In considering the patient's fitness for the contemplated operation, the first matter to be investigated was the condition of the heart and the blood pressure. The difference between the diastolic and systolic pressures was known as the "pulse pressure"; the percentage ratio between the pulse and diastolic pressures was the "cardiac energy index"; the normal figure varying between 25 and 75. The cardiac index gave a valuable indication of whether or not the patient had a good chance of surviving the operation. Any doubt on this score should be resolved by taking an electrocardiogram. Especially in hyperthyroidism an ordinary basal determination was necessary to determine the general metabolism, and the lung condition should be inquired into, with a skiagram to supplement if necessary. To look into the genito-urinary system the urine was tested by culture for organisms and by urea concentration. If this was omitted it might be found that the kidneys would not bear the anæsthetic or the post-operative period. The hæmoglobin and urea content of the blood should be estimated, a blood count taken as well as ascertaining the blood group. Should there be any question of jaundice or hæmophilia, the clotting time must be known, also the blood chlorine and cholesterol. A Wassermann test must be included. The degree of thoroughness of this investigation could vary with the severity of the contemplated operation. In a general way, there must be some rest before the operation; several days in bed before a severe operation.

The modern view on purgation before operation was that the patient's normal excretory functions should continue; no aperient other than the accustomed one should be given. Castor oil as often given was a factor in producing dehydration before operation; it gave rise to grossly irregular peristalsis, with stirring up of the intestinal fauna and flora, and not infrequently to impaction of fæces. It might even cause paralytic ileus. Castor oil was, he thought, responsible for more empty cots than any other single cause he knew. In major operations on the large intestine and rectum after several days' preliminary aperients and lavage the bowels should be allowed to rest for two clear days before operation. What was most potent in maintaining the patient's reserve, keeping up the carbohydrate metabolism, and preparing him for the anæsthetic and the insult to his tissues, was glucose. This should be administered, in greater or less degree, to all patients about to undergo operation; it could be given as barley sugar or added to orange or other juices. The patient's ordinary diet should be continued to within three hours of the operation, glucose being added to the drinks taken. Especially on the night preceding the operation should sleep be sound; this could be ensured if necessary by one of several drugs. On the day of operation the aim was that the patient should go to sleep in his bed, and wake up in the same place some hours after the operation. He used a combination of omnopon and scopolamine. Frequently that put the patient to sleep in a few minutes, and after the operation he might not know he had been away from his bed. In using hyoscine it was important to realise that this drug contained two alkaloids; the effect of one was stimulating, the other sedative. These forms were not standardised in the British Pharmacopœia; he therefore procured hyoscine of the sedative type from the continent. Rectal injection of avertin he used occasionally in submaximal doses, but not for abdominal cases, as it caused post-operative paresis of the intestine; nor in cases likely to bleed much. The barbiturates had a distinct sphere of usefulness. Only one anæsthetic was proof against criticism—namely, nitrous oxide and oxygen. This anæsthesia was pleasant to the patient, it was never associated with post-operative complication, after it vomiting was practically unknown; it could be used in young and old, and for every type of operation. Even so, it should be given by a skilled anæsthetist. There was no excuse for using chloroform; it was a powerful poison and should be found only in the hospital museum.

So far, said Mr. Abel, he had presupposed the patient to be in a normal state except for the trouble calling for the operation. No major operation on the mouth or pharynx should be done until the teeth were in a satisfactory condition. Preferably the patient should be edentulous. If heart or lungs were defective, the choice of anæsthetic should receive special consideration. Should the hæmoglobin be less than 50–60 per cent., the operation should be deferred pending feeding up or blood transfusion. If the urea was high, the bladder should be drained, either through a catheter, or suprapubically. Diabetes or excess of sugar in the urine must be recognised before operation and treated accordingly. He always carried glucose and insulin with him when operating in suburbs or provinces. If the projected operation was to be on the biliary passages, jaundice or any hæmorrhagic state must have suitable treatment, with the object of avoiding severe hæmorrhage after the operation. He recommended the intravenous injections of calcium chloride, 10 c.cm. of a 10 per cent. solution, combined with injections of 15 units of parathyroid extract. In jaundice, 500–1000 c.cm. of 10 per cent. glucose in normal saline should be given intravenously the day before operation. If the hæmoglobin was less than 50 per cent. or red cells less than 4,000,000, blood should be transfused. If no anæmia was present, blood transfusion was better deferred until after the operation; then one was sure of a pint of non-anæsthetised blood being in the patient, with a stimulation of the bone-marrow to blood-cell production, and mobilisation of the blood cholesterol. For shocked patients the great standby was morphia. If vomiting occurred before the operation the stomach should be washed out.

AFTER.

In the constitutionally normal patient after operation two factors had to be combated: shock, and the effects of the anæsthetic. For the first of these, warmth was very important: gamgee tissue jacket and hot electric blanket, rest in bed, heroin or morphia, with injections of glucose in normal saline per rectum, subcutaneously or intravenously. Failure of respiration was best treated by injections of alpha lobeline. After an operation which was sure to be followed by considerable shock 500–750 c.cm. of blood should be transfused, preferably before the patient left the table. This measure had resulted in a definite lowering of the mortality after some severe operations, such as that for carcinoma of the rectum. With the patient sitting up there was less danger of lung complications.

About diet there was still much difference of opinion; the question was specially important in abdominal cases. He believed in as complete rest as possible to the alimentary canal. After operation, Nature placed the abdomen at rest, the muscles protectively formed a splint, and peristalsis was inhibited by the painful impulses from the operation site. If the patient had been guarded against dehydration before operation, thirst was not likely to be intense. To allay it the chewing of pineapple chunks might be allowed, the fibre being put out. Milk should be deferred for three or four days; when given it should at first be peptonised. After operation no purge should be given until the bowels of themselves showed signs of activity. After the second day an enema was given; he found turpentine, black treacle, or ox gall very satisfactory. No tubes should be left in the abdomen longer than 36 hours, otherwise there was a liability of spread of infection from skin inwards. Usually his patients were sitting about the ward on the third day after operation; if they could be gently on the move there was less danger of complications and of abdominal weakness.

A serious result of combined anæsthetic infection and shock was disturbance of the carbohydrate metabolism. There was now, he said, a general feeling that what was formerly known as acidosis did not exist as a common post-operative condition; what occurred after operation was rather a state of alkalosis. Whether a patient had excess of alkali in the blood stream or an excess of acid depended on the relative loss of water or salt. If the patient was dehydrated, an acid condition supervened; if the loss of salt was predominant, the patient had alkalosis, even though the urine might be acid. The loss of chloride due to vomiting and to the anæsthetic lowered the osmotic pressure of the blood, leading to retention of bicarbonate in the blood plasma. It occurred sometimes in those who had taken considerable alkali for medical reasons. In a difficult case it was impossible to distinguish between alkalosis and acidosis without making a chemical examination of the blood. Paralytic ileus and acute dilatation of the stomach were caused by excess of alkali in the blood. The prevention of alkalosis consisted in giving 10 per cent. glucose in normal saline per rectum by means of Murphy's drip. If a patient vomited 24 hours after operation, the stomach should be washed out. Some preferred duodenal drain for this. In paralytic ileus pituitrin and cathartics should be carefully avoided; they were like flogging a dying horse. Sodium chloride, with glucose, should be given intravenously for several days. Paralytic ileus was associated with vagal paralysis and the formation of a toxin, similar to that of *B. welchii*. Mr. Abel had had many successes in desperate cases following the use of the direct vagal stimulant, acetylcholine, and with anti-gas gangrene serum.

Discussion.

Mr. CECIL ROWNTREE spoke of the importance of the psychological aspect, which predominated to the patient. Nowadays surgeons had the privilege of working in association with anæsthetists who were keenly alive to this. Patients did not now fear that they would feel pain, but they dreaded the atmosphere of the surgery. Mr. Rowntree agreed that gas and oxygen was the ideal anæsthetic, but it was not always possible to secure its expert administration. Sometimes the patient strongly insisted that his own doctor should give the anæsthetic, and he chose ether, so that this was the drug the patient got—more or less. Every means should be used to ensure skilled anæsthesia. Unlike Mr. Abel, he believed in castor oil in operation cases; having given it, he knew there would be no prolonged distension, and he thought it cut out many post-operative difficulties. He did not see post-operative ileus in his practice, and that might be because he gave castor oil. He had a practical suggestion to offer: it would be a real advance if there were "pre-operative beds" in hospitals; these would be in charge of an enlightened physician—i.e., a physician with surgical leanings—who would assess and report on the risks of each patient.

Mr. H. P. WINSBURY-WHITE said that in urological cases it was very important to avoid diagnostic instrumentation within a short time of the proposed operation. He referred, for instance, to cystoscopy in cases of enlarged prostate. After cystoscopy, a proportion of patients developed retention of urine, while some would have catheter fever—a very unpleasant occurrence before operation. Another undesirable procedure was instrumental pyelography. Intravenous pyelography had now been introduced, and had largely done away with the necessity of the instrumental method. In dilated kidney, where the opaque medium was introduced and could not be withdrawn because there was obstruction, there might be considerable reaction from the irritant medium. When instrumentation was essential a sufficient interval should afterwards elapse before operation. After urological operations careful and unremitting attention should be given to the patients; the surgeon must decide when he would cease irrigation, whether he would use drainage-tubes, and also urethral instrumentation. Bad judgment in these matters was liable to precipitate a dangerous crisis. In preparing bladder cases for operation he had found castor oil excellent; admittedly its post-operative use was bad. For prostate cases, nitrous oxide and oxygen was a good anæsthetic, and he preferred the addition of a little ether. He had seen no disadvantage from the ether.

ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN.—The number of new in-patients (268), new out-patients (11,824), and out-patient attendances (53,266) last year were all the largest on record, and the annual report notes, as a sign of the recognition of the hospital as a treatment centre for skin diseases, that a third of the new out-patients were sent by medical practitioners. The weekly cost of in-patients (268) has been reduced from £3 11*s.* 11*d.* to £3 3*s.* 10*d.* The length of stay averaged 36 days as against 41 in 1929.

THE INTER-STATE POST-GRADUATE ASSEMBLY OF NORTH AMERICA.

THIS association met in London at the house of the Royal Society of Medicine on May 26th, when Sir THOMAS HORDER, chairman of the British Isles committee, welcomed the delegates and gave an address entitled Some Medical Hints. He deplored the replacement of the aphorism in medical teaching by the lengthy article, and began with some aphorisms on alcohol.

Alcoholism.

The acquired causes of the alcohol habit, he said, were mainly psychological: the drab life of the poor, the ennui of the rich, the state of "misère," and success achieved too early. Alcoholic beverages at the end of the day tended to promote sleep in those accustomed to them and insomnia in those unaccustomed to them. Anomalies of temperature in illness were not seldom explained by alcoholic addiction; morphia might produce the same effect. Spirit-drinking was a potent cause of inflammation of the whole alimentary tract, from gingivitis to colitis and proctitis. Symptoms of duodenal dyspepsia were not infrequently the result of relative excess, and the discomfort was often relieved by resort to the cause—no doubt one of the explanations of the aperitif habit. Hunger with discomfort was relieved by the cocktail, but demanded increasing amounts of the remedy. Alcoholics tended to bleed more often and more profusely than non-alcoholics; hæmatemesis, hæmoptysis, and hæmaturia were all examples. The prognosis in alcoholic cirrhosis was uniformly bad in hospital patients, especially when ascites appeared, but was often better among private patients. In considering the prescription of alcohol in diets it should be remembered that the physician's principle in ordering a regimen was not the most meagre diet on which the patient could live but the diet on which he could live most comfortably and efficiently. The withdrawal of alcohol in the cure of alcoholism must be determined by the individual case. If the main indication was physical—if a tissue craving had been established—the gradual method was probably essential, but if the main indication was psychological, it was often more dramatic and therefore better to break altogether, but the patient must be under close observation. Success depended on the absence of disappointment. A frank talk with the patient and his agreement were a sine quâ non. In doubt, the gradual method was probably safer. In prognosis, the doctor's confidence in the patient's ability to abstain should be in inverse ratio to the patient's own confidence.

Influenza and Some Abdominal Conditions.

There was no exact criterion in the diagnosis of influenza; the nearest approach was a clinical picture more easily recognisable during an epidemic than at other times and varying in different epidemics. The most characteristic lesion was pulmonary—an acute bronchiolitis with weak breath sounds and copious small râles. The signs often seemed quite inadequate to explain the degree of illness and the persistence of the pyrexia. It was a fallacy to think lightly of congestion of the lung. A frank lobar consolidation was far better than a series of congestive patches with no hope of a crisis. The most helpful therapeutic agent available was fresh air, and it was all too often denied to the patient. "A draught" was just what he wanted, but he was often "cooked" with excessive blankets; the amount of bedclothes should be determined by the temperature and not by the patient's feelings. Cradling and sponging were useful.

Abdominal examination was of vital importance. The abdomen should be inspected from the head and foot of the bed as well as from the side, and from the level as well as from above. The question of symmetry was vital; the human abdomen in health was absolutely symmetrical. Auscultation was generally omitted altogether, but every now and then it yielded information of the highest value—e.g., perisplenic friction; or a bruit over a hypernephroma, suggesting a blood-vessel of such magnitude that the patient would be unlikely to survive removal. The distinction between pain and tenderness was significant. The gall-bladder, being contracted and adherent, was often impalpable in cholecystitis. Tuberculous peritonitis was much more often diagnosed—correctly—in the absence of direct evidence of tuberculosis than of its presence; the disease was more often than not confined to the abdomen, especially in children. Even ascitic fluid often gave negative response to tests. One of the most decisive clinical signs was the formation of indurations; these must be distinguished from encysted fluid, tubo-ovarian mating, and appendicular inflammation.

Gastric ulceration was not necessarily malignant because the patient was elderly; age of itself gave no help in differential diagnosis. A frank hæmatemesis highly favoured a diagnosis of simple ulcer Cancer of the stomach and colon was a disease sui generis and was not grafted on chronic ulcer, inflammation, or displacement. The commonest history in carcinoma of the stomach was perfect digestion up till a few months before the patient was first seen.

Mr. DONALD ARMOUR spoke on the

Treatment of Head Injuries.

The treatment, he said, concerned not only the immediate recovery of the patient, but also his ultimate restoration to normality. The damage to the contents was far more important than the injury to the skull itself. "Minor" head injuries often had major sequelæ, and were too frequently neglected. He outlined the anatomy and physiology of the cerebro-spinal and cerebral blood circulations. A delicately balanced equilibrium was maintained, he said, between the production and absorption of cerebro-spinal fluid and the osmotic and hydrostatic pressure of the blood, but gross changes in blood pressure affected the cerebro-spinal fluid pressure. The intracranial pressure depended on five factors: the volume of the blood in the brain, cord, and coverings; the volume of the cerebro-spinal fluid; the volume of the brain; and the tension of the dura and skull. The normal positive pressure depended on the closed-box system of the cranium, variations in volume of either the fluid, blood, or brain being compensated by variations in one of the other two—i.e., in practice by expression of fluid or blood. The margin for their elimination was small, and any increased pressure was bound soon to produce symptoms. Mr. Armour then described the symptoms of interference with the cranial circulation, and the stages of compensation, venous stasis, and cerebral anæmia. If the symptoms were produced by sudden pressure, much greater than that of the blood, the skull was distorted and might or might not be fissured. The effects of deformation were not revealed by inspection of the skull. Early X rays were therefore useless in head injury, and constituted a pitfall in prognosis. The sudden very great increase in intracranial pressure affected all systems, but the choroid plexuses were particularly vulnerable. Symptoms were due to hyperacute compression, producing general cerebral anæmia, and to contusions caused by the deformation of the skull. Any injury of the brain produced œdema leading to venous stasis. Hæmorrhage was the most important result of injury in the production of symptoms, and its rate of progress was the most significant factor. It was important to ascertain the intracranial pressure with a view to prognosis and treatment. The blood pressure was no guide, but the manometric estimation of cerebro-spinal fluid pressure was of the utmost value. Normal pressure varied over a wide range, but pressures above 250 mm. of water were suspicious and over 300 mm. definitely indicated pathological change. Examination of the optic discs for papillary stasis was helpful. Early ocular signs were dilatation of the retinal veins, followed later by blurring of the edges. In local compression ophthalmoscopic examination might have localising value, and the veins of the scalp, forehead, and eyelids might confirm the diagnosis. The absence of blood in the cerebro-spinal fluid did not exclude hæmorrhage, but it seemed that both acute and chronic changes in the central nervous system followed the introduction of blood into the fluid; neuralgic headache, delirium, slight increase of pulse-rate and pyrexia, Kernig's sign, and post-cervical rigidity. The irritating blood should be removed by lumbar puncture or decompression. The value of lumbar puncture was not fully appreciated; in milder cases of tension it often postponed operation until a better time or obviated it. It mitigated the headache, irritability, and vertigo of patients not needing decompression. Intravenous or oral hypertonic saline or glucose reduced intracranial tension; magnesium sulphate had been found to be better than sodium chloride, but the least toxic and most effective solution for intravenous use was dextrose. Cases not requiring operation should be kept in bed, propped up (to reduce pressure), and kept free from all forms of external stimuli. Mild sedatives and purgatives—preferably magnesium sulphate—should be given.

No operation was indicated if there was no increase of tension—i.e., in about two-thirds of the cases of head injury. No operation whatever should be performed during the period of initial shock or in the terminal stage of medullary œdema and collapse. In the absence of increased pressure operation was not indicated. The ideal period for intervention was the stage of capillary anæmia, as shown by a slow pulse and slight rise in blood pressure, in time to avert medullary compression. It was most important to note whether the degree of coma varied with the cerebro-spinal fluid pressure. Mr. Armour then described the operation of decompression.

Dr. STRICKLAND GOODALL spoke on

The Right Ventricle.

He thought that the right ventricle was apt to be neglected. Its function was to supply energy for the pulmonary circulation. The efficiency of the right heart depended on adequate filling, myocardial integrity at the pulmonary base, an efficient tricuspid tensing mechanism, and free outlet. The ventricular contraction started in the right papillary muscle, which tensed the tricuspid valve. The bundle system constituted a large motor end-plate and distributed the stimulus throughout the whole of the myocardium. The tricuspid valve might become cient through dilatation of the ring to which it was attached; through direct damage, as in endocarditis, or through damage or inadequate stimulus to the right papillary muscle. The contractility of the pulmonary base might be affected by infarction or interference with its blood-supply, or by interference with its nerve-supply. The right branch of the bundle of His consisted of two main branches: one crossed in the moderator band to the right papillary muscle and the other arbourised round the pulmonary base. If the main branch were damaged, both valve and base were damaged and the right ventricle only acted by overflow from the left. If, however, the tricuspid branch only was affected the electrocardiographic picture would show normal T_1 but very small R_2. The electrocardiogram showed what the heart muscle was doing, but did not show why. If the base branch was damaged the result would be defective contractility with only secondary reflux through the valve. The T wave in the first lead could thus be inverted in two ways.

The most important relation of the right heart was the stomach which in the young lay immediately beneath it and was fitted with an automatic release to regulate gastric pressure. Therefore in youth there was never any real effective pressure on the heart. With age the arteries lengthened, the heart lost tone, and became triangular and came down on the stomach, which by this time had lost its automatic release so that its pressure varied with its contents. A hard stomach came into contact with a soft heart, and might start fibrillation, extrasystoles, a right ventricular paroxysmal tachycardia, or an anginal attack. In Dr. Goodall's experience, 80 per cent. of heart cases first got symptoms after a meal, and 70 per cent. of unexpected deaths occurred after a meal. Every heart case should be dieted and the stomach attended to from the first. Mechanical embarrassment of the heart should be remediable. Cases could only be properly treated after cardio-analysis.

With age, or after infective diseases, the heart became atonic, sessile, or "concertina"; this was no more characteristic of syphilis than of any other infection. This heart was a large heart, an inefficient heart, a soft heart, boot-shaped in X ray, and showing a slapping apex-beat, with inversion of the T wave in lead III. and left-sided preponderance, and it was often irregular, owing to extrasystoles. It often developed right branch block—obviously enough, since the right branch of the bundle of His was responsible for right ventricular tone. Right branch block might be temporary, during anginal attacks, before death, or in acute right-heart strain; it was often the underlying cause of chronic cough. The commonest variety of block was in the branch going to the papillary muscle and the least common was in that going to the base. There were four main causes of block: mechanical strain, arterio-sclerosis, syphilis, and rheumatism. The prognosis in syphilitic cases was very bad; it was better in the arterio-sclerotic and best in the rheumatic group. Right branch block was not very common in mitral stenosis.

The coupling beat due to overdose of digitalis was always an extrasystole and usually started in the right ventricle, because digitalis was usually given to patients with right-heart strain, and the first expression of poisoning appeared in the most damaged part. If a left-heart failure were poisoned by digitalis the left heart was coupled. Prognosis in mitral stenosis was grave if the T wave in the first lead was poor, indicating thin myocardium about the pulmonary base.

REVIEWS AND NOTICES OF BOOKS

The Medical Annual, 1931.

Edited by CAREY F. COOMBS, M.D., F.R.C.P. Lond., and A. RENDLE SHORT, M.D., B.S., B.Sc., F.R.C.S. Eng. Bristol: John Wright and Sons, Ltd. 1931. Pp. 603. 20*s.*

L'année médicale pratique.

Edited by Dr. CAMILLE LIAN. Paris: René Lépine. 1931. Pp. 635. Fr.26.

WITH this edition the "Medical Annual" reaches its forty-ninth year of useful service to the profession. A number of new treatments for everyday ailments are described, some of which will be of great value to the practitioner. As an example may be quoted the method of firm strapping for chronic ulcer of the leg—a simple procedure which will constitute a great advance if the well-supported claims for its efficacy prove to be justified. Another simple and apparently valuable measure is the "hydration treatment" of epilepsy, while insulin has found two more fields of usefulness in anorexia nervosa and diphtheria. The articles on food and the public health bring out two points which may prove to have great importance: the use of antitoxin for botulism and the increasing incidence of *Brucella abortus* infection. Recent advances in the treatment of colitis and diverticulitis, alcoholism and drug addiction, and high blood pressure are described in detail. Studies in the endocrine system have revealed a hyper-insulinism, analogous with hyperthyroidism, and the usefulness of surgical treatment for osseous disease associated with cyst or tumour in the parathyroid gland. Fresh light is being thrown on blood diseases; for instance, those in which the leucocytic picture is grossly altered, and pernicious anæmia. From studies in the latter disease has been established the interesting fact that persons with a defective secretion of hydrochloric acid are more liable than others to certain diseases. The shortage of hydrochloric acid in the asthmatic child is another observation which may lead to therapeutic developments. The practitioner will find useful hints on the treatment of painful heel, burns, and rectal prolapse. A section new to this volume is that on affections of the teeth, which stresses the value of proper diet and of sunlight. The value of submammary saline infusion before any active interference is undertaken in cases of placenta prævia is discussed in the midwifery section. The section on ophthalmology describes a new occupational disease—a conjunctivitis contracted in the artificial silk industry. The use of contact glasses for conical cornea or ignipuncture for detached retina, and the diagnosis and treatment of pink-eye are discussed. The volume includes, besides its clinical material, an index of new preparations and appliances, a classified list of the books of the year, and of medical institutions, homes, spas, and periodicals, and an official and trade directory, all efficiently indexed. It will be as welcome to the profession as were its predecessors.

The tenth volume of the French equivalent of our Medical Annual includes an index of the volumes from 1927 to 1930. It is a useful little book, though less exhaustive than its British prototype. Illustrations are lacking, except for some electrocardiograms in the article on angina, and two photographs illustrating correction of mammary atrophy by omental graft. The list of contributors is a distinguished one, and the book should be of interest to English as well as French practitioners. It contains, in addition to therapeutic material, a review of those legal enactments passed during the year which concern medical subjects, and a list of pharmaceutical specialties, instruments, and books.

Surgery. Its Principles and Practice.

Fourth edition. By ASTLEY PASTON COOPER ASHHURST, A.B., M.D., F.A.C.S., Professor of Clinical Surgery in the University of Pennsylvania. London: Henry Kimpton. 1931. With 15 coloured plates and 1063 illustrations. Pp. 1189. 45*s.*

THIS text-book of surgery owes much to the clinical experience, judgment, and care of its author. Since practically all of the 1063 illustrations are original and are taken from the author's own cases, we can expect to find in the text the considered opinions of a surgeon of wide knowledge and experience. The work reads pleasantly, and is free from the repetitions of descriptions culled from other sources which make too many text-books dull. The matter is divided into three sections—general, systematic, and regional surgery, and clear, concise descriptions of operative procedures are given, one method of operative treatment at least for each pathological condition. Special regions are dealt with only in so far as they fall within the province of the general surgeon, but within this limit they are adequately discussed. The work is beautifully printed and bound, and the illustrations are well selected and well produced. Dr. Ashhurst has spared no pains in securing illustrations, and, if only for this reason, his book is admirably suited to the needs of the student, whose opportunities of seeing the less common conditions are, of necessity, scant.

Bright's Disease.

Observations on the Courses of Different Types and on the Resultant Changes in Renal Anatomy. By a Group from the Hospital of the Rockefeller Institute for Medical Research, consisting of: DONALD D. VAN SLYKE, EDGAR STILLMAN, EGGERT MOLLER, W. EHRICH, J. F. MCINTOSH, L. LEITER, E. M. MACKAY, R. R. HANNON, N. S. MOORE, and CHRISTOPHER JOHNSTON. London: Baillière, Tindall and Cox. 1930. Pp. 130. 13*s.* 6*d.*

THIS work, which previously appeared in the journal *Medicine*, is now reprinted as Vol. XVIII. of "Medicine Monographs," and so is available in handier form. Many medical men interested in the subject will be glad to preserve what is one of the most valuable publications of recent years concerning Bright's disease. The bulk of its contents is made up by full case reports illustrative of the various types of nephritis, and it is noteworthy that the group of workers responsible adopt, with very minor change, the classification of Volhard and Fahr—that is to say, they recognise three main groups: a hæmorrhagic group, primarily affecting the glomeruli; an arterio-sclerotic group, corresponding to the ischæmic group of many modern writers; and, lastly, a degenerative or nephrotic group. Full accounts of the biochemistry are given in all cases, and the inclusion of post-mortem findings in each instance permits clinical and biochemical data to be accurately coördinated with the histology. English observers familiar with the detailed histology contained in the monograph by Dorothy Russell (Medical Research Council Special Report Series, No. 142) may find the section on morbid anatomy in this volume somewhat disappointing. The American publication, if less exhaustive in detail, is easier to follow, and the adequate attention given to biochemical findings is satisfactory. The student who is accustomed to regard a monograph as a work which includes a review of the literature will be disappointed at the paucity of the bibliography here supplied. The references are quite inadequate for a work of such importance. It is difficult, for example, to understand how the classical work of Gull and Sutton can have been ignored, and perhaps still more remarkable is the omission of all reference by the authors to the work of their distinguished compatriot, A. M. Fishberg.

The last decade has seen a notable revival in scientific interest in medical diseases of the kidney, and this monograph is a worthy contribution to this movement.

Radiations from Radioactive Substances.

By Sir Ernest Rutherford, O.M., D.Sc., Ph.D., LL.D., F.R.S., Nobel Laureate, Cavendish Professor of Experimental Physics in the University of Cambridge; James Chadwick, Ph.D., F.R.S., Fellow of Gonville and Caius College, Cambridge; and C. D. Ellis, Ph.D., F.R.S., Fellow of Trinity College, Cambridge. London: Cambridge University Press. Pp. 588. 25*s*.

The students who were brought up on Rutherford's "Radioactivity," published in 1904, were ready and waiting for his next volume, entitled "Radioactive Substances and their Radiations," which appeared in 1912. This book was soon out of print, and once again an eager crowd, ever increasing in numbers, awaited the publication of another standard work of reference by the author. They had long to wait, but the book now issued is worth waiting for. Praise would be impertinence; one does not praise a revelation of a new world of knowledge. Some idea of the extent of the growth in the subject of radioactivity is gained from the title, about which Lord Rutherford says in his preface: "For these reasons, I have thought it desirable to confine this new work mainly to an account of the radiations from active matter and their application to physical problems. The way in which the long series of radioactive transformations has been unravelled is only referred to in an incidental manner."

This book will be accounted at once as the standard work of reference on the subject for English readers.

John Chalmers DaCosta.

Selections from the Papers and Speeches of John Chalmers DaCosta, M.D., LL.D. By Samuel D. Gross, Professor of Surgery at the Jefferson Medical College, Philadelphia. London: W. B. Saunders Co., Ltd. Pp. 440. 30*s*.

In this large book, but not too large for the range of its subjects, Dr. DaCosta puts together a series of papers contributed to American medical journals, forming the substance of addresses delivered to American medical societies and associations. Philadelphia looms large in the chapters, for they include a character sketch of the famous Prof. Gross, the founder of the professorial chair which the author fills; the stories of the old Blockley and Jefferson hospitals and the oration delivered at the jubilee meeting of the Philadelphia County Medical Society; biographical notes on William Williams Keen, "the most notable figure in the Jefferson Medical College"; and an example of a Samuel Gross oration. Of chapters of more general interest one describes medical Paris during the reign of Louis Philippe; another records the performances of Napoleon's famous military surgeon Baron Larrey; another summarises the virtues and failings of Samuel Pepys fairly; and another gives a detailed description of Dickens's doctors in which the great novelist is found to have treated the medical profession unfairly, but in which, perhaps, too much stress is laid upon the presentations of obvious caricatures. The book, which is dedicated to Prof. Harvey Cushing, should interest many readers.

Grosse Biologen.

Eine Geschichte der Biologie und ihrer Erforscher. By Prof. Ernst Almquist. Munich: J. F. Lehmann. 1931. Pp. 143. RM.8.

Prof. Ernst Almquist, of Stockholm, has written a short history of biology in the form of 23 biographical sketches of men who were curious enough to inquire into its secrets. The book is a sequel to Prof. Philipp Lenard's popular "Grosse Naturforscher," a series of scientific biographies which began with Pythagoras and Euclid, going on through Galileo, Kepler, Descartes to Faraday, Helmholtz, Bunsen, and Crookes. Almquist begins with William Harvey and goes on through Linnaeus, Mendel, Virchow, Pasteur, and Koch to Darwin, De Vries, and Carl von Nägeli, then returning rather surprisingly to Aristotle, Francis Bacon, and John Stuart Mill. He devotes a chapter to the mistaken orientation of present-day biology on which he holds strong views. He finds progress chiefly among those who have done experimental work and have not allowed mere theorising to carry them beyond what can be proven. The book is embellished with admirable photographs and is a stimulating contribution to biologic thought.

REPORTS AND ANALYSES

"ORYO" CRISPBREAD.

(MADE IN SWEDEN.)

ORYO, LTD., 91/3 BISHOPSGATE, E.C.2.

The package contained 8·7 oz. of thin biscuit-like material, the separate pieces (26) measuring 4¼ in. by 2½ in. On analysis the following results were obtained:—

Moisture	6·66	per cent.
Ash	2·40	" "
Fat	1·65	" "
Protein	12·25	" "
Crude fibre	2·00	" "
Digestible carbohydrates ..	75·04	" "
Calorie value (per lb.)	1603	

These figures support the claim that the crispbread is prepared from whole grain rye. By reason of its crispness Oryo is easy to masticate, and this helps the digestive process; in addition it has a very agreeable flavour. As it is cut into slices ready for use, the handling of it before serving is reduced to a minimum. When consumed with butter or other fatty material Oryo constitutes an attractive food material.

THE LANCET.

LONDON: SATURDAY, MAY 30, 1931.

EPIDEMIC JAUNDICE.

DURING the past few months fresh facts have been added to our knowledge of epidemic jaundice. It is evident that there are at least two epidemic diseases characterised by jaundice and by a number of other clinical symptoms in common. These two diseases are leptospiral jaundice and epidemic catarrhal jaundice, or, as Rolleston and McNee prefer to call it, common infective hepatic jaundice. Both diseases appear to be world-wide in their distribution and by clinical means alone their differentiation is by no means easy. It is therefore important that every epidemic should be investigated both clinically and bacteriologically. Such an exhaustive investigation has recently been carried out by J. Taylor and A. N. Goyle[1] on the causation and epidemiology of the jaundice that occurs in the Andamans. Jaundice has been rife in these islands for a very considerable time, and during the last 40 years has been studied by numerous workers. F. A. Barker, in 1926, was the first to demonstrate the presence of leptospira, while two years later, in our own columns, H. C. Brown showed that antibodies to leptospira were present in the blood-serum of jaundiced patients, bringing forward evidence that in the sera examined there were antibodies which, while quite distinct from those produced by the London human and rat strains, were allied to certain strains of leptospira from Sumatra. As a method of diagnosis, Taylor and Goyle find that blood culture is of great value provided it is carried out between the third and sixth day of illness. The serological relationships of the 28 strains of leptospira isolated were also investigated with the result that there appear to be two distinct serological groups. In studying the relationship of *L. icterohæmorrhagiæ* to the Akiyami A strain, K. Yang and M. Theiler[2] have lately raised the question whether it is legitimate to recognise a new strain simply because there is a demonstrable quantitative difference in the potency of the immune serum as manifested for example by the agglutination test. The findings of Taylor and Goyle are, however, so definite that they appear to warrant the serological grouping of the Andaman strains. In discussing the differential diagnosis of leptospiral jaundice, Taylor and Goyle say that in catarrhal jaundice the general pains, albuminuria, conjunctival congestion, and tendency to hæmorrhage are absent. To this it is difficult to agree, for some or all of these symptoms may be encountered in cases of epidemic catarrhal jaundice.

Epidemic non-leptospiral jaundice has also recently received considerable attention both in this country and abroad. One such outbreak, involving the pupils of three schools, was recorded in our issue of March 28th by J. A. Glover and Joyce Wilson, while another has recently been investigated in Surrey by G. M. Findlay, J. L. Dunlop, and H. C. Brown.[3] In its epidemiological and clinical features this Surrey outbreak was very similar to those recorded by W. G. Booth and C. C. Okell[4] in 1928 from Surrey, by M. T. Morgan and Brown[5] in the same year from Northamptonshire, and by W. N. Pickles[6] in 1930 from Yorkshire. The incubation period was found to be a long one and varied from three to five weeks. In leptospiral jaundice, on the other hand, according to Taylor and Goyle, and others, the incubation period is from six to eight days, while V. de Lavergne and Robert-Lévy[7] record an incubation period of about five days when the leptospira gain entrance by the mouth and 15 days when they pass through an injured skin surface. An examination of the differential leucocyte count may also be of service in distinguishing leptospiral and epidemic catarrhal jaundice. Taylor and Goyle, as the result of a very large series of blood examinations, come to the conclusion that the most striking feature of the differential count is the relative increase in the number of polymorphonuclear leucocytes. In epidemic catarrhal jaundice, on the other hand, according to Findlay, Dunlop, and Brown, an increase in the polymorphonuclear leucocytes is present, if at all, only during the first few days of the disease. Instead there is a decrease in the number of polymorphonuclear leucocytes with a corresponding increase in the number of lymphocytes, large mononuclears, and transitional cells. In America, C. M. Jones and G. R. Minot (1923) and E. Thewlis and W. S. Middleton (1925) have recorded similar blood changes in epidemic catarrhal jaundice. In the course of the investigation of the Surrey epidemic numerous unsuccessful attempts were made to transmit the disease to guinea-pigs, and to determine the presence of immune bodies to leptospira in the serum. Efforts to infect monkeys (*Macacus rhesus*) either by the inoculation of blood or by spraying with washings from the nasopharynx of patients in the pre-icteric stage of catarrhal jaundice were also unsuccessful, as were attempts to transmit the disease to rabbits, rats, and mice. The failure to infect Indian monkeys with epidemic catarrhal jaundice occurring in this country is in agreement with the findings of Beeuwkes, Walcott, and Kumm,[8] who were also unable to infect monkeys with the form of jaundice which has recently occurred in epidemic form in West Africa.

Findlay, Dunlop, and Brown also discuss the relationship of epidemic catarrhal jaundice to acute yellow atrophy of the liver, or, as it is preferably called, acute necrosis of the liver. In this country there has been but one recorded fatal case of epidemic catarrhal jaundice—that reported by Morgan and Brown. Abroad, however, and more especially in Sweden, acute yellow atrophy has occurred almost in epidemic form as a sequela of epidemic catarrhal jaundice. In 1927 acute yellow atrophy of the liver was responsible for 84 deaths in Sweden, 42 cases being met with in Stockholm alone. As H. Bergstrand [9] points out, the initial symptoms of acute yellow atrophy of the liver are identical with those of catarrhal jaundice; then, quite suddenly, there appear the well-known signs of liver insufficiency. The reason why epidemic catarrhal jaundice should be so benign in this country yet on occasions so malignant abroad is at present unknown. Possibly the acute necrosis of the liver is due to some secondary infection which acts on an organ primarily damaged by the epidemic catarrhal jaundice. In certain cases of acute yellow atrophy of the liver Bergstrand, for example, has obtained *Streptococcus viridans* in pure culture from the duodenum. While there is now ample evidence that leptospira are ætiologically responsible for one form of infectious jaundice, there is as yet no indication of the causal agent of epidemic catarrhal jaundice. Failure to isolate any bacterium of ætiological significance does not, of course, rule out a bacterial origin. It does, however, suggest the possibility that epidemic catarrhal jaundice may have to be added to the ever-growing number of diseases caused by ultra-microscopic viruses.

CANCER AND RACE.

ONE of the legends surrounding the cancer problem is that Jews are relatively immune from cancer. Another is that they are particularly susceptible to cancer. Either of these two assertions, if substantiated, would be of considerable general importance, because it would indicate the existence of a factor of racial susceptibility in the ætiology of cancer. The Jews, as ROGERS WILLIAMS has pointed out, are particularly suitable for the investigation of such a problem because, although they have acquired the general habits of the non-Jewish populations among which they live and are subjected to the same general environment, they have maintained themselves racially pure. Dr. SORSBY has attacked this problem by comparing [10] the recorded cancer mortality in various Jewish communities—London, Amsterdam, Vienna, Budapest, Warsaw, Lodz, and Leningrad—with each other and with that of the non-Jewish populations in these different cities. In collecting this material considerable difficulties had to be overcome in order to exclude statistical fallacies which have been clearly recognised by the author. As a result of these investigations the conclusion is reached that the total recorded mortality from cancer varies in different Jewish communities tending to approach that of the non-Jews of each particular city, so that there is no evidence of a racial factor so far as the general mortality from cancer is concerned.

There are, however, striking differences in the organ incidence of cancer between Jews and non-Jews. Thus in all communities investigated the incidence of cancer of the uterus is much lower among Jewish women than among non-Jewish women, the incidence for Jewish women varying from about one-half to one-third of the incidence in their non-Jewish neighbours. The same is true for cancer of the penis among men, not one case of cancer of the penis having been found in the 2252 male cancer deaths recorded among the Jews of London and Vienna, although from the incidence among non-Jews 12 cases were expected to have occurred. A higher organ incidence among Jews was found for the lower part of the gastro-intestinal tract and for the ovaries. These differences in the organ incidence are subjected to a detailed discussion, and the conclusion is reached that they are not due to racial factors but to environmental factors. Thus the immunity from cancer of the penis is attributed to circumcision, while the relative freedom from cancer of the uterus is explained as being the result of the greater sexual hygiene imposed upon Jews by religious prescriptions. This latter explanation seems however hardly consistent with the author's own data. For while it is true that for each community the incidence of cancer of the uterus is always lower for Jewish women than for their non-Jewish neighbours, a comparison of this incidence among the different communities shows extremely wide variations both for Jewish and for non-Jewish women. Thus the Jewish women of Budapest suffer from cancer of the uterus as frequently as the non-Jewish women of Vienna and Warsaw, and even more frequently than the non-Jewish women of Amsterdam. It should be remembered that the recent very detailed investigations carried out by an international statistical committee under the auspices of the Health Organisation of the League of Nations on a closely related question—namely, the notable differences in the incidence of cancer of the breast and uterus in Dutch and in English women—has failed to find any environmental factors which could reasonably be made responsible. As regards the higher incidence of cancer of the intestinal tract among Jews Dr. SORSBY frankly admits that he is unable to offer an explanation.

These differences in the organ incidence of cancer, which may frequently be found when different groups of populations are compared, are indeed very puzzling. What is even more puzzling is the fact, to which attention has been drawn in the recent annual reports of the Imperial Cancer

---

[9] Über die akute und chronische Gelbe Leber-atrophie, Leipzig, 1930.

[10] Cancer and Race. A Study of the Incidence of Cancer Among Jews. By Maurice Sorsby, M.D. London: John Bale, Sons, and Danielsson. 1931. Pp. 120. 7*s.* 6*d.*

Research Fund, that the groups of populations in which they occur may nevertheless have the same total incidence of cancer. The most striking example is offered by a comparison of the cancer incidence in men and women in this and certain other countries, a comparison which with an obviously different organ incidence presents an approximately equal total incidence from cancer. Dr. SORSBY's work presents another example of this phenomenon, for in most of the Jewish communities investigated by him men and women suffered in about equal numbers from cancer. Dr. SORSBY offers no comment upon this curious fact. But unless one is satisfied to pass it off as a mere chance effect, which is a priori improbable, this equality in the total incidence of cancer requires an explanation as much as do differences in the organ incidence of cancer. The subject has been discussed in a recent paper by Dr. W. CRAMER[11] in which the view is expressed that the incidence of cancer in man is determined not only by the one extrinsic factor, namely, chronic irritation, but also by an intrinsic factor, namely, the general susceptibility to the development of cancer of the individuals whose organs are being subjected to the various forms of chronic irritation.

ROYAL SOCIETY CONVERSAZIONE.

MANY people who went to the conversazione given by the Royal Society on May 20th probably put the occasion to its proper use and spent most of their time talking to one another. But the exhibits were as well staged and as entertaining as usual, and there was a good deal of medical and biological interest. Dr. J. S. Owens had a further improved model of his automatic apparatus for measuring smoke impurity in the air in which the motive power is supplied by a large weight; it can therefore be used in places where no other source of power is available. We hope that it will be of use in making his methods and results more widely known until we are all ashamed to burn smoky fuel in our houses; his records through the 24 hours conclusively condemn the domestic fire in its present state. Dr. W. B. Brierley showed a film illustrating the formation of the cell inclusions in plants affected with virus diseases, worked out by himself and his colleagues at Rothamsted. The first sign of the inclusions is the appearance of small proteid particles in the streaming cytoplasm of the infected cells. These particles grow larger and fuse into a few big aggregates, and ultimately most of them are contained in a single large mass which finally tends to break down with the appearance of a number of proteid crystals. Cell inclusions, some in the cytoplasm, some within the nucleus, occur in most (but not all) virus diseases in animals and plants; their appearance is often highly characteristic and may be useful for diagnostic purposes as in, e.g., the "Negri bodies" of rabies. Evidence has recently been obtained by Prof. J. C. G. Ledingham and others that in animals these inclusions are made up of a number of minute particles which may not unreasonably be supposed to be the individual elements of the virus itself. The Rothamsted observations suggest that the particles are the result rather than the cause of the disease, though they are not wholly incompatible with the other interpretation, and the bodies in plants may possibly be of a different kind from those found in animal infections. Mr. F. W. Sansome, of the John Innes Institution, had some tomato plants in which a proportion of the adventitious shoots representing regeneration after amputation contained twice the normal number of chromosomes; some of these shoots, amputated in turn, would double their chromosome number again—changes associated with an alteration in the shape of the leaves but leaving the plant otherwise much as before; appearances are due to quality rather than quantity of nuclear material. Animal growth and differentiation was illustrated by a particularly clear demonstration by Mr. C. H. Waddington, of the Strangeways Laboratory. In chick embryos grown in tissue cultures a developing primitive streak, transplanted to another part of the embryo, can induce the formation of a neural plate in ectoderm which would not normally form such a structure; isolated pieces of primitive streak also have this inductive capacity, and duck tissue can act similarly on a chicken embryo. And such are the capacities of growing tissues that the rest of the embryo can regenerate a primitive streak that has been removed. The late Dr. Strangeways was evidently right in thinking that pathologists would learn much from the methods of tissue culture. Prof. Elliot Smith showed the skulls of the Peking man and the Taungs ape, and the Natural History Museum had a case of models of some of the monstrous animals that live in the depths of the sea and pass as fishes. Useful methods for staining bones and cartilage in toto were illustrated by Mr. H. W. Parker and Dr. G. R. de Beer. Rather striking was the large proportion of exhibits which came from research institutes and groups of investigators; the teaching school and the individual worker are progressively becoming less prominent.

BIRMINGHAM HOSPITALS.—Sir Charles Hyde, president of Queen's Hospital, has inaugurated two more beds in that institution, each of the endowed value of £1250, presented by the students of Birmingham University from the proceeds of their last carnival day. Since 1921 the students have contributed £20,698 to the hospital and they have set themselves the task of endowing a whole ward.—Last year 1060 in-patients were admitted to the wards of the Birmingham and Midland Ear and Throat Hospital, a reduction of 468, but their average stay was longer—12·29 as against 10 days. The reduction in numbers is accounted for by the necessity of closing the wards on several occasions on account of infectious cases. There were 9078 new out-patients who made 40,042 attendances. The bulk of the patients of both categories were admitted through the contributory scheme.—The reception hall of the out-patients' department at the Children's Hospital, Birmingham, has been decorated by four students of the Birmingham Art School, under the superintendence of Mr. Collins, the principal. The work, which has taken more than two years, consists of a series of panels, covering the walls of the hall to a height of several feet, depicting the story of Noah's ark.

ANNOTATIONS

A MODERN LINER.

The new Bibby liner *Worcestershire* is a ship of 11,000 tons register (19,000 displacement), 500 feet long, with two Diesel-Sulzer engines, which give her some 340 miles for her daily run, and should take her to Rangoon in about 23 cruising days. She carries 290 passengers (all first class) on four decks amidships, and our representative who visited her at Tilbury found that the old standards of comfort have been far surpassed. On the main deck, specially ventilated by thermotank punkah louvres and by ports, are cabins for 100, and the dining saloon which has, in addition, overhead fans for comfort. On this deck is the doctor's cabin and the surgery. Above it is the main promenade deck, where are the barber's shop and the children's playroom, fitted with see-saw, rocking-horse, and so forth. On the upper promenade deck are, from behind forward, besides the cabins, the veranda café, the smoking-room, and the lounge, while on the upper deck is the drawing-room. On each of the three upper levels are wide stretches of deck, shaded, and it is hoped cool, plenty of room being reserved for games and exercise. The cabins are comfortable; each has a porthole, also a bed, wardrobe, electric fan, fixed basin, and ventilator. The officers are lodged on the navigating bridge, one deck higher. Down below are the usual offices, bakery (coke-fired oven, electric kneader, and ice-cream mixer), cold pantry (electric refrigerator), and the galley, which cooks by coal, oil, steam, or electricity, as suits best the work of the moment. Right aft is the steam laundry, with electric irons for passengers to use. Also at this end is the hospital, and on the decks below are the galleys and other offices for the native crew—mostly from Chittagong. This accommodation is good, and far in advance of the 72 cubic feet per man required by law; they have also good baths and hot water readily obtainable alongside, and their latrines are separated by light bulkheads into cells for individuals. Forward are the European crew, five quartermasters, two deck boys, and 80 stewards. All have iron frame beds with spring bottoms, on iron supports, good-shaped mattresses (the "donkey's breakfast" of old has passed away) and bedding, all provided by the company. There are the usual ventilators and portholes (windscoops also for these), electric fans, radiators, lockers for clothes, and a table and stools, all of which help to make the stewards comfortable when off duty. There are also hot and cold baths for them. The touchstone of the sanitary achievement of a ship is the state of her water-closets, but these were all locked up, the ship being in dock. One key was found of a w.c. for crew; it was a cell of good size, painted white, and there was a closet pedestal with a good flush. It was quite satisfactory, and an enormous improvement on pre-war construction. The others on board were said to be similar; they were also described as supplied with latrine paper, but none was seen here in dock. An unexpected sight was a row of carbonic acid cylinders, to be used for extinguishing unwanted fires.* For protection against damage by grounding, the ship has a double bottom extending all her length. The modern care of dock labourers by the Home Office factory inspection was evident in the long straight ladder-ways to the lower hold (recently ordered), from which cargo was being discharged. This care for these men caused some sarcastic comment from seamen, who felt they were not equally protected; nor in their youth and strength did they need to be. But it is right and much good has been done.

The ships of this line gave satisfaction as hospital ships in the war, and three days before our representative's visit 4000 men, women, and children had been on board in a rally for the good of local hospitals. Yet everything had been put quickly right, and the ship was not only a sanitary satisfaction, but, as every seaman desires, she looked a picture—a credit to her officers and crew.

CRIMINAL LUNATICS.

The latest figures concerning criminal lunacy do not encourage complacency. The Criminal Statistics for 1929 (the latest issued) show that at the end of that year there were 910 criminal lunatics under detention in England and Wales. No fewer than 414 of these had been charged with murder, 140 with attempted murder, 21 with manslaughter, 55 with felonious wounding, and 46 with the misdemeanour of malicious wounding. The danger to public safety is self-evident. Another 28 were charged with rape, indecent assaults on females, or the defilement of young girls. The mere danger to property is illustrated by the total of 31 who were charged with arson. In the face of these figures, the public may begin to realise that there is reason for abating the persecution of medical practitioners who perform the thankless task of certifying the insane. The Mental Treatment Act has raised hopes of better protection for the public as well as of better treatment for the mentally afflicted. Out of 145 criminal lunatics who were received into asylums during the year under review, 45 were "King's Pleasure Lunatics," that is to say, 20 were found insane on arraignment and 25 (four-fifths of whom had been charged with murder) were found guilty of the act charged but insane at the moment of committing it; 100 were certified insane after conviction. Does not this last-named figure suggest that the legal view of criminal responsibility is still too rigid? In how many of these 100 cases must there not have been, before the commission of the criminal act, an abnormality of mind obvious to the medical profession though invisible to the eyes of the law?

Some further information as to criminal lunatics appears in the annual reports of the Prisons Commissioners; the latest report for England appears to be that for 1928. The Medical Commissioner therein states that in addition to the totals of men and women certified as insane in local prisons or found insane by the courts, 1699 men and 504 women were remanded to prison for observation, reports being made later to the court upon their mental condition. It thus appears that there is adequate machinery for inquiry and report; the results indeed must be invaluable to the courts when disposing of the cases of accused persons. But perhaps it is not too optimistic to look for the day when these cases of mental instability will be observed and suitably treated before the patient comes in conflict with the criminal law. Though the Medical Commissioner's report (for 1928) had some interesting comments on encephalitis lethargica and moral deterioration, the rest of the report of the Commissioners for England is not particularly informative as to criminal lunacy. The corresponding report for Scotland (available for the year 1929) gives rather fuller details, especially in respect of the type of insanity of each inmate admitted to the Department at Perth Prison, and in respect of the cost of maintenance.

---

* It is worth consideration whether these cylinders can safely be kept in the forward alleyway, just outside several crew spaces. In a collision one or more might perhaps be broken.

PLANS OF CAMPAIGN AGAINST MALARIA.

In the latest annual report of the Ross Institute Sir Malcolm Watson deals at length with the malaria policy of the Institute, and maintains that the proposals of the League of Nations Malaria Commission, as he believes to be advised for Europe, would result in leaving millions of malaria-stricken races in the tropics to struggle helplessly with the disease until they become strong and healthy. He characterises it as one of the most astounding propositions he has ever heard. It should not be forgotten that there are two lines of attack in the antimosquito campaign, antilarval and anti-imaginal. Sir Malcolm, with immense experience of their benefits, naturally lays stress on antilarval measures. The Commission has laid stress on anti-imaginal measures, being, it is clear, convinced that actual infection takes place nearly always in the house. Some of the grounds for this conclusion must be experiences such as that of Watson himself—namely, that to remove the dwelling to half a mile from anopheline breeding grounds, without altering the locality of the daily work of its inhabitants, gives practical immunity from malaria. But if a house can by its very cleanness, lightness, and airiness be made distasteful to the adult anopheles, the same end is attained as if it were placed at a distance from the site of pupal emergence of these imagines; and the possession of a home of this kind is rendered possible only by raising the human standard of life. That there are these two practical and supporting lines of approach to the antimosquito campaign few will question; to determine which is the more useful in particular circumstances seems to give the strongest support to the policy of the Ross Institute, which is one of research and experiment in field and laboratory, undertaken in close coöperation with sanitation, medicine, and industry. Apart from all those considerations of duty and humanity which must bring many subscriptions to the Institute, the sums of money received form, as Sir Patrick Manson is quoted as saying of their like, "an investment yielding a most liberal return to the country that makes them."

THE GERSON DIET FOR DERMATOSES.

THE results recently recorded[1] do not support the more enthusiastic views of previous writers on the Gerson-Sauerbruch-Hermannsdorfer salt-free diet. The cases included four of lupus vulgaris, one of lupus verrucosus, two of varicose leg ulcer, two of chronic ulcer, one of seborrhœic dermatitis, and one of neurodermatitis. In none of the tuberculous cases was a cure achieved, although there was definite involution and inhibition of extension. The two leg ulcers remained in statu quo after four months of the treatment. In the neuroderma case the usual eosinophilia fell from 10 per cent. to 4 per cent., although all previous attempts to influence it, by X rays and other means, had failed. The pruritus was also relieved but relapsed three weeks later. A similar incomplete result was achieved in the case of seborrhœic dermatitis, but both the cases of chronic eczema were discharged cured after two months' dieting—one of them having previously resisted almost every conceivable treatment, as an in-patient for 11 months. Some interesting investigations on the blood calcium, sodium chloride, sugar, and alkali reserve of the blood, and the pH of the urine were carried out at the same time as the salt-free dieting. On the whole there was a slight rise in the calcium content, no change in the sodium chloride, and none that was at all noteworthy in the alkali reserve. The pH of the urine showed a definite movement to the acid side, although no such tendency of the whole organism as is posited by Hermannsdorfer could be demonstrated. In their conclusions the authors say that the Gerson salt-free diet is of considerable value in cases of tuberculosis cutis, and might be found even more helpful when combined with actinotherapy and other methods as is done by Jesionek and others. The main purpose of their investigation was to ascertain the constitutional effects, if any, on the organism as a whole, and in particular how the general change in environment affects the growth and persistence of the tubercle bacillus. They think that further progress awaits elucidation of the essential mechanism of the treatment—which may have some relation to the chloride and water content of the skin itself.

THE LEBANON HOSPITAL.

THIS year sees the thirtieth anniversary of the Lebanon Hospital for mental diseases at Asfuriyeh, Beirut. Thirty years ago the state of the mentally afflicted in Syria was pitiable. Except for a collection of bare and wretched cells in Damascus, there was no provision for their care or treatment, and their fate was almost worse than that of the insane in this country in the Middle Ages. A Swiss missionary, Theophilus Waldmeier, decided in 1896 to retire from the Brummana Mission in order, at the age of 64, to set forth on a crusade to establish an asylum in Syria. He spent two years visiting asylums in England, Europe, and America, and in appealing to a wide public for funds. The hospital, which he opened in 1900, was an international venture. It began as an old farmhouse, amid a few sparse trees, with 15 beds, and untrained mountain girls as attendants. Now there are 219 beds, tended by capable nurses, amid groves of trees and gardens. The annual report[1] shows that during last year 163 patients were admitted, and there were 219 in residence on March 31st, 1931. During the year 48 patients were discharged relieved, 26 recovered, and 16 died. Even in Syria there is a large proportion of voluntary patients, and the hospital consulting-room serves as a valuable out-patient department. There is considerable overcrowding and many applications have to be refused, despite the addition last year of an upper storey to one of the women's pavilions and a new corridor of 11 single rooms for women. Open-air care and occupational therapy were practised at the Lebanon Hospital from the first. The patients are engaged in mattress-making, carpentry, gardening, laundry work, the olive oil soap industry—from the olive trees on the estate—and the making of leban, a form of sour milk. In the early days little or nothing was paid by or for the patients, but now the French Government pay a small capitation fee for the very poor, while the private patients give according to their means. The hospital is a teaching centre; its medical superintendent is professor of psychiatry at the American University at Beirut and holds weekly clinical classes at the hospital. Senior students spend two months as resident assistants and help in the laboratory work. Nurses are also trained here. The London general committee is appealing for financial help for the necessary extension of accommodation and for an endowment fund, and we hope these will soon be forthcoming.

THROMBOSIS OF THE ANTERIOR SPINAL ARTERY.

Dr. A. M. Ornsteen,[1] of Philadelphia, who reports two cases of his own, maintains that thrombosis of the anterior spinal artery is commoner than is generally supposed. Acute spinal paralysis may take place without violence to the spinal column, and apart from hæmatomyelia, acute transverse myelitis or vertebral disease. Spinal strain is usually the exciting factor in the thrombosis, but the underlying factor is generally syphilitic disease of the blood-vessels. The clinical manifestations vary according to the extent and level of the occlusion. When the upper portions of the anterior spinal arteries are occluded a bilateral spastic motor syndrome results, giving rise to paralysis of the upper and lower limbs with loss of deep sensibility. Occlusion of the second portion of the anterior spinal artery produces symptoms of amyotrophic lateral sclerosis with dissociation of sensation of the spinal type more or less irregular in its distribution. In obliteration of smaller branches of the anterior spinal artery the symptoms of paraplegia are less marked and do not involve all parts of the extremities. Early and adequate antisyphilitic treatment is advisable in all cases. Ornsteen's first patient was a man aged 54 in whom disturbance of deep sensibility in addition to bilateral pyramidal tract involvement indicated a lesion of the lower part of the medulla oblongata, while atrophy of the shoulder girdle and segmental dissociation of sensation in the right forearm showed that the occlusion of the anterior spinal artery extended down into the cervical region. In the second case, that of a woman aged 24, the symptoms suggested occlusion of the anterior spinal artery in the cervical region. The issue is not recorded in either case.

THE ZÜND-BURGUET TREATMENT OF DEAFNESS.

A FRANK report of his experiences in the treatment of deafness by the electrophonoïde method of Zünd-Burguet has been published by Mr. R. Graham Brown, of Brisbane.[2] After a visit to Mr. Zünd-Burguet in Paris in 1926, he obtained the apparatus and began to use it with enthusiasm, but after carefully observing 40 consecutive cases, he was satisfied that the benefits were very few and slight. He remarks that in deaf people we have not only the deafness and noises in the head to contend with, but also that "fullness in the head" which is a frequent symptom. Most of his women patients believed that this symptom was improved by the treatment, but not so the men; and he observes that deaf female patients are very easily "buoyed up" by almost any form of treatment, and their responses to tests must be carefully scrutinised. In only a few cases was tinnitus lessened to a degree which made the treatment worth while. In the 40 consecutive cases 14 patients were males and 26 females; only three of the males reported any improvement in hearing, two of these relapsed to the previous condition, and the third showed no improvement to tests. Of the 26 females, 12 reported improvement, four of these relapsed, four of the remainder showed no objective improvements on testing; in one the improvement was very slight, and in one a second course gave no result; of the remaining two patients one reported a slight, and the other a very great improvement in hearing. Mr. Graham Brown has given a summary of these 40 cases in tabular form, and has included in the details the presence or absence of tinnitus and of the sensation of fullness; the unsatisfactory nature of the results does not seem to be due to insufficient treatment, for several of the patients underwent very prolonged courses. Negative results, such as these, are not often published, but are useful in assessing the effect of any method of treatment.

GWATHMEY ANÆSTHESIA IN LABOUR.

THE method devised by Gwathmey for procuring painless childbirth has not, we believe, been tried to any great extent in Great Britain. It may be that practitioners shy at the numerous hypodermic and intramuscular injections, in addition to those made per rectum, or it may be that they have been convinced that the claim for "synergism" between morphia and magnesium sulphate has been convincingly disproved by Gwathmey's own countrymen. At any rate, the method has been so little reported on here that the paper[1] by O'Donel Browne will be read with interest. Although he deals with only 41 cases, these have been carefully studied at the Rotunda Hospital, and therefore the conclusions deserve respect. The procedure consisted in: (1) placing the patient in a quiet room and plugging the ears with cotton-wool; (2) when pains occurred at two- to three-minute intervals a soap-and-water enema was given, morphia gr. ¼ hypodermically, and 2 c.cm. of 50 per cent. magnesium sulphate intramuscularly; (3) 20 minutes later a second intramuscular injection of the same quantity of magnesium sulphate was given. Usually two or three hours' relief from pain followed. When this began to wear off the patient was placed in the left lateral position, and the anal region was liberally smeared with vaseline. A small rectal tube containing one ounce of warm olive oil was passed about six inches up the bowel. A bottle containing ether 2½ oz., quinine alkaloid grs. 20, absolute alcohol ♏ xl., and olive oil ʒiii., was warmed in lukewarm water and its contents were allowed to flow very slowly down the rectal tube. Finally, one ounce of olive oil alone was run in. The process took about 20 minutes, after which the tube was withdrawn and a pad of cotton-wool applied to the anus. Introduction of the rectal anæsthetic is made between pains, and above the presenting part. On the average two of these rectal instillations were needed, the time between them being five hours. Browne believes that the magnesium sulphate prolongs the relief given by the morphia without increasing its toxic effect. The bowel was washed out at the end of labour. The average duration of labour, from the time when the cervix was two to three fingers' dilated, was 17 hours in primiparæ and six hours in multiparæ. Ether was eliminated from the child's lungs. There was in no case any need for resuscitation, and delay in the second stage was not abnormal. As regards alleviation of pain, 21 patients had no recollection of any pain after the beginning of treatment, 13 had marked relief, 6 had moderate relief, and only 1 woman was quite conscious of her labour.

CENTRAL BUREAU OF HOSPITAL INFORMATION.

AN event of importance to all those interested in hospitals is the merging into a Central Bureau of the corresponding organisations of the Incorporated Association of Hospital Officers, the British Hospitals Association, and the Joint Council of the Order of Saint John of Jerusalem and the British Red Cross Society. In the new Bureau all the information previously collected and issued by these bodies is now pooled. The chief activity of the past year has been the preparation of the first edition of the Hospitals Year Book, which retains everything of general interest that previously appeared in "Burdett's Hospitals and Charities." The work has been heavy, but the result will prove to be worth the effort. The Year Book is appearing in two main sections: a report giving particulars of the work done and of finances and kindred matters; and a directory of institutions, with addresses, names of chief officials, and other particulars. In addition to hospitals, dispensaries, and convalescent homes, the Year Book enumerates nursing institutions, homes for the mentally and physically defective, medical universities, and administrative and collecting societies. The publication price has been fixed at 15*s.*, but hospitals and kindred institutions may obtain copies for 10*s.* if they order them direct from the publishers.

In addition to the Year Book, the Bureau publishes memoranda on topics which concern hospitals. During 1930 these publications covered such subjects as outside laundry work for larger hospitals, rubber flooring, working arrangements of X ray departments in hospitals of 50–100 beds, and the cost of building of hospitals recently constructed. Many other memoranda apply to particular districts or groups of hospitals. The advice and assistance which may be obtained from the Bureau is being sought more frequently by boards of management of voluntary hospitals, particularly in connexion with the selection of sites and the preparation of plans for new buildings, or with investigation into the costs of administration. In the course of this work the director has visited hospitals in various parts of the country and the Bureau has prepared reports. He has also visited several towns to discuss local problems with the committees of hospitals, or to address public meetings on behalf of local institutions. The Bureau has also assisted, as in previous years, in the distribution of money raised for a group of hospitals. The list of the Bureau's activities is published in the eleventh report of the Joint Council[1]; it covers more than a full page and embraces topics of amazing variety. Its aims (summarised), in addition to publishing the Year Book, are to collect data concerning all matters of administrative interest; to make inquiries for those responsible for guiding hospital policy; to establish a library of hospital literature, and to act as a clearing house of information. Its services are available without further fee to all hospitals which are members of the British Hospitals Association. An organisation of this kind grows in usefulness in proportion to the use that is made of it, and hospitals can best serve themselves and each other by taking the Bureau into their fullest confidence.

MINERS' NYSTAGMUS.

THERE are two schools of thought on miners' nystagmus, one looking on it as a local affection of the eyes due to long hours of work in darkness, while the other regards it as a manifestation of psychoneurosis.[1] In a paper[2] by Mr. W. J. Roche, of Newport, Mon., both these points of view are recognised. As is clear from Prof. Collis's lectures, reported on p. 1220 of our present issue, the condition is of great economic importance. Mr. Roche says that between 1910 and 1929, with a diminution of the total number of men employed underground, the incidence of the disease increased threefold, despite many of the improvements as to lighting recommended by a committee of the Medical Research Council in 1922. The percentage of the underground workers receiving compensation in 1929 was 1·2, at a cost of £440,000. Yet this only represents a small proportion of the cases of coal-miners with oscillations of the eyes. In the underground workers examined by Mr. Roche they were present (though not necessarily constant) in 23 per cent. The great majority of these men are not incapacitated, and they only have to cease work if such symptoms as vertigo or photophobia supervene. The school which looks upon the oscillations of the eyes as the main feature of the disease is confronted by two puzzling facts—first, that whereas only a small percentage of underground workers are incapacitated, more than 20 per cent. of them show nystagmic oscillations, the great majority without any disabling symptoms; and secondly, that since the general substitution of the one-candle power electric lamp for the old hand lamp the number of men disabled by the disease has not only not diminished but actually increased. In spite of this Mr. Roche believes that the main cause of the condition is defective lighting, and he explains the last-mentioned anomaly by saying that the electric light with clear glass is dazzling, and causes disturbing after-images. The ideal light for mines is the cap lamp worn on the miners' head, but it is heavy and the men do not like it. As a compromise he advocates a four candle-power electric light with frosted glass. He himself, on taking on hewer's work as an experiment, found this much more effective and less irritating than the one candle-power clear glass lamp.

MEMORIALS TO CLEMENS VON PIRQUET.

ON May 12th two impressive ceremonies took place in Vienna at the unveiling of memorials to the late Prof. Clemens von Pirquet, director of the University Kinderklinik, who died in 1929. In the Centralfriedhof, where his grave is among those granted by the city of Vienna to her most distinguished citizens, the memorial takes the form of a sculptured relief symbolic of his work for children, with a portrait in profile by Prof. Müllner. This was unveiled by Dr. Schober, the present Foreign Minister and late

---

[1] See annotation in THE LANCET, May 2nd, p. 981.

[2] Brit. Jour. Ophthalmology, April, 1931, p. 211.

Chancellor, and the speakers included Dr. Miklas, the President of the Republic, the American Minister, Dr. Grassberger, the Dean of the Medical Faculty of the Vienna University, and Dr. Tandler, on behalf of the city. They bore witness not only to Pirquet's achievements as scientist and physician, but to his great work for the Austrian children in the years following the late war. Speeches were also made by representatives from the Deutsche Gesellschaft für Kinderheilkunde, the Lister Institute, and the Medical Research Council of Great Britain and the Union International de Secours aux Enfants, while Prof. Nobel, formerly first Assistant at the Kinderklinik spoke on behalf of the pupils of the late professor. The unveiling in the garden of the Kinderklinik of a portrait bust of Pirquet, executed by Prof. Heu, took place in the afternoon and was of a more intimate character. Around the pedestal were grouped numerous laurel wreaths with inscriptions testifying to the international character of Pirquet's work. The ceremony was opened with singing by a choir of children from the tuberculosis sanatorium on the roof of the Klinik which Pirquet founded and in which he always took the deepest interest. After the bust had been unveiled by Prof. Arzt, the vice-dean of the Medical Faculty, there were speeches by Prof. Hamburger, the present director of the Kinderklinik, by Miss Harriette Chick, representing the Lister Institute and the Medical Research Council, with whose researches on nutrition in Vienna after the war Prof. Pirquet generously coöperated, by Dr. Noeggerath of Freiburg for the Deutsche Gesellschaft für Kinderheilkunde, and by Dr. R. Wagner on behalf of Pirquet's former staff at the Klinik and his pupils in general. The matrons of the Kinderklinik and of the Schwesternschule in Dresden spoke of what he did for the nursing profession in Austria and other parts of Europe.

INDUSTRIAL HYGIENE AT THE FRANKFORT CONFERENCE.

THE German Industrial Hygiene Society has an extensive educational programme. No less than 36 brochures dealing with various occupational risks have been issued. Current advances in knowledge are communicated to meetings held in the large German towns to which medical men, scientific technical workers, and factory administrators are invited. Lectures are given to medical men and post-graduate classes held. Much effort is expended on the instruction of the workmen; in Germany they experience the same difficulty as we do in securing cleanliness, and getting the men to wear goggles and use respirators. Fortunately, the leaders of German trades-unions are among the most zealous collaborators of the Society. In a presidential address, delivered to the Section on Industrial Hygiene at the conference held by the Royal Institute of Public Health at Frankfort-on-Maine last week, Lord Leverhulme described a test which is claimed to be of considerable value in preventing accidents, and also in increasing output. Dr. Kurt Seesemann, of Mülheim (Ruhr), uses boards on which are printed in no order of sequence all the numbers between (say) 1 and 25, and 10 and 49. The examinee has to indicate the numbers in their natural sequence with a pointer, and to call them out while he is timed with a stop-watch. It is found possible in this way to discover persons whose perceptive faculties are exceptionally dull, and so to avoid employing them on work at which emergencies frequently arise. Dr. Seesemann claims that these tests also help in the wise distribution of labour in the factory, so that quick workers are not grouped with slow workers who would inevitably lower their standard of output; also that it is possible to discover workers who are particularly sensitive to monotony, and to employ them accordingly. At the same section Dr. E. W. Hope (Liverpool) also emphasised the part played by fatigue in proneness to accidents. One of the early signs of fatigue is a slight incoördination of the muscles, a condition likely to cause accidents. Investigators of the American Public Health Services found that when output rose above a certain level, involving industrial fatigue, the number of accidents showed an accelerated rate of increase—about fourfold, in fact—thus a 5 per cent. increase of output under these circumstances coincided with a 20 per cent. increase of accidents. Fatigue as a factor will be most operative at the end of the shift and day. It appears to affect women more than men; women working on a 12-hour day had two and a half times as many accidents as when working on a 10-hour day, but the men's accidents showed no difference.

WE regret to record that Dr. William Dobinson Halliburton, F.R.S., emeritus professor of physiology in the University of London, died on May 21st at Exeter, at the age of 70.

WE have also to announce the death of Sir Herbert Waterhouse, consulting surgeon to Charing Cross Hospital and for many years president of the Medical Defence Union. He was 67 years of age.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lt.-Comdr. T. C. H. Neil is appointed to *Calypso.*

ROYAL ARMY MEDICAL CORPS.

The undermentioned Capts. to be Majs.: J. W. Hyatt, J. R. S. Mackay, P. A. Stewart, E. P. N. Creagh, C. V. Macnamara, F. K. Escritt, and O. A. Whitfield.

ARMY RESERVE OF OFFICERS.

Lt.-Col. W. J. Waters, having attained the age-limit of liability to recall, ceases to belong to the Res. of Off.

TERRITORIAL ARMY.

Capt. J. M. Smeaton to be Maj.

The King has conferred the Territorial Decoration upon Lt.-Col. George Langrigg Leathes Lawson (retd.).

NEW CHILDREN'S HOSPITAL AT LUTON.—On May 13th Sir Harold Wernher formally opened the enlarged building of the Children's Hospital, erected at a cost of £20,000 on a site at the rear of the old Children's Sick and Convalescent Home, which now becomes an administrative block. The new provision includes two wards, each of 20 beds, two single-bed wards, and an operating theatre. The wards were completed last autumn to the design of Mr. S. O. Parrott, but the formal opening has been postponed until the whole scheme, which includes the laying out of some beautiful gardens, was completed. Sir Walter Kent, president of the hospital, in welcoming the guests, made a spirited defence of the voluntary hospital principle and gave some account of its achievement in Luton, including the Bute Hospital paying ward scheme. The new hospital, it was pointed out, would require a larger annual income than before, and one of the visitors expressed his intention of leaving a legacy sufficient to endow two beds.

SPECIAL ARTICLES

THE WORLD CONFERENCE ON WORK FOR THE BLIND.

(BY A SPECIAL CORRESPONDENT.)

DURING the last few years there has been a remarkable development of the international side of the movement for the prevention and alleviation of blindness. An important step was taken by the publication in September, 1929, of a report by the League of Nations on the Welfare of the Blind in Various Countries, the report being based on the replies of 26 Governments to a questionaire issued by the League in response to a request by the British Government in 1927 that inquiries should be made to ascertain what was being done in various countries for the welfare of the blind. This report, though dealing primarily with the provision made for the welfare of persons who have become blind, contains much valuable information on the causes and prevention of blindness, and constitutes the most comprehensive description that has yet been given of the modern movement for the prevention and alleviation of blindness. The appearance of the report coincided with the foundation of the International Association for the Prevention of Blindness, which held its first session at Scheveningen, Holland, at the conclusion of the International Congress of Ophthalmology, which had taken place there and in Amsterdam in September, 1929. The second annual meeting of the board of governors of the Association was held in Brussels in October, 1930, when it was decided to set up national committees in the affiliated countries, and a British committee is now in process of formation.[1]

But the importance of preventive work must not be allowed to obscure the necessity of alleviating the lot of those who have become blind. Accurate statistics of the prevalence of blindness can hardly be said to exist, but it has been estimated that if blindness be defined in economic terms—e.g., as in the Blind Persons Act, 1920, which defines a blind person as one who is "so blind as to be unable to perform work for which eyesight is essential"—the number of blind persons in the world is probably not less than 6,000,000. The problems of alleviation therefore cover an extensive ground.

Blindness may be alleviated in many ways, but obviously the most effective is to provide the blind person with a useful and remunerative occupation. It was to explore the possibilities of this form of alleviation that the President of the United States in March, 1930, issued invitations to 50 countries, asking them to send delegates to a World Conference on Work for the Blind, to be held in New York City in April, 1931. The invitations were sent out at the request of the American Foundation for the Blind, the American Association of Institutes of the Blind, and the American Association of Workers for the Blind.

OBJECTS OF THE CONFERENCE.

Briefly stated these were:—

(1) To promote international comity by bringing about more intimate personal acquaintance among leaders in work for the blind in the various countries.

(2) To give workers for the blind detailed information regarding activities in other countries which *may suggest* ways of improving the work at home.

(3) To establish means of effecting more rapid interchange of information regarding developments in work for the blind as to: (*a*) practical types of employment; (*b*) methods of instruction; (*c*) new appliances for overcoming the handicap of blindness; (*d*) prevention of blindness.

(4) To promote the coöperative use of embossed literature through interchange of books and sheet music among libraries, and exchange of periodicals, especially among countries speaking the same language. (NOTE.—This exchange of periodicals may be carried on both by publishers and by individual readers.)

(5) To enlist the coöperation of workers for the blind in various countries in the promotion of work of international interest, such as the establishment of uniform codes among countries speaking the same language, and furthering the movements to establish uniform embossed codes for music, classical languages, and higher mathematics.

Delegates from 34 countries, including ten from Great Britain, attended the conference, which, after a reception at the International House on April 13th, was held at the Pennsylvania Hotel, New York, from April 14th to 17th inclusive. On April 19th the foreign delegates were taken on a nine-day tour of visitation to representative agencies for the blind in Philadelphia, Washington, Pittsburgh, Cleveland, and Boston. In Washington the delegates had the honour of being received by the President and Mrs. Hoover, and the tour included a visit to Niagara Falls. The conference was re-convened on April 29th in New York, where the final session was held on the following day.

WORK FOR THE BLIND.

At the present time the labours of those who seek to secure remunerative employment for the blind are rendered unusually difficult by reason of the prevailing industrial depression and consequent widely spread unemployment. Moreover, the development of modern industry has seriously affected some of the hand industries which have been regarded as specially suitable for the blind worker. In the field of basket-making and brush-making, for instance, the market is flooded with cheap machine-made articles. The rapid increase in the popularity of the gramophone and the radio has lessened the demand for teachers of the pianoforte, and also for pianoforte tuners, these callings being amongst the most lucrative in which blind persons without exceptional gifts can engage. The development of the "talkies" has similarly reduced the opportunities of blind musicians for finding employment in cinema theatres.

Notwithstanding these disadvantages, the conference afforded ample evidence that in many countries blind persons are to a surprising extent making good in a large variety of occupations. The employed blind may be ranged into four groups: first, those who have set up for themselves in business or professions; second, those who are employed side by side with sighted workers in factories and commercial undertakings; third, those employed in sheltered workshops; fourth, those working in their own homes under the supervision of an agency for the blind. The first group comprises persons of exceptional gifts who have profited by a sound general education and vocational training. For those who have aptitude for business a commercial enterprise normally offers the most promising opportunities for success, and, in America particularly, considerable numbers of blind persons are occupying business positions of responsibility and importance. The blind have made a successful entrance into various fields of professional activity. In Germany there are 41 blind lawyers, and 15 blind parish clergymen, and four important professorships are held by blind men. In France, special attention has been devoted to the training of the blind for the musical profession, and among the past pupils of the *Institution Nationale des Jeunes Aveugles de Paris* are several organists who have achieved distinguished success, such as Mr. Louis Vierne and Mr. André Marchal, who have recently made concert tours in the United States. In the provinces, eight graduates of the *Institution Nationale* are cathedral organists.

---

[1] THE LANCET, March 14th, 1931, p. 605.

The main problem, however, is to find employment for persons without conspicuous ability—for the rank and file; and it is encouraging to note that experience steadily increases the number of occupations in which blind persons can work with success. In Germany, where the disablement law of 1920 requires that 2 per cent. of employed labour shall be disabled, promising results have been obtained from the employment of blind workers side by side with sighted workers. In this respect the Siemens-Schuckerts Company have set a notable example. The blind persons employed at the firm's factory near Berlin had had no previous technical training, and nearly all would have been classified as unemployable. They were put to simple operations and quickly became proficient. The firm state that 70 per cent. of their blind workers are of normal efficiency.

An interesting paper on the subject of finding employment for the blind in work for which eyesight was formerly considered essential was read by Captain E. A. Baker and Mr. J. F. Clark, of the Canadian National Institute for the Blind, who pointed out that the problem of securing a job for a blind person was essentially one of salesmanship. There is a good deal of disinclination among employers to offer jobs to blind persons, and "placement" officers must not only be well informed as to the capabilities of blind workers but must also possess "sales ability."

THE PRINTING VISAGRAPH.

One of the most remarkable of the conference exhibits was the "printing visagraph," which was demonstrated by its inventor, Mr. Robert E. Naumburg, of Cambridge, Mass. The object of the visagraph is to enable blind persons to read printed matter that has not been issued in Braille or other embossed type. The instrument produces on a thin sheet of aluminium a magnified image of a printed page, and is intended for use by the blind person himself. It resembles a flat-top desk used in offices, and consists of two parts—the sending part and the receiving part. On the left half of the instrument—i.e., the sending part—the book which it is desired to read is pressed upward, right side up, against a flat glass plate. Above the book is the "lighthouse," which contains a lamp and a selenium, or photo-electric cell, sensitive to light. The "lighthouse" travels along the printed line from left to right, and as it travels the letters of the line are reproduced in embossed letters on the aluminium sheet on the right-hand half of the instrument—i.e., the receiving part—and can then be read as they appear on the sheet by the fingers of the blind reader.

MISS HELEN KELLER.

To many of those attending the conference the most memorable event was the appearance at the opening meeting on April 13th of Miss Helen Keller, who gave an address of welcome, which was repeated sentence by sentence by Mrs. Macy. Miss Keller remained on the platform until the end of the meeting, and followed the speakers closely, the speeches being communicated to her by Mrs. Macy through the medium of the finger alphabet. Miss Keller, as is well known, has been blind and deaf since she was 18 months old, and her attainment to her present position, in spite of the stupendous disadvantages of total deprivation of sight and hearing, is surely one of the most outstanding triumphs of the human spirit. The presence at the opening meeting of this beautiful, accomplished, and radiantly happy lady was an event of good omen for the conference, and there were many who agreed with the remark of one of the delegates that it would be a good thing if the world's pessimistic writers could be collected into that room to look at Helen Keller.

MEDICINE AND THE LAW.

Illegal Sale of Horticultural Poisons.

On May 19th successful prosecutions were undertaken in the Birmingham police-court by the Pharmaceutical Society against three companies and eight individuals in respect of the sale of poisonous substances for horticultural purposes. The preparations, apparently intended as an insecticide for fumigation of green-houses and similar uses, contained nicotine to an extent which made them a deadly poison. Section 4 of the Poisons and Pharmacy Act of 1908 allows persons who are not duly registered pharmaceutical chemists or chemists and druggists, to sell poisonous substances "to be used exclusively in agriculture or horticulture for the destruction of insects, fungi or bacteria, or as sheep dips or weed killers which are poisonous by reason of their containing arsenic, tobacco or the alkaloids of tobacco," provided that the seller has a licence from the local authority and that he complies with prescribed regulations. The Section further provides that such licensed seller is not to be exempt from other requirements under the Pharmacy Act of 1868. Article 14 of the Regulations made in this connexion in 1909, as modified by fresh provision successively in 1911 and 1920, requires that the poisonous substance be sold in an enclosed receptacle distinctly labelled with the name of the substance and the word "Poison" and with the name and address of the seller, and also with a notice of the special purpose for which it has been prepared. The Regulations also require that the licence shall set out on the back *inter alia* Section 17 of the 1868 Act, which directs the seller to enter all sales in a book. The defendants charged at Birmingham had apparently omitted to label the substance as "Poison," to print on the wrapper their name and address, and to enter the sale in the register. Each defendant was fined £1 11*s*. 6*d*. with costs.

The incident is instructive in view of the changes contemplated by the Pharmacy and Poisons Bill which proposes to repeal, amongst other enactments, both Section 17 of the 1868 Act and Section 4 of the 1908 Act. There has been not a little criticism of the fact that the provisions which the Bill proposes to substitute will take away from the qualified pharmacist a considerable part of his work and give it to unqualified persons who do not understand the nature of the dangerous substances which they are allowed to handle.

Carbon Monoxide Poisoning.

A jury lately awarded £1700 damages to a child whose parents had been found dead in the bathroom of a house at Carshalton. The senior Home Office analyst stated that death was due to coma following inhalation of carbon monoxide; the plaintiff's case was that gases generated by a gas-burner in the kitchen had found their way into the bathroom by way of the linen-shoot. As usual the cause of action was framed both as breach of contract and breach of duty. The claim alleged that the house was not fit for habitation but dangerous by reason of the gas-burner not having a chimney flue pipe or other outlet; further, that the burner was negligently installed so that the products of combustion were emitted direct into the house. The defendants (from whom the deceased man had taken the house) knew, argued the plaintiff's counsel, of the existence of a dangerous trap, or ought to have known of it, and were under a duty to warn the occupier. The defendants denied all these allegations. The jury found that death was due to carbon monoxide coming from the boiler, that the gas-heater installed by the defendants had no flue and, in connexion with the shoot to the bathroom, was dangerous for use in a dwelling-house, and, finally, that the defendants did not know it was dangerous but ought to have known it. On the effect of this last finding legal argument was necessary. Defendant's counsel said that, if the danger had been concealed, his clients would have been equally liable whether they knew or ought to have known of its existence. But here there was nothing concealed; the dead householder could see all that the defendants could see. The gas-heater, he said, was not dangerous in itself, though it might be dangerous through defect in its construction or the way in which it was worked. The defendants, he argued, had only the duty to give warning of the danger actually known to themselves, and the jury had found that the defendants had no knowledge which could be communicated. Mr. Justice Hawke ruled that the findings of the jury amounted to a decision that the defendants had been negligent in dealing with a dangerous thing (presumably the gases generated by the boiler in the kitchen); he gave judgment for the plaintiff but granted a stay of execution pending appeal. It is the kind of case that may occur elsewhere and, as there seems to be some uncertainty as to the legal liability, an authoritative ruling will be welcome.

THE SWEEPSTAKES AMENDING BILL.

AN interesting debate took place in the Dáil last week on the second reading of the Sweepstakes Amending Bill, or, to give it its proper title, the Public Charities Hospitals (Amendment) Bill, 1931. The Bill proposes to enlarge the scope of the principal Act in two directions, so as to include new classes of hospital. In the first place, five institutions are included by name. It is understood that these institutions are ineligible under the present Act, in that they do not maintain the requisite number of free beds. In the second place, one-fourth of the proceeds is to go to the county—i.e., rate-supported—hospitals for the purpose of improvement or equipment; "the idea being," said the Minister, "that none of the proceeds should go to the maintenance of patients or directly to the relief of the rates." (One may ask whether equipment is not a duty of the ratepayers, and whether money from an outside source devoted to equipment is not in relief of the rates.) The Bill also provides new machinery for deciding various points concerning sweepstakes by means of a committee of reference which will, in particular, examine the claims of the several charities which apply for participation, and decide on the distribution of the funds. Mr. MacEntee, although not opposing the Bill, pointed out certain dangers in the reliance coming to be placed on sweepstakes. He pointed out that some of the hospitals were being induced to undertake capital expenditure which would impose on them further commitments for maintenance and operation, which, if sweepstakes were to be discontinued, would involve them in grave financial difficulties. On the other hand, Mr. Davin thought that as long as the money was coming from outside countries, there was no reason for discontinuing the sweepstakes, but he thought they should be under the direct control of the State. Sir James Craig thought that some of the hospitals named in the Bill would require scrutiny in committee. As the introducer of the original Act he confessed himself "rather appalled" by the success of the scheme he had started, and he appealed to the Minister to consider whether he should curtail the period for which the original Act was to run. Mr. Good pointed out that while there was a well-informed opinion in favour of amalgamation of the smaller hospitals, the present method of distribution of funds tended to perpetuate the small hospitals, efficient and inefficient. The sweeps might, on the other hand, be used to carry out amalgamation. Several deputies expressed disapproval of the whole system, Mr. Haslett declaring that the Act had made the country a byword among the nations. The Minister, in reply, agreed with Mr. Good that the present would be a suitable time to consider amalgamation, although the question did not arise under the Bill. The second reading of the Bill was agreed to.

SWITZERLAND.

(FROM AN OCCASIONAL CORRESPONDENT.)

A SUCCESSFUL ACTION FOR NEGLIGENCE.

AN interesting case of medical responsibility has just been decided by the Federal High Court. In July, 1927, five children of a family in the Lower Engadine developed an affection of the throat. The local practitioner diagnosed in all cases common sore-throat and, when asked by the parents, strictly denied the possibility of diphtheria. As the disease showed no sign of improvement the surgeon of the next district hospital was called in for consultation, with the result that two of the children were transferred to the isolation hospital at Schuls with the diagnosis of diphtheria. Despite injections of serum they both died within the next few weeks. The father of the children, being of opinion that their death was due to wrongful diagnosis, lodged a complaint against the practitioner and asked damages amounting to francs 10,000. District court and cantonal court dismissed the complaint. Both courts, however, agreed that the practitioner did not make use of all methods, such as bacteriological examination, to detect the nature of the disease; that it was possible, even probable, but not certain, that with immediate proper treatment death could have been avoided. The plaintiff lodged an appeal with the Federal High Court. The appeal was successful and damages amounting to francs 3000 were awarded to the parents. The Federal High Court based its decision on the admission of a causal relation between the insufficient treatment and the death of the children. The High Court further stated that wrong diagnosis alone was not sufficient to hold a doctor responsible. In doubtful cases it was, however, the duty of the doctor to use all modern methods to explore the nature of a disease. If this was not done the doctor was negligent and could be held responsible. Both the district and the cantonal court were of opinion that the plaintiff had to prove conclusively and strictly that death could have been avoided by early treatment with serum injections. In most cases such proof was impossible. It was enough for the plaintiff to show that the negligence of the doctor was the probable cause of death. The Federal High Court regarded as generally admitted that with proper serum treatment mortality in diphtheria had been enormously reduced. Therefore the court in the present case found it sufficiently proved that with proper treatment the two children most probably could have been saved.

OVERCROWDING IN THE MEDICAL PROFESSION.

This little country has been widely blamed for making it increasingly difficult for foreigners to practise within its borders, but the truth is that the profession is becoming more and more overcrowded. In Switzerland we have one doctor to 1244 inhabitants, a proportion which compares oddly with other countries. In Germany there is one doctor to 1494 inhabitants, in Holland one to 1538, in Denmark one to 1613, in Sweden one to 2947. And despite all warnings the entry is increasing. In 1929 117 students qualified in Switzerland; in 1930, 138. The same plethora is to be seen in the dental and veterinary professions. The situation is such as to have given the Federal Minister of the Interior occasion to write in his last annual report: "All our observations make us fear that the medical professions are becoming more and more overcrowded and that their standard will be gradually lowered. The situation must be remedied. The question is only how this can be effected. One of the remedies proposed, the *numerus clausus*, is not available. We shall approach the subject in conjunction with the medical faculties and the professional groups."

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

ALL-INDIA MEDICAL CONFERENCE.

THIS year the conference so named was held at Poona, Dr. Jivraj Mehta presiding. As one of India's leading medical politicians no more suitable president could have been chosen. Each year the scientific veneer of this conference wears thinner and its political nature becomes more apparent. The chairman of the reception committee referred to the "antiquated policy of the medical administration of the country which must be thoroughly overhauled," drawing a picture of mediocre I.M.S. officers being given all the best medical appointments over the heads of more highly qualified independent practitioners. But he had by no means stolen all the president's thunder. Dr. Mehta described the action of the General Medical Council in refusing to recognise certain Indian degrees as an undisguised blessing; while it was important for India to have a central organisation of its own to control and correlate medical education and for securing and safeguarding their rights, he considered it essential that the council should have a non-official majority. He drew the attention of the conference to the fact that it was proposed to exclude licentiates from the all-India register, but did not appear to commit himself to a definite opinion on this point. The Bill in question was originally an official measure and in previous conferences was attacked as an attempt on the liberty of the medical profession; it is now criticised because it is insufficiently comprehensive. There was a suggestion of reprisals in Dr. Mehta's remark that in his opinion one of the first acts of the new council should be to ensure that only persons registrable in India should be employed in the civil, military, or naval forces. At present of course nearly all British qualifications are so registrable. Dr. Mehta did not approve of the intrusion of the I.M.S. into the civil side of medical practice and he took exception to the present method of recruitment. He also criticised the composition of the governing body of the Indian Research Fund and of the way they administered this fund. The rank and file of the conference were not to be outdone by their president; no less than 47 resolutions were passed, nearly all disapproving of something or other. They disapproved of the Round Table Conference because it had been suggested there that European doctors should be recruited to look after the European civil officials; they passed votes of censure on the police for interfering with the Congress first-aid volunteers; they condemned the government for providing an insufficient number of facilities for medical education and then again for building too many medical schools, for not providing sufficiently qualified teachers and for paying their teachers too much, and in fact for everything that they had or had not done. The brunt of the criticism fell on the European officers of the I.M.S. for being incompetent, for being overpaid, and for even existing at all—as far as civil practice was concerned. The Red Cross administration was attacked by an officer who had recently been associated with it. All the resolutions were carried unanimously, but the conference was not very constructive.

MALARIA NEAR CALCUTTA.

The political situation being quieter the daily press have discovered a malaria scare. The flesh of Calcutta's citizens is made to creep daily by headlines such as "Deadly mosquito advancing on Calcutta," "Firebelt to save Calcutta from malaria epidemic," "Aeroplanes may have to be used," and the like. The facts are that a few months ago a somewhat sharp outbreak of malaria at some of the mills a few miles down the river from Calcutta was investigated. *Anopheles ludlowi* was found to be the cause of it; 90 per cent. of the mosquitoes were of this species and of a large number dissected 24 per cent. were found to be infected. The spleen rate in the area was 90 per cent. Most of the spleens were small, suggesting a recent infection. *A. ludlowi* was known to exist further down the river nearer the sea, but had not been found so near Calcutta before, and fear has been expressed that it might invade the salt lakes from whence the prevailing south wind would soon blow them into Calcutta itself. This species has already been reported in certain places on the river north of Calcutta; it is suggested that they may have been carried there by country boats. The director of public health considered the situation serious enough to persuade the Minister in charge of his department to call a meeting consisting of the chairmen of local bodies, the public health authorities, and experts from the School of Tropical Medicine. The general consensus of opinion was that no very drastic action was called for, it was agreed to make a systematic survey of the whole area concerned and special investigation into the local conditions which could have accounted for the recent invasion of this species. The press campaign may do good if it succeeds in drawing the attention of the Calcutta Corporation to the fact that mosquito control might be much better than it is at present.

POPULATION AND DISEASE.

Full figures of the recent census are not yet available, but the first returns show that there has been a considerable increase in the population throughout the whole country during the last decade. Bengal shows an increase of 7 per cent. over the previous census figures. Now that war has been eliminated, pestilence and famine mitigated as population-controlling factors, it is for someone to indicate how the growth of population is to be controlled in future. At present one square mile has to accommodate and support 600 persons on an average throughout the Bengal Presidency. With the diminution in mortality from so-called tropical diseases, such as cholera, plague, malaria, and kala-azar, there has certainly been a considerable rise in the death-rate from tuberculosis. People are flocking to the towns, not only for economic reasons but because of the better water-supplies and the lesser risk of malaria, and Nature is showing her usual tendency to adjust the balance. In his presidential address to the Tuberculosis Association of Bengal, Sir Stanley Jackson spoke in glowing terms of the activities of this association, probably the most useful of which is that of organising house-to-house visits by voluntary workers who give instruction in hygiene. A promising feature of this work is that it has been organised mainly by Indians.

THE HAFFKINE INSTITUTE.

When Waldemar Haffkine, who died in Switzerland last October, went to Bombay in 1893 at the invitation of the Government of India, he could have had little idea of the extent to which the institute which now bears his name would expand. The original laboratory was utilised for the preparation of plague and cholera vaccines. The report for 1929 shows that in addition to the vaccine department, which serves the whole of India and some countries beyond, research in pharmacology, biochemistry, and other directions is being carried on alongside clinical and general pathological work. The institute has in fact become one of the most important medical activities in the Presidency. New work on plague vaccine has been undertaken for the League of Nations, with the aid of grants from the Indian Research Fund, into such problems as prolonging the period during which the vaccine retains its potency, cutting down the time required for production, using agar instead of broth for cultures, diminishing dose and toxicity without loss of efficiency. In two respects progress is recorded. The vaccine has been found to retain its potency for 18 months, or two years when kept in cold storage; the process of manufacture can be cut down from 12 to six weeks without loss of efficiency, which will make it possible to comply more rapidly with urgent demands. On the other hand, the original broth preparation still holds its own, and there is no evidence that toxicity or dosage can be reduced. Work is being continued on the early detection of contaminants, and on the best method of standardising a virus whose minimal lethal dose can be determined within such narrow limits. With regard to treatment, the quest for a more efficacious serum is still being pursued; judging from its effect on animals, the latest product appears more potent than any previous one and it is hoped shortly to test its value in human plague. The halogenomercuriphenols possess a high germicidal power against *B. pestis* in the test-tube and a safe dosage is being determined with a view to therapeutic test. In the pharmacological department the investigation of indigenous drugs continues, but the director remarks that those who look for startling discoveries will be disappointed. The chief value of this inquiry may be to clear away the superstition and tradition on which the indigenous systems of medicine so largely depend. Inquiries are also being made into maternal morbidity, mortality in childhood, anæmia in pregnancy, stillbirth, and tuberculosis. In the Bombay Presidency the bovine type of bacillus seems to play a negligible part in the causation of human surgical tuberculosis; this is in conformity with the fact, previously known, that in Bombay, where they are seldom housed, tuberculosis of cattle is infrequent, whereas in the colder northern regions of India, where they are housed in winter, the disease is more common. Another important feature of the work of the institute is the production of antirabic vaccine. The Paris strain of fixed virus is now being used exclusively for treatment, but it is yet too early to say whether it is better than the strains hitherto employed.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED MAY 16TH, 1931.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 166; scarlet fever, 1469; diphtheria, 897; enteric fever, 26; pneumonia, 1028; puerperal fever, 44; puerperal pyrexia, 91; cerebro-spinal fever, 63; acute poliomyelitis, 5; acute polio-encephalitis, 1; encephalitis lethargica, 16; dysentery, 16; ophthalmia neonatorum, 134. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on May 19th–20th was as follows: Small-pox, 200 under treatment, 8 under observation (last week 232 and 4 respectively); scarlet fever, 1231; diphtheria, 1470; enteric fever, 14; measles, 188; whooping-cough, 435; puerperal fever, 31 (plus 13 babies); encephalitis lethargica, 188; "other diseases," 150. At St. Margaret's Hospital there were 22 babies (plus 7 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 2 (0) from enteric fever, 38 (2) from measles, 11 (2) from scarlet fever, 24 (7) from whooping-cough, 25 (4) from diphtheria, 40 (16) from diarrhœa and enteritis under two years, and 44 (8) from influenza. The figures in parentheses are those for London itself.

West Hartlepool and Tynemouth reported deaths from enteric fever. Only 2 deaths from meningococcal meningitis occurred in London. Five deaths from measles were reported from each of Birmingham and Liverpool, 4 each from Leeds and Sunderland. Birmingham reported 3 deaths from whooping-cough. Diphtheria claimed 4 victims at Liverpool and 3 at Manchester. Diarrhœa was credited with 5 deaths at Liverpool, 3 each at Birmingham and Manchester. Stoke-on-Trent reported 4 deaths from influenza, Stockport 3, no other great town more than 2.

The number of stillbirths notified during the week was 273 (corresponding to a rate of 41 per 1000 births), including 47 in London.

PUBLIC HEALTH SERVICES

SCHOOL MEDICAL SERVICE.

—	No. on roll.	Average attendance.	Routine inspection.	Special examinations and reinspections	Percentage of defects.
County of Leicester..	38,312	34,813	11,006	10,140	16·8
Torquay ..	4,008	3,507	1,279	6,589	21·6
Bootle ..	11,527	10,433	3,520	15,708	35·0

County of Leicester.

Dr. J. A. Fairer's report is so full of information that the routine work must be dismissed in a few words by saying that it is manifestly carried out with efficiency, and though no new schemes have been started in the county during the year there has been a steady development of the orthopædic work, with promise of further coöperation with the city clinic and the opening of several new clinics. The clinic at Coalville is equipped with a visiting orthopædic surgeon and a fully trained masseuse, who gives electrical, radiant heat, and plastic treatment, as well as massage. Throughout the county a special effort is made to include the pre-school children, and Dr. Fairer regrets that the ascertainment of crippling is so incomplete. This work is easier in urban areas where nursery schools are established. Despite difficulties progress has been made towards the supervision of every child from infancy to adolescence. With this ideal in mind there has been established community of staff, carrying forward of information, and availability of treatment. An account is given of a scheme at a central school, where an excellent hot dinner is provided at 3½*d.* per head, with an average gain in weight of nearly half a pound in five months more than in a control group. The girls who assist get valuable lessons in domestic hygiene, and all the children learn good behaviour. Another measure, based on the work of Dr. Corry Mann, is the provision of milk under controlled conditions to 8681 children. In a test group of these weight increased by nearly three-quarters of a pound more in a twelvemonth than in a control group. Dr. J. F. Davidson gives an account of a tour of inspection of physical training; he was struck by the obvious enthusiasm and enjoyment, contrasting with the listless movement in special exercises of ten years ago. Nowadays exercises and games coördinate the whole physical and mental tone. For all school-children, and especially where lighting and ventilation are not up to the mark, there can be no more effective antidote to fatigue than organised games in the open air. A still greater gain lies in the development of sportsmanship and social responsibility. With Dr. Davidson's report should be read that of the chief organisers, who lay similar stress on all-round activities, though they naturally dwell more on ideals and progress than on theoretical achievements. The report contains a study of a scheme for teaching sex hygiene, data on the physical condition of young children, and a continuation of the research on myopia. All this, done in the face of shortage of staff from illness, is evidence of zeal and efficiency.

Torquay.

Dr. T. Dunlop, in his brief introduction to Dr. J. V. A. Simpson's report, says that the high standard of school medical work in the town has been maintained, although there have been no new developments apart from the completion of arrangements with the Torbay Hospital for dealing with tonsils and adenoids. It is a disappointment to us that Dr. Simpson gives no account of his work on ultra-violet rays in the atmosphere, or of the technique and results of his investigation of the ventilation of the sun lounge at the baths. Crippling defects are now dealt with adequately at the clinic in the town which forms part of the county orthopædic scheme. In all other departments the story is one of progressive development, including extension of treatment facilities to the pre-school child. Last May a new school on the Derbyshire plan was opened on ideal premises with individual towel and model cloakroom arrangements for each child, giving opportunity for the school-child to practise the hygienic way of life. Improvements in the old schools will have their influence on the pupils, and through them on home conditions. In many schools the tone has improved; the wearing of school caps and colours has made scholars take a much keener interest in their personal appearance. An excellent account is given of work at the open-air school. Special mention is made of the rheumatic children, of whom a register is kept, each case being studied individually. Owing to the favourable climate several of them can attend the open-air school, though they are kept at home on wet days and obtain rest and medical treatment on the appearance of any active recurrence. Two severe heart cases have been sent to the Rosehill Children's Hospital.

Bootle.

Dr. F. T. H. Wood exemplifies in his writings and actions the widening concept of the functions of school medical service. The old idea of confining the work to the detection and removal of existing defects is being left behind; the newer aims a physical and mental culture. In the words of Si George Newman's report: "Is it a child with som remnants of school information only that the natio needs at 14 or 15 years of age, or is it a child physicall fit and alert, sound in sense and limb, disciplined i body and mind?" The education of children i practical hygiene and development of physique an well-being can be furthered in two ways: the prope teaching of hygiene in schools, and the provision o expert guidance in physical training. Many of th new developments in Bootle are of preventive value Nutrition is being kept up by the provision of mil or milk food to some 3600 children, not because th average standard of nutrition is low (a table show that the average weight was slightly higher in 193 than in any of the preceding four years) bu because the number of children deemed under nourished is higher this year. The demands on th clog fund indicate the growing economic need. Th work of the remedial exercise clinic is also largel preventive, or at least corrective, directed as it i to the improvement of posture and muscular action Many of the defects dealt with are postural, lik spinal curvature and flat feet; habitual, like mouth breathing; or developmental, like rickets: and in the last class, the majority were below school age Special attention is being directed to the preventio of defects already found in children when they ente school. Of the three-year-old children 202 were full examined at the infant consultation, apart from th much larger number partially examined. Nurser schools form part of the programme for the future meanwhile baby classes for children from 4 to were started in four schools, with excellent results Largely preventive, too, is the work of the rheumatism clinic, which has afforded material for a limite inquiry by Dr. McCloskey. His conclusions generall agree with those of other writers, but he find rather more relation of rheumatism to tonsilla enlargements and sore-throats; only 28 per cent. o his cases had no signs or symptoms in the throat The hope is expressed that the teaching of hygien will soon be formally included in the school curri culum; physical training is being greatly influence by instructors who as yet belong primarily to th secondary schools. A brief note shows the excellence of the results.

CORRESPONDENCE

THE CLEAN MILK PROBLEM.

To the Editor of THE LANCET.

SIR,—I have read your leading article of May 9th with great interest, and note that you suggest that we ought to follow the advice of Dr. Savage and enable large local authorities "to require all milk produced or consumed in or entering their area, other than certified or Grade A (T.T.) milk, to be pasteurised." If that suggestion were carried out at an early date it would mean, for all practical purposes, that only an infinitesimal quantity of fresh milk would be available in our large cities. In view of the great improvements in our milk-supplies which are being effected by the milk industry, throughout the country under a voluntary system, and of the necessity for a much more thorough study of the nutritional value of different kinds of milk than has yet been carried out, it would appear that it might be advisable to adopt some less drastic procedure at the present juncture.

The work of Daniels and Stearns,[1] Ladd, Evarts, and Franks,[2] and Lewis[3] appears to demonstrate that there is a real difference in the nutritional values of fresh milk and milk that has been treated. This view is supported by R. A. Fisher and S. Bartlett[4] in their reading of the results of the Lanarkshire experiment. A study of their letter to *Nature* shows that in their opinion the results obtained in this experiment demonstrate that the boys and girls who received raw milk increased both in weight and height much more than those who received pasteurised. They also note that the boys gained greater relative benefit than the girls. This conclusion is very interesting when considered in relation to the work of C. V. Mattick and J. Golding,[5] who fed generations of rats on raw, pasteurised, and sterilised milk, and found that the weights of the bucks were much more rapidly affected by the different types of milk that were given to them than those of the does. The fact that Fisher and Bartlett's conclusions were reached quite independently of Mattick and Golding gives weight to them.

All the recent experiments on milk feeding in schools have demonstrated that those children who received the milk did much better than those who did not receive it. From these results two conclusions may be drawn; first that milk is a wonderful foodstuff, and second that the ordinary diets of these children did not enable them to attain the highest physical standard. This conclusion is confirmed by J. B. Orr and M. L. Clark in a study[6] of the diets of 607 families in Scotland which showed that in fact "the great majority were incapable of supporting the optimum-rate of growth." The chief medical officer of health of the Board of Education in his annual report for 1929 has also stated that "there is evidence to show that there is a large amount of 'subnormality' amongst secondary school-children, not severe enough to be labelled malnutrition, but which judged in relation to the period of the child's life, and the heavy and competitive strain of the secondary school curriculum, may lead to serious conditions of ill-health."

It would appear that at the present time two steps at least are necessary. On the one hand, to ensure that a complete study of the nutritional values of different types of milk shall be carried out; and on the other, to be careful that any legislation which may be passed shall ensure the progress of the production of a clean milk which is free from disease and not be limited to regulations which would tend to reduce the supplies of fresh milk in our large cities to a negligible quantity. This has been the effect of compulsory pasteurisation in all those countries which have hitherto adopted it.

I am, Sir, yours faithfully,
R. STENHOUSE WILLIAMS.

AIR MOVEMENT IN SANATORIA.

To the Editor of THE LANCET.

SIR,—As one of the 50 members of a group which visited Canada and America last summer to study tuberculosis, I was struck, as we all were, by the difference in the circulation of air inside their sanatoria and hospitals and ours. This difference is primarily due to the necessity they are under of using meshed nets to prevent insects getting into the wards and verandas. I was reminded myself of the feeling of being in a camp bed netted against mosquito or sandfly. Now, assuming that their results are about as good (or as bad) as our own, does this observation not suggest that we may be overdoing the open-air treatment in this country? I am aware that, now that sanatoria here utilise such methods as artificial pneumothorax, phrenic avulsion, exercises, and so forth, the basic element of open air is not as outstanding a feature in treatment as it was years ago. Nevertheless a patient told me the other day that he had left a sanatorium as they invited him to enter a bed covered with snow—and in my opinion he acted rightly. There must be a number of clinicians still with us who were on the staff of chest hospitals before sanatorium treatment came into being, and it would be of interest to learn what value they set on the movement of air in treatment. Personally I have modified my principles of treatment very considerably. I have been struck too, in motoring through towns and villages in winter time, by the fact that there are no more open windows than there were when sanatorium benefit came into force in 1912.

I am, Sir, yours faithfully,
J. D. MACFIE.

Winsley Sanatorium, near Bath, May 21st, 1931.

CHAIRS OF PHYSIOLOGY.

To the Editor of THE LANCET.

SIR,—In the generous review of my booklet on the history of physiology of the Clio Medica series, which appeared in your issue of May 2nd, attention is directed to the chair of physiology at the University of Glasgow, and the statement is made that when McKendrick succeeded Buchanan in 1876, the title of the chair was changed from "Institutes of Medicine" to "Physiology." This would place it before the Waynflete chair at Oxford, which was created in 1878. Before publishing the statement that the Oxford chair was the second in Great Britain, I inquired of Prof. E. P. Cathcart, of Glasgow, as to the circumstances of the founding of his chair. In a letter dated March 3rd, 1930, he replied that the designation Institutes of Medicine "was changed by Ordinance No. 31, dated 5 June, 1893, to Physiology (without any reason being given in the Ordinance—merely the bald statement)." I realise that the question merely involves a quibble as to the official designation of a chair, for McKendrick, in a very real sense, *was* a professor of physiology in 1876; but if Prof. Cathcart's statement is correct, I believe it justifies the assertion made in my book that the chair of physiology at Oxford was second in Great Britain, being preceded only by the chair at Edinburgh, which was renamed in 1874.

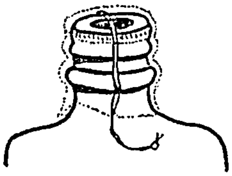
I am, Sir, yours faithfully,
J. F. FULTON.

New Haven, Conn., U.S.A., May 12th, 1931.

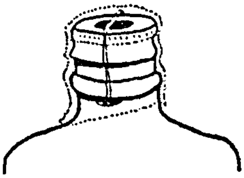
APPARATUS FOR BLOOD CULTURE.

To the Editor of THE LANCET.

SIR,—We have tested the apparatus for blood culture described by Dr. J. E. McCartney in THE LANCET of March 14th, and are satisfied that it is a great improvement on that previously in use in this laboratory, especially in reducing the risk of accidental contamination of the medium. The method of removing the viscap suggested was to run the edge of a penknife around the screw cap, so cutting through the viskap, to insert the point of the knife under the upper half of the viskap, and to flick off the latter. In practice this was not always quite so easy as it appeared, and occasionally the viskap tended to adhere rather firmly to the metal cap. Dr. G. C. Dockeray suggested to me the use of a thread under the viskap as a method of removing this covering, and the following arrangement has now been adopted by us.



Front.



Back.

When the medium has been placed in the bottle and the screw cap tightened, a stout linen thread is firmly tied around the neck of the bottle, below the projecting glass rim which is situated at a lower level than the edge of the metal cap. The two ends of the thread are brought over the top of the cap and down the other side of the neck, and the viskap fitted on. After sterilising and drying, the viskap holds the thread in place. When required for use, the two projecting threads are pulled, so splitting the viskap, which either flies off itself or can be flicked off. The illustrations, for which I am indebted to Dr. H. J. O'D. Burke-Gaffney, make the method of attaching the thread clear. In them the position of the viskap is indicated by the dotted lines.

I believe that this slight modification will still further improve the exceedingly useful apparatus described by Dr. McCartney.

I am, Sir, yours faithfully,
JOSEPH W. BIGGER.

School of Pathology, Trinity College, Dublin,
May 18th, 1931.

HUGHLINGS JACKSON MEMORIAL.

To the Editor of THE LANCET.

SIR,—Since the publication of the letter in your last issue additional subscriptions have come in from Dr. Russell Brain, Dr. Percy Kidd, Prof. Ashley Mackintosh, Dr. F. M. R. Walshe, Prof. Harvey Cushing (Boston), Dr. Bernard Sachs (New York), and Dr. Edwin Bramwell.

I am, Sir, yours faithfully,
WILFRED HARRIS.

56, Wimpole-street, W., May 25th, 1931.

CLINICAL TYPES OF HÆMOPTYSIS.

To the Editor of THE LANCET.

SIR,—Reading your report (p. 1136) of Dr. Hebert's excellent paper at the Tuberculosis Association on May 15th, I am led to wonder whether the classification he suggests is not rather too complicated for practical purposes, and whether indeed it is possible to distinguish clinically between arterial and venous hæmoptysis. The classification which I have advocated for some years is:—

1. The initial hæmoptysis, usually small—say a mouthful—but which may range from a trace only to a large quantity of blood. This indicates active disease, whether it be the first manifestation, or merely an indication of recrudescence, and the treatment for it is the treatment for active disease.
2. The small recurrent hæmoptysis occurring in chronic cases slight or severe, often associated with secondary infections. This can usually be ignored, and the patient reassured.
3. The severe hæmoptysis giving symptoms due to loss of blood, requiring treatment to that end, and often best dealt with by an artificial pneumothorax. Pathologists have told me that these large hæmoptyses often arise from cavities near the root of the lung.

I am, Sir, yours faithfully,
ERNEST WARD.

Paignton, May 26th, 1931.

TUBERCLE BACILLI IN THE BLOOD.

To the Editor of THE LANCET.

SIR,—In the final paragraph of your annotation on this subject on p. 1148 of your last issue there is, I think, a slight confusion as regards the medium. The "asparagin" medium is the latest one employed by Prof. Löwenstein, and although I am experimenting at the present time with this medium, the results published in my article were obtained by the use of Löwenstein's original egg medium.

I am, Sir, yours faithfully,
H. M. SCHWABACHER.

May 27th, 1931.

OVERCROWDING AS A FACTOR IN OUTBREAKS OF CEREBRO-SPINAL FEVER.

To the Editor of THE LANCET.

SIR,—While Prof. Dudley's reply in THE LANCET of April 18th throws further very interesting light on his views, the fresh data he presents may be thought to be not wholly convincing. He supports his objection to my theory in regard to the importance of atmospheric humidity (indoor humidity in particular) as a factor in outbreaks of cerebro-spinal fever by referring to three facts of argument: (1) that the carrier-rate was (presumably during the war period) often as high in ships as in barracks; (2) that the morbidity of influenza and tonsillitis is at times as high to-day on ships as formerly when ventilation was non-existent; (3) that meningitis, in its most general acceptation, was a rare disease in the Fleet over the 20 years 1860–79, when ventilation was as bad in sea-going ships as in training ships.

The reasons to which I wish to call attention are: (1) Gordon's English types I., II., III., and IV., and Nicolle's corresponding French types A and B, of agglutinating sera, for differentiating between agglutinable and non-agglutinable strains (that is, between epidemiological and non-epidemiological meningococci), did not come into general use before the middle of 1916 or early in 1917. As is generally known, the introduction of these sera eliminated much confusion and greatly enhanced the value of subsequent carrier-rate findings. In the absence of qualifying information as to the relative proportions of agglutinable and non-agglutinable meningococci met with, and of *identical* experimental factors, might not the statistical value of comparative carrier-rate determinations be considered a little vitiated? (2) Considering morbidity as a function of bacterial resistance, rather than in the sense implied by Prof. Dudley, the still high morbidity of influenza and tonsillitis infections would surely be explained by the greater resistance of this group of germs to external conditions—e.g., ventilation—than the meningococcus. (3) The meningococcus not being discovered before 1887, can relevant statistics of anterior date be altogether relied upon in a discussion of this kind?—I am, Sir, yours faithfully,

Alexandria, Egypt, May 19th, 1931. A. COMPTON.

OBITUARY

SEYMOUR TAYLOR, M.D. Aberd., F.R.C.P. Lond.,

CONSULTING SURGEON TO THE WEST LONDON HOSPITAL.

WE regret to announce the death of Dr. Seymour Taylor which occurred on May 30th at 21, Wembley Park-drive, in his eightieth year. He had recently retired from practice.

Seymour Taylor was born at Derby in 1851, the son of Mr. Thomas D. Taylor of that town. His preliminary education was received at a private school until he entered the University of Aberdeen as an under-graduate. Here he joined the medical faculty, later completing his medical education at St. Thomas's Hospital, where he was a prizeman. He took the diploma of M.R.C.S. in 1872 and the M.B., C.M. Aberdeen in 1877, proceeding to the M.D. degree in 1881. At St. Thomas's Hospital he was for some time demonstrator of anatomy, and in 1886, while still holding that post, he was appointed assistant physician to the West London Hospital, beginning then his long connexion with that institution. He held the demonstratorship of anatomy at St. Thomas's for another four or five years, and throughout all his clinical work he was always greatly interested in structural anatomy; he was an examiner at different times in the subject at the English Conjoint Board and at the University of Aberdeen. At the West London Hospital he was a vigilant member of the staff, taking especially great pains in the out-patient department with the diagnosis and treatment of the very varied cases which reached the institution. His thoroughness and also his kindness were obvious to his patients, thus removing any impression due to the direct and sometimes abrupt nature of his interrogatories. In 1900 Taylor became full physician to the hospital, and in this year he was elected F.R.C.P. He was also physician to the North London Consumption Hospital, but he made no direct studies of pulmonary disease. He was always a general physician, though he took special interest in cardiology.

Seymour Taylor made considerable literary contributions to medicine and wrote one book which passed deservedly through three editions. This was his "Index of Medicine," which was published in 1894. The simple design of the work was that it should be a handy manual for students preparing for final examinations, and for this purpose the arrangement of the subject matter was admirable, while many practitioners found the volume a handy one for reference. Other contributions deserving of notice are the analyses of the cases of enteric fever treated in St. Thomas's Hospital during the period 1878–1881, and published in St. Thomas's Hospital reports; to these reports, indeed, he made frequent contributions, usually displaying anatomical knowledge. Several papers on aortic insufficiency were published in THE LANCET, and contributions appeared from him in various journals dealing with anatomical points as they came up for notice. He wrote also a series of papers on Acute Pneumonia and another series on Health for the Middle Aged, the latter of which was published in a volume.

Dr. Taylor was consultant physician to the Equitable Assurance Society after many years connexion with that body; and among other interests of an active professional life he was ex-president of the West London Medico-Chirurgical Society, a medical officer to the Board of Education, had been treasurer of the Medical Defence Union, and was on the Council of Epsom College. To the interests of this last institution he was particularly devoted, missing very few meetings of the Council and contributing usefully to its deliberations until shortly before his death.

Dr. Seymour Taylor married Edith, eldest daughter of Edgar W. Bishop, of Hendon Park, Mill Hill.

ALFRED T. MacCONKEY, M.B., D.P.H. Camb.

BACTERIOLOGISTS in all parts of the world who are familiar with the use of MacConkey's medium must have felt that a break with the past had occurred when the death of Dr. A. T. MacConkey was announced. During the past five years he had been living in retirement in Surrey, where he died on May 17th.

Alfred Theodore MacConkey was born in 1861, the youngest son of the late Rev. Andrew MacConkey, of West Derby, Liverpool. He received his scientific training at Caius College, Cambridge, and obtained honours in the Natural Science Tripos. He proceeded to Guy's Hospital, whence he graduated M.B., B.Ch., in 1889. He held the post of senior house surgeon at Guy's, and then settled in practice at Beckenham in Kent. He had acquired a reputation as a sound, capable, and well-liked practitioner, when, after an attack of influenza, he had a nervous breakdown; he decided to abandon general practice and to turn aside into the quieter paths of bacteriological research.

After working for a time with Washbourn and Eyre in the laboratories of his old hospital, he was associated, as bacteriologist, with the Thompson-Yates laboratories in Liverpool under the late Sir Rubert Boyce. His appointment about this time as assistant bacteriologist to the Royal Commission on

Sewage Disposal, whose working headquarters were at Leeds, determined the trend of his researches during the early years of the century. The problems that called for solution fascinated him, and his interests were soon deeply engaged in the technical part of the work. During the period 1900–1909 the results of his investigations were published in a number of papers, which embody his pioneer researches upon the classification of the lactose-fermenting bacteria of intestinal origin, and upon the differential criteria and the significance of this group as contaminants of water, milk, and foodstuffs.

The introduction of his bile-salt medium put into the hands of bacteriologists a simple and effective tool for the separation of the typhoid-dysentery group of bacilli, and it proved of especial value in the estimation of coliform bacteria in the routine examination of water-supplies. Bile-salts had been added to media as early as 1889, and MacConkey's first experiments with them were made in 1897; in 1900 he used a bile-salt lactose agar for the purpose of isolating *B. typhosus* and *B. coli communis.* The addition of neutral red as a differential colour indicator for colonies that either do or do not ferment lactose was suggested in 1902 by Grünbaum and Hume, and this improvement in the method was adopted by MacConkey. He was one of the first to appreciate the importance of noting and comparing the biochemical activities of the intestinal group of bacilli with the object of defining their specific characters and their relationships.

In November, 1901, he joined the staff of the Lister Institute, London, as an assistant in the bacteriological department. The change proved to be the second turning-point in his career, for his transference soon afterwards to the serum department of the Institute at Elstree, then under the charge of the late Prof. George Dean, diverted his energies to the solution of the problems which surround the preparation of toxins and antitoxins. In April, 1906, he became the head of the department, and he remained at Elstree until his retirement in April, 1926, at the age of 65 years. He continued the early work of his colleague, Prof. J. C. G. Ledingham, on serum concentration, and developed the technical processes for refining and concentrating antitoxic sera. There are workers in many countries who owe their practical knowledge of the subject to the information which MacConkey freely put at their disposal. In 1912 he contributed to the reports of the Plague Research Commission in India an interesting paper on the production and titration of antiplague serum, which showed that the specific antitoxin can be concentrated by the usual methods, and that it is associated with the pseudo-globulin fraction the serum proteins.

During the years of the war MacConkey took a keen interest in the prophylaxis and treatment of tetanus by means of antitoxin, and he published several papers on the subject; some of them collated the experience of numerous observers in many countries, and others gave an account of experimental work carried out by himself and his colleagues. He served as a member of the War Office Committee for the investigation of tetanus. In his published articles he entered a strong plea for devoting special attention to the early signs and symptoms of tetanus, on the ground that the antitoxin is likely to influence the disease only when administered as soon as the symptoms are recognisable. The limited response to his appeal and the scanty information which came to hand disappointed him, but it is probable he had not sufficiently realised the difficulty of discriminating between the early subjective symptoms of tetanus and those which were attributable to sepsis, to traumatic shock, and to the nervous strain from which the patients were suffering.

During the war MacConkey put his energies without stint into the task of enlarging and organising his department to meet the increasing demands made upon it by the army authorities for tetanus antitoxin, anti-dysentery serum, and anti-meningococcus serum. The strain of the work weakened his resistance, and rendered him subject to influenzal attacks; these gave rise to an obscure cardiac disability from which he never really recovered.

Dr. G. F. Petrie writes: "MacConkey was a man of a quiet disposition, of simple tastes, and with a natural charm of manner, which was most evident in his home and among the pleasant surroundings of his garden at Elstree, where Mrs. MacConkey and he dispensed amiable and delightful hospitality. He was a lover of animals, and a skilful gardener with a passion for cultivating roses. He was a good raconteur, and possessed a keen sense of humour. He held tenaciously to his opinions, and this feature of his character and the steady persistence with which he pursued refractory technical problems may doubtless be traced to the sturdy independence of the Northern Ireland stock from which he came. The high standard by which he was wont to judge the conduct of others led him at times to assume an unyielding attitude, but those of his friends who knew him best believed that this was a defensive reaction on the part of a modest and sensitive nature; it is certain he followed closely his fine ideals of service."

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS.

WHITSUNTIDE ADJOURNMENT.

ON May 21st, in the House of Lords, the Workmen's Compensation Bill passed through committee. Their lordships adjourned for the Whitsuntide recess until June 5th. The House of Commons adjourned on May 22nd until June 2nd.

HOUSE OF COMMONS.

WEDNESDAY, MAY 20TH.

Price of Milk in London.

Sir WALTER PRESTON asked the President of the Board of Trade if he was aware that one of the principal retail milk-supplying firms in London was charging 2*s.* per gallon for milk for which they only paid the farmer 9½*d.* per gallon delivered at the London termini; and whether, in view of the importance of milk as a diet for children and invalids, he could take steps to correct the difference between the wholesale and retail prices.—Mr. W. R. SMITH (Parliamentary Secretary to the Board of Trade) replied: I am aware that the usual retail price of milk in London is as stated. The price paid to the farmer under the Terms of Settlement approved by the Permanent Joint Milk Committee varies according to circumstances, but I have no information as to the particular case referred to. I have no power to alter the prices of milk but the Consumers' Council Bill contains provisions which would invest the Board of Trade with certain powers to deal with prices found to be excessive.

Experiments on Living Animals at Reading.

Mr. FREEMAN asked the Home Secretary whether he was aware that Mr. S. P. Male, of Reading, had, during 1930-31, performed a number of experiments on living animals for the purpose of gland grafting, calculated to give pain;

t no licence had been granted to this gentleman; and at action he proposed to take in the matter.—Mr. SHORT nder Secretary for the Home Office) replied: My right n. friend has inquired into the facts of this case and ds that the operations in question were performed by . Male in the ordinary course of veterinary practice for e purpose of treatment of the patients. They were, erefore, not experiments within the meaning of the levant statute, and my right hon. friend has no jurisdiction the matter.

Mr. FREEMAN: Is no licence required in a case of this scription even although pain is caused?

Mr. SHORT: My right hon. friend has no jurisdiction at all.

Infantile Mortality in Scotland.

Miss LEE asked the Secretary for Scotland (1) the counties Scotland where there were the highest and lowest infantile ortality-rates, and the deaths per 1000 in these two unties, and (2) the average infantile mortality-rate for ottish counties.—Mr. WESTWOOD (Under Secretary for otland) replied: The average infantile mortality-rate r the whole of Scotland, excluding burghal areas in 1930, as 69 per 1000 births. The mean of the rates for e individual counties (again excluding burghs) was 61 er 1000. The highest rate was 89 per 1000 in Dunbartonhire, and the lowest was 23 per 1000 in Bute. If my hon. iend intended to include burghal areas, the answer to uestion No. 53 would be that the highest rate was 100 er 1000 in Wigtownshire and the lowest 25 per 1000 in ute; but I should have to make further inquiry as to erage rates.

Public Health Meat Regulations.

Mr. THORNE asked the Minister of Health the date of the scission of the order made under the Public Health Meat egulations, 1908, prohibiting such imports as boxed loins nd legs of pork, boneless beef, and other forms of scrap eat used by sausage manufacturers; the reason for the iginal prohibitions; and what fresh facts were disclosed justify the rescission.—Miss SUSAN LAWRENCE (Parliaentary Secretary to the Ministry of Health) replied: he Public Health (Foreign Meat) Regulations of 1908 and 909 were revoked in 1925, but their substance was re-enacted ith slight modifications by the Public Health (Imported ood) Regulations, 1925. The importation of scrap meat e., meat which affords insufficient means of identification ith definite parts of a carcass) is still prohibited, the reason r the prohibition being that such meat cannot be atisfactorily inspected at the time of importation. Boxed ins and legs of pork have never been regarded as scrap neat and their importation has always been allowed if they re accompanied by official certificates recognised as atisfactory by the Minister of Health. The official certifiate of a number of countries have been recognised for this urpose at various dates from 1909 to 1929.

THURSDAY, MAY 21ST.

Government and the Factories Bill.

Sir KINGSLEY WOOD asked the Home Secretary the present position with regard to the Factories Bill.—Mr. CLYNES replied: As I explained in reply to a previous question the Government have been anxious to proceed with this Bill during the present session if it seemed practicable, having regard to other commitments, to carry it through all its stages. I am afraid that in view of the legislation to which Parliament is already committed, and the present state of business, a postponement of this Bill for the present session appears now to be inevitable.

Shortage of R.A.M.C. Officers.

Lieut.-Colonel FREMANTLE asked the Secretary to the Treasury whether the proposed inter-departmental committee to inquire into the shortage of officers of the Royal Army Medical Corps had yet been appointed; and, if so, if he would state the terms of reference and personnel of the committee.—Mr. PETHICK-LAWRENCE (Financial Secretary to the Treasury) replied: The Committee has not yet been set up. It is, however, hoped that it will be possible to announce its composition and terms of reference in a few days' time.

Lieut.-Colonel FREMANTLE: In the composition of this committee is consideration being given to the fact that a great deal depends on the future career offered in civil life after these officers retire, and is it considered therefore possible to include some representatives of the civil services which employ the services of medical officers?

Mr. PETHICK-LAWRENCE: I am afraid I should have notice of that question.

Insane and Mentally Deficient Persons.

Sir NICHOLAS GRATTON-DOYLE asked the Minister of Health how many insane and mentally deficient persons had been a charge on the funds of the State and local authorities in each of the years 1928, 1929, and 1930.—Mr. GREENWOOD replied: The following is the information asked for:—

Chargeable to the State.

—	On Jan. 1st—		
	1928.	1929.	1930.
Mentally Deficient Persons.			
In State institutions ..	690	785	884
Insane Persons.			
Criminals	803	910	909
In naval and military hospitals	174	163	152
"Service" and "ex-Service" patients	5,543	5,402	5,295
Total (insane) ..	6,520	6,475	6,356

Chargeable to Local Authorities.

Insane Persons.			
—	122,754 (*a*)	125,534 (*a*)	126,941 (*a*)
Mentally Deficient Persons.			
In institutions (under Order)	17,683 (*b*)	19,138 (*b*)	20,629 (*b*)
Under Section 3 (M.D. Act, 1913)	170	172	177
Guardianship	1,143 (*b*)	1,372 (*b*)	1,559 (*b*)
In "places of safety" ..	265 (*b*)	261 (*b*)	216 (*b*)
Total (mentally deficient)	19,261 (*c*)	20,943 (*c*)	22,581 (*c*)

(*a*) Including cases chargeable to board of guardians, and cases in public assistance institutions and in receipt of outdoor relief.

(*b*) 50 per cent. of cost contributed by the State. (N.B.—Under the Local Government Act, 1929, the State contribution of 50 per cent. ceased on March 31st, 1930.)

(*c*) Not including cases under statutory supervision.

Nurses' Hours and Wages.

Mr. BROCKWAY asked the Prime Minister whether the Government was prepared to provide facilities for the further stages of the Nursing Profession (Wages and Hours) Bill.—Mr. MACDONALD replied: I regret that I can hold out no hope of time being found for the discussion of this Bill.

Lieut.-Colonel FREMANTLE: Will the right hon. gentleman recognise that there is no demand for this Bill among the nursing profession, and that it is a political stunt of the Labour party?

No further answer was given.

Co-operative Societies and Insurance Prescriptions.

Sir KINGSLEY WOOD asked the Minister of Health whether he proposed to make such alterations in the present regulations as would permit co-operative societies to make a monetary payment to their customers in respect of national health insurance prescriptions.—Mr. GREENWOOD replied: This matter has been the subject of very recent legal proceedings, and until the period for appeal against the decision has expired it would not be proper for me to make any statement.

Approved Societies' Funds.

Mr. THOMAS LEWIS asked the Minister of Health the amount actually credited to approved societies in accordance with Section 4 of the National Health Insurance Act, 1926, as amended by Section 21 of the National Health Insurance Act, 1928, for the purpose of preventing insured persons who were in arrears from being, or continuing to be, subject to reduction or suspension of benefits.—Mr. GREENWOOD replied: The sum of £500,000 available in respect of arrears in the contribution year ended July 7th, 1929, is in process of distribution to approved societies. The distribution of the £500,000 in respect of arrears in the contribution year ended July 6th, 1930, is awaiting the receipt of returns from the societies.

JEWISH HOSPITALS.—Last year the London Jewish Hospital (108 beds) received 1600 in-patients, a considerable increase; out-patient attendances increased from 60,444 to 65,873, chiefly by reason of patients referred for treatment to special departments. The weekly cost of each in-patient went up from £3 2*s.* 8*d.* to £3 4*s.* 7*d.*—The foundation-stone of the Bernhard Baron extension of the Victoria Memorial Jewish Hospital in Manchester was laid recently by Mr. J. H. Thomas, Secretary of State for the Dominions, Sir Louis Baron, Sir William Cundiff, and Mr. R. Barrow-Sicree. This marks the beginning of an extension, to cost £40,000, which will provide 25 additional beds, 11 private wards for paying patients, two new theatres and other accommodation.

MEDICAL NEWS

University of Cambridge.

On May 22nd the following degrees were conferred :—

Sc.D.—A. S. Parkes.

M.B. & B.Chir.—F. G. Wood-Smith.

Lane Presentation.—The presentation to John Lane, senior steward of the anatomical department, will be made on Tuesday, June 2nd, at 5 P.M., in the Anatomy School. It will consist of a gold watch and chain, together with a cheque, a short address, and a list of the subscribers.

Royal Colleges of Physicians and Surgeons of England.

At the Final Examination of the Conjoint Board, held from April 13th to May 4th, the following candidates were approved in the undermentioned subjects, but are not eligible for the diplomas of the Colleges :—

Pathology.—J. H. Beale, Sheffield ; E. H. S. Bebb, London ; H. T. L. Broadway, St. Thomas's ; S. B. Bromberg, St. Mary's ; J. Burdon-Cooper, Univ. Coll. ; T. Chadderton, Manchester ; Barbara G. C. Clarke, Univ. Coll. ; R. C. Cohen, Univ. Coll. ; J. G. Connell, Sheffield ; F. N. Corfe, L.D.S. Eng., Guy's ; E. H. de B. Crowther-Smith, Guy's ; E. J. Currant, London ; D. Davidson, Univ. Coll. ; R. T. Elven, Guy's ; C. D. Evans, St. Mary's ; A. C. Gladstone, St. Thomas's ; H. F. Green, St. Bart.'s ; A. Greenberg, St. Bart.'s ; H. J. Griffiths, Middlesex ; M. A. F. A. Hadi, Birmingham ; Winifred S. Hall, Univ. Coll. ; W. Hedgcock, St. Thomas's ; A. Hollinrake, St. Bart.'s ; Mary T. Howard, Charing Cross ; S. V. Humphries, St. Thomas's ; B. Hynes, Middlesex ; J. M. Jackson, St. Bart.'s ; Annie L. Jones, Univ. Coll. ; L. Kessel, and J. S. Lane, Guy's ; H. H. Langston, St. Bart.'s ; E. S. Lee, Westminster ; A. A. Lewis, Guy's ; J. T. R. Lewis, Middlesex ; P. Lewis, Leeds ; W. H. Lewis, Guy's ; M. A. Lloyd, St. Bart.'s ; I. A. MacDougall, Guy's ; G. J. McFarlane, St. Thomas's ; J. G. McGrath, Manchester ; J. W. McLaren, St. Thomas's ; R. L. Mansi, St. Bart.'s ; W. A. Mayne, St. Thomas's ; C. F. Mayo-Smith, St. George's ; G. J. Meikle, Middlesex ; T. F. B. Noble, London ; N. C. O'Byrne, St. Thomas's ; C. G. Owen, Edinburgh and St. Mary's ; G. T. Partridge, St. Bart.'s ; R. C. T. Pearson, St. Thomas's ; F. W. J. Platts, King's Coll. ; Joyce A. Pope, Manchester ; C. R. D. Porter, and T. W. H. Porter, Middlesex ; S. Prakash, M.B., Charing Cross ; Eluned M. Puleston-Jones, Lond. Sch. Med. ; H. M. Rashid, Birmingham ; G. F. Rees-Jones, Univ. Coll. ; B. Roberts, Univ. Coll. ; I. C. Robertson, St. Thomas's ; G. Scott, Middlesex ; M. Shankhla, Leeds ; J. R. S. Sharp, Guy's ; R. E. H. Simpson and D. G. Snell, St. Thomas's ; W. P. Stamm, Guy's ; S. Sutton, Manchester ; G. H. Taylor, Guy's ; Winifred P. Thomas, Univ. Coll. ; H. H. Thompson, Manchester ; W. F. Townsend-Coles, London ; Patricia I. Unsworth, Liverpool ; H. C. M. Walton, St. Mary's ; J. H. West, St. Bart.'s ; Shirley E. Whitaker, Univ. Coll. ; H. G. Williams, St. Thomas's ; H. T. S. Wise, King's Coll. ; F. H. Wood, Birmingham ; S. L. Wright, Univ. Coll. ; J. Zeitlin, London.

University of Liverpool.

The title of professor emeritus has been conferred on Dr. Edward William Hope, formerly professor of public health in the University and medical officer of health for the city and port of Liverpool.

University of Manchester.

The University Court has resolved to grant the honorary degree of master of science to Dr. Alexander Brown Ritchie, for over 20 years school medical officer of the city of Manchester.

University of London.

At a meeting of the Senate on May 20th Dr. E. L. Kennaway was appointed to the University chair in experimental pathology (tenable at the Cancer Hospital (Free)). Dr. Kennaway has been chemical pathologist at the hospital since 1921. The title of professor of pathological chemistry was conferred on Mr. C. R. Harington, Ph.D., F.R.S., in respect of the post held by him at University College Hospital Medical School. The title of emeritus professor of experimental pathology was conferred on Sir Charles Martin, M.B., F.R.S., and that of emeritus professor of biochemistry on Mr. Arthur Harden, D.Sc., F.R.S., on their retirement from the Lister Institute of Preventive Medicine.

The Dunn exhibitions in anatomy and physiology for 1931 were awarded respectively to E. W. Bintcliffe, of St. Bartholomew's Hospital Medical College, and S. O. Aylett, of King's College.

Convocation has reappointed Sir Ernest Graham-Little, M.D., M.P., as a member of the Senate.

University of Leeds.

When the centenary of the School of Medicine is celebrated on July 1st the honorary degree of Doctor of Science will be conferred on Sir Walter Fletcher, F.R.S., secretary of the Medical Research Council, and on Sir Gowland Hopkins, F.R.S., professor of biochemistry in the University of Cambridge. The honorary degree of Doctor of Laws will be conferred on Dr. Alfred George Barrs, emeritus professor of clinical medicine in the university; Sir John Bland-Sutton, formerly President of the Royal College of Surgeons of England; Lord Dawson of Penn, President of the Royal College of Physicians of London; Dr. Arthur Hawkyard, Lord Mayor of Leeds; Sir George Newman, chief medical officer to the Ministry of Health and the Board of Education; and Dr. Jane Walker, medical superintendent of the East Anglian Sanatorium, Nayland.

Papworth Village Settlement.

Mr. Greenwood, the Minister of Health, last week laid the foundation-stone of a new hospital for women at the Papworth Village Settlement for Sufferers from Tuberculosis.

Research Defence Society.

The annual general meeting of this society will be held at the house of the Medical Society of London, 11, Chandos-street, Cavendish-square, W., on June 10th, at 3.30 o'clock, when the Stephen Paget memorial lecture will be delivered by Dr. H. H. Dale, director of the National Institute for Medical Research, on the Effect of Research on Curative Medicine. Lord Lamington, the President, will take the chair.

Charing Cross Hospital Medical School.

In view of the success of the recent Sunday post-graduate course, it has been decided to hold another during the next two months. It begins on May 31st with a lecture at 10.45 A.M. by Dr. W. J. Adie on Sudden Attacks of Nervous Origin, and one at 11.45 by Mr. Peter Daniel on Diseases of the Colon. Particulars will be found each week in our Medical Diary. Application for membership of *the* course should be made to the secretary of the school, 62, Chandos-street, W.C. 2.

Royal Institute of Public Health.

At the inaugural meeting of the congress of the Royal Institute of Public Health, held in the University of Frankfurt a. Main on Tuesday, May 19th, the Harben gold medal of the institute was presented to Prof. William Henry Welch, of Baltimore, in recognition of his eminent services to the public health. At the same meeting the rector of the University presented to Sir William Smith, the principal of the institute, the Ehrlich-Weigert medal of the Medical Faculty. On the following day the Oberbürgermeister, on behalf of the city of Frankfurt, presented to the institute the medal of honour of the city "in remembrance of the congress, which was the first to be held on German soil for 19 years," and handed the medal to Sir Thomas Oliver, the distinguished representative of the institute.

Belgrave Hospital for Children.

Last year 2210 in-patients were admitted; they cost £3 3*s.* 7*d.* per head. Ninety-five per cent. of them came from South London. As soon as means are available the overcrowded out-patients' department is to be rebuilt. A ward of 12 beds is now available for the children of parents of moderate means, at a fee of £3 3*s.* per week; the medical staffs' fees are fixed in accordance with the circumstances of the parents. What is claimed to be a new departure in hospital practice has come into operation recently. Arrangements have been made with practitioners in the neighbourhood whereby consultations with members of the staff may be arranged at reduced rates for parents who cannot afford the ordinary consultants' fee. These consultations are available only on the recommendations of the practitioner.

Lord Mayor Treloar Cripples Hospital and College.

On Founders' Day, Monday next, June 1st, Admiral Sir Roger Keyes will open the Portsmouth block of the hospital, and Lord Burnham will preside at the function.

Royal London Ophthalmic Hospital.

Last year there was a surplus of income over expenditure of £1798. Towards the second portion of the reconstruction scheme, which will cost £40,000, there is now available £13,500. There is a daily average of 478 out-patients.

St. Bartholomew's Hospital, Rochester.

Last year there were 1935 in-patients and 9201 new out-patients. Each in-patient costs £8 5*s.* 11*d.* (residence 21·9 days) and each out-patient 6*s.* 8*d.* The first year's working of the Association of Friends (contributory scheme) produced £4000, of which £3000 was entirely new money.

King's College Hospital.

The annual festival dinner, over which Lord Burnham presided, took place at Merchant Taylors' Hall last week when £6000 was raised. It was stated that the hospital is 200 beds behind the needs of the population served, and that in 1930 expenditure exceeded income by £13,500. Nearly half the income was provided by patients' payments. An appeal is being made for £27,000 to facilitate the provision of larger accommodation for private patients.

Royal Free Hospital.

The annual report states that by the end of 1930 the Eastman Dental Clinic had been completed and was in working order, and the venereal diseases clinic rehoused, while the Albert Levy wing was well advanced. The completion of the nurses' home is to be proceeded with as soon as possible. The year ended with a deficit of £5457, and "the General Fund is now insolvent to the extent of £25,517."

Composition and Description of Food.

The Minister of Health and the Secretary of State for Scotland have appointed a committee to inquire into the working of the law as to the composition and description of articles of food other than milk, and to report what alterations, if any, in the law or its administration appear to be desirable. Sir Frederick Willis, is the chairman and the members include Dr. J. M. Hamill. The secretary is Mr. W. J. Peete, of the Ministry of Health, to whom communications may be addressed.

King Edward VII. Hospital, Windsor.

Two wards have been added to this hospital, and during 1930 a third theatre was provided at the cost of Sir Joseph Skevington and his brother, Major Skevington. The pathological department has been removed to more convenient quarters, and the old department has been converted into a chapel which was last week dedicated by the Bishop of Buckingham. The contributory scheme last year produced £9646, an increase of more than £1000.

Bolingbroke Hospital: Proposed Extension.

In the annual report the governors call attention to the dilapidated condition of the old mansion portion of the building at Wandsworth which is "almost impossible" to remedy. They are therefore contemplating an extension which, in addition to providing further beds for patients, will not only replace the accommodation of the old building, but will enable it to be demolished to make room for additional wards. Last year there were 2458 new in-patients who stayed an average of 16·2 days, as against 15·8 days in 1929.

University College Hospital.

Last year there were 8898 in-patients (540 beds) and 81,895 out-patients. The average stay of each in-patient was 20·39 days; the cost per occupied bed was £181, and each out-patient cost 5*s.* 3*d.* A speech clinic has been instituted which deals with stammering and other speech defects, and it has been decided to establish a department of clinical research under the charge of Sir Thomas Lewis. Eight private wards have been provided in the Royal Ear Hospital, and the general committee have in mind the establishment, when circumstances permit, of a private hospital of 100 beds on a site in the immediate neighbourhood. The income last year was £107,448 and the expenditure £106,537.

Kent County Ophthalmic and Aural Hospital.

As the result of the recent extensions in-patients increased last year by 550, and the out-patients numbered 33,741, of whom 21,642 were ophthalmic cases. In addition there were 5765 ophthalmic and 2281 aural casualties. Candidates for various treatments brought up the total number of out-patients to 41,637, an increase of nearly 10,000 over 1929. Owing to the cost of alterations and improvements, and the addition of 33 beds, the hospital has a debt of £20,000. Last year the contributory fund provided over £13,000.

Donations and Bequests.

Among other bequests the late Sir Harold J. Reckitt left £5000 to the Hull Royal Infirmary; £2000 to the Hull and East Riding Convalescent Home; £1000 to the Victoria Children's Hospital, Hull; £800 to the Royal County Hospital, Chichester; £600 to the Hull Dispensary, and £200 to the Emsworth (Hants) Cottage Hospital.

New Infirmary at Chard.

A new infirmary has been added to the Chard Public Assistance Institution. It has cost £10,000, is a two-storey building of concrete, and has 48 beds. The nursing staff are placed in an adjoining bungalow.

Royal Eye Hospital.

It is proposed to rebuild this hospital, at St. George's-circus, Southwark, at an estimated cost of £150,000. The beds would be increased from 46 to 80, and more private wards would be provided, together with larger space for research work and out-patients.

Lyndhurst Maternity Block.

Miss Fenwick, president of the Fenwick Cottage Hospital, Lyndhurst, has presented the institution with a completely equipped maternity block formed by the conversion of some cottages close to the main building. There are two three-bed wards.

St. George's Hospital.

At the annual court of governors last week Prince George, the President, stated that the income last year was £87,388, and the expenditure £83,825. There were 5000 in-patients and 4000 operations. Lord Greville, the treasurer, said that the hospital is faced with the prospect of making an appeal for a large sum either for an entirely new building or for complete reconstruction of the old one.

Hospital Surpluses.

Last year the Queen's Hospital for Children, Hackney-road, had a credit balance, the first for 20 years, of £1408, as compared with a deficit of £1618 in 1929.—St. Helen's Hospital had a surplus of £1019 and St. John's Hospital for Diseases of the Skin, £1111.

Victoria Hospital for Children.

The average daily number of in-patients in 1930 was a fraction over 105, as compared with 94 in 1929, and their average weekly cost fell from £3 9*s.* 9*d.* to £3 7*s.* 6½*d.* The cost of maintaining the hospital and the convalescent home at Broadstairs was £26,386; the income was £24,251. During 1930 the ladies' association granted £715 to the hospital.

Enlargement of Bolton Infirmary.

The first extensions of this institution since it was built 50 years ago, consisting of the Nathan Barnes and Colin Cooper wards, were recently formally opened by Mrs. Colin Cooper, widow of one of the donors, and Miss Barnes, sister of the other donor. Each ward has cost £10,000.

Bath Orthopædic Hospital.

A new ward for 20 babies was recently opened by Mrs. Stanley Wills at the Bath and Wessex Children's Orthopædic Hospital. The addition, which is due to the generosity of her son, Mr. R. D. Wills, brings up the accommodation to 92 beds. Of the £30,000 required to complete a scheme for a further 50 beds, £18,250 has already been raised.

Royal Salop Infirmary.

Since the Road Traffic Act came into force and insurance of motorists became obligatory this institution has recovered between 60 and 70 per cent. of the cost of treating patients injured in motor accidents. The expenditure last year was £20,658, leaving a deficit of £2778. Among the receipts the two historic annual fixtures, the anniversary service and the infirmary ball, produced between them over £2200.

Paybody Convalescent Home.

A new ward which has been added to the Paybody convalescent home of the Coventry and district crippled children's guild at Allesley, near Coventry, was opened recently by Sir Edward Iliffe. The ward, which has cost about £5000, provides accommodation for 20 boys and 20 girls. There are between 1100 and 1200 children on the books of the guild.

Metropolitan District Nursing Association.

At the annual meeting last week it was stated that last year the nurses from the Bloomsbury home paid more than 57,000 visits, and that the work of the St. Pancras home had been so heavy that, notwithstanding the addition of another nurse, continuous help had to be given by the main home. There is a deficit of £1000 upon the St. Pancras branch.

Medical Diary

Information to be included in this column should reach u in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.
FRIDAY, June 5th.—9.30 A.M., LARYNGOLOGY. Summ Meeting. Papers and Demonstrations:—Dr. A. Br Kelly and Prof. Leonard Findlay: Congenital Shorte ing of the Œsophagus, and the Thoracic Stoma Resulting Therefrom. Dr. H. Graham Hodgson: T Radiography of Sinusitis (with Film). OYAL NORTHERN HOSPITAL, Holloway-road, N.
TUESDAY, June 2nd.—3.15 P.M., Dr. P. O. Ellison and Dr. Janet Vaughan: Demonstration in the Pathological Department.

NIVERSITY OF BIRMINGHAM.
TUESDAY, June 2nd.—3.30 P.M. (at the General Hospital). Mr. H. H. Sampson: Clinical Surgical Cases.
THURSDAY.—4 P.M., Prof. Blair Bell: Maternal Disablement (Last Ingleby Lecture).
FRIDAY (at the Queen's Hospital).—3.30 P.M., Prof. Billington: Demonstration of Surgical Cases.

Appointments

DMAN, G. E., M.B., B.S. Lond., has been appointed Honorary Assistant Physician to the Derbyshire Royal Infirmary.

rtifying Surgeons under the Factory and Workshop Acts: BROMS, D., M.B., Ch.B. Edin. (New Galloway District, Kirkcudbright); MURRAY, A. R., M.B., Ch.B. Edin., Poulton-le-Fylde, Lancaster.

Vacancies

For further information refer to the advertisement columns.

rrington Victoria Hospital.—Hon. Anæsthetist. Also H.S. £150.
ert Dock Hospital, Connaught-road, E.—Dental Surgeon.
fast, Campbell College.—Res. M.O.
rmingham Ear and Throat Hospital, Edmund-street.—H.S. At rate of £150.
mingham General Hospital.—Res. Surg. Reg. £100–£120–£140. Two Res. Anæsthetists. Each £120. Also Res. H.S. £70.
mingham, Highbury Hospital, Moseley.—Res. Asst. M.O. £300.
rmingham, P.H. Dept.—Asst. M.O. for Tuberculosis Section. £400.
ckburn Royal Infirmary.—4th H.S. £150.
ry County Borough.—Asst. M.O.H., &c. £500.
ncer Hospital, Fulham-road, S.W.—H.S. At rate of £100.
nterbury, Kent and Canterbury Hospital.—H.P. and H.S. Each at rate of £125.
rdiff, King Edward VII. Welsh National Memorial Assn.—Area Asst. Tuber. Physician. £600.
rdiff, Llandough Hospital.—Med. Supt. £750.
rlisle County Borough.—Asst. M.O.H. £650.
ntral London Throat, Nose and Ear Hospital, Gray's Inn-road, W.C.—Hon. Assts. to Out-patients' Dept.
esterfield and North Derbyshire Royal Hospital.—Cas. O. At rate of £200.
ty of London Hospital for Diseases of the Heart and Lungs, Victoria Park, E.—H.P. At rate of £100.
nnaught Hospital, Walthamstow, E.—Res. H.P. At rate of £100.
ventry and Warwickshire Hospital.—Res. H.S. £125.
rby, Derbyshire Hospital for Sick Children.—Res. H.S. and Res. H.P. At rate of £150 and £130 respectively.
rby, Derbyshire Royal Infirmary.—Ophth. H.S. £150.
ncaster Royal Infirmary.—H.S. At rate of £175.
rham, County Council.—District Tuber. M.O. £500.
rham County Council and Chester-le-Street U.D.C.—District Tuber. M.O. and M.O.H. £800.
st London Hospital for Children and Dispensary for Women, Shadwell, E.—Res. Cas. O. £125.
sex Administrative County.—Asst. County M.O.H. £500–£600.
eter, Royal Devon and Exeter Hospital.—Res. Sen. H.S. £250. Also Res. H.S. and H.S. to Spec. Depts. Each at rate of £150.
ucester, Gloucestershire Royal Infirmary, &c.—H.S. At rate of £120.
mmersmith Hospital, Ducane-road, Shepherd's Bush, W.—Res. Med. Supt. £950.
ospital for Sick Children, Great Ormond-street, W.C.—H.S. and H.P. Each at rate of £100.
ford, King George Hospital.—H.S. At rate of £100.
dderminster and District General Hospital.—H.S. £150.
ng's Lynn, West Norfolk and King's Lynn Hospital.—Jun. H.S. At rate of £125.
ncaster Royal Infirmary.—Jun. H.S. £130.
eeds Hospital for Women.—H.S. At rate of £50.
eicester Royal Infirmary.—H.P. At rate of £125.
ondon, Female Lock Hospital, 283, Harrow-road, W.—H.S. At rate of £150.
ondon Temperance Hospital, Hampstead-road, N.W.—Cas. O. and H.P. At rate of £120 and £100 respectively.
acclesfield, Cheshire County Mental Hospital, Parkside.—Asst. M.O. £350.
Manchester Babies' Hospital, Burnage-lane, Levenshulme.—Sen. and Jun. Res. M.O.'s. At rate of £125 and £50 respectively.
Manchester and District Radium Institute.—Asst. M.O. At rate of £300–£500.
Manchester Ear Hospital, Grosvenor-square, All Saints'.—H.S. £150.
Manchester, Royal Children's Hospital.—Sen. M.O. for Out-patients' Dept. £300.
Manchester Royal Infirmary.—H.S. for Central Branch, Roby-street. At rate of £100.
Manchester, Withington Hospital.—Two Asst. M.O.'s. Each at rate of £275.
Miller General Hospital, Greenwich-road, S.E.—H.P., H.S. Each at rate of £125. Also Out-Patient Officer. At rate of £150.
National Hospital for Diseases of the Nervous System, Queen-square, W.C.—Hon. Asst. Radiologist.
Newcastle-upon-Tyne, Hospital for Sick Children.—H.S. At rate of £100.
Nottingham General Hospital.—Cas. O. At rate of £200.
Oldham Royal Infirmary.—H.P. and Cas. O. Each at rate of £175.
Plymouth, Central Hospital.—H.S. At rate of £140.
Princess Louise Kensington Hospital for Children, St. Quintin-avenue, North Kensington, W.—H.S. At rate of £100.
Queen Mary's Hospital for the East End, E.—Hon. Asst. Obstet. Surgeon and Gynæcologist. Hon. Neurologist. Res. M.O. and Cas. O. At rate of £200 and £150 respectively. Also H.P.'s and H.S.'s. At rate of £120.
Reading, Royal Berkshire Hospital.—Res. Anæsthetist. At rate of £150.
Rotherham Hospital.—Cas. H.S. £150. Also Sen. H.S. £200.
Royal Free Hospital, Gray's Inn-road, W.C.—Res. H.P.'s and H.S.'s to Special Depts. Unit Anæsthetist and District Obstet. Asst. £100. Also Cas. O. £150.
Royal Free Hospital, Eastman Dental Clinic, Gray's Inn-road, W.C. Res. H.S.
Salford Royal Hospital.—H.P. and H.S. Each at rate of £125.
Sheffield Children's Hospital.—H.P. and Third Res. M.O. At rate of £100 and £80 respectively.
Sheffield, Jessop Hospital for Women.—Three Asst. H.S.'s. Each at rate of £100.
Southampton County Borough.—M.O.H. &c. £1250.
Southampton, Royal South Hants and Southampton Hospital.—Res. H.P. and 2 H.S.'s. All at rate of £180.
Stoke-on-Trent, Longton Hospital.—H.S. £120.
Walsall, County Borough.—Asst. Tuber. O., &c. £750.
Walsall General Hospital.—H.S. At rate of £150.
West Bromwich, Great Barr Children's Homes &c.—Asst. Res. M.O. £275.
West Bromwich, Hallam Hospital.—Res. H.S. £250.
West London Hospital, Hammersmith-road, W.—H.P. and two H.S.'s. All at rate of £100.
Westminster Hospital Annexe, 66, Fitzjohn's-avenue, Hampstead.—M.O. At rate of £300.
Windermere, Ethel Hedley Orthopædic Hospital for Crippled Children.—Res. H.S. £150.
Windsor, King Edward VII. Hospital.—Two H.S.'s. Each at rate of £100.
Wolverhampton, Royal Hospital.—H.S. At rate of £100.
York County Hospital.—H.S. Also Res. Anæsthetist and Asst. H.S. Each £150.
York, The Retreat.—Sen. Asst. M.O. £400–£500.

The Chief Inspector of Factories, Home Office, S.W., announces a vacancy for a Certifying Factory Surgeon at Grosmont (Yorks, N. Riding).

Births, Marriages, and Deaths

BIRTHS.

BARKER.—On May 20th, at Jesmond, the wife of Valentine Holland Barker, M.R.C.S., L.R.C.P., of a son.

PARKER.—On May 20th, at Sandgate, Kent, the wife of Dr. F. Gerald Parker, of a daughter.

WILSON.—On May 22nd, at Cedar House, Radlett, Herts, the wife of Dr. A. G. Wilson, of a daughter.

MARRIAGES.

RICHARDSON—LEA.—On May 20th, at Marylebone, Gilbert Richardson, M.A., M.D., of Manor House, N.W., to Hilda, daughter of the late C. A. Lea and of Mrs. Lea, of Elsworthy-terrace, South Hampstead, N.W.

DEATHS.

GOOD.—On May 21st, on board s.s. *Carina*, Arnold Saxty Good, M.R.C.S., L.R.C.P., of High Bickington, N. Devon.

HALLIBURTON.—On May 21st, at a nursing home in Exeter after an operation, William Dobinson Halliburton, M.D., F.R.S., Emeritus Professor of Physiology, King's College, London.

MORTON.—On Whit Sunday, suddenly, at Gillingwood, Ulundi-road, Blackheath, S.E., John Edmondson Morton, M.R.C.S., L.R.C.P.

TAYLOR.—On May 20th, 1931, at 21, Wembley Park-drive, Seymour Taylor, M.D., F.R.C.P., late of Seymour-street, W. 1, and St. Thomas's Hospital, in his 80th year.

WATERHOUSE.—On May 23rd, at Wimpole-street, W Sir Herbert F. Waterhouse, M.D., F.R.C.S., aged 67.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages and Deaths.

EAST HAM MEMORIAL HOSPITAL.—In 1930 this hospital, which has now received full recognition as a training school for nurses, admitted 1481 patients, an increase of 079, and the 6140 new out-patients made 23,259 attendances. In-patients costs £3 12*s.* 7*d.* per week, a fall on the previous year of 8*s.* 9*d.*; out-patients cost about 5*s.* 4½*d.* each. The total deficit at the end of the year was £15,922.

NOTES, COMMENTS, AND ABSTRACTS

THE COAL-MINER.

TWO Chadwick public lectures on the Coal-miner, His Health and Occupational Diseases, were given in London by Prof. E. L. Collis on May 15th and 18th. Describing a visit to a mine, he said that the light given by safety lamps, which had to be used in most coal pits, was less than that given by the candles which, of old, miners placed in their caps, and so brought fairly close up to the coal upon which they worked with the pick. The illumination to-day was so dim that the eyes of miners became affected; they could not be held steady, but oscillated involuntarily. These eye movements occurred in many miners, of whom a few were troubled with distressing eye movements and incapacitated from work. Miners' nystagmus topped all other occupational diseases added together for which workmen's compensation was paid; it was estimated to cost the mining industry about £1,000,000 a year.

The number of claims for compensation among coal-miners was very high. Thus in 1929 23 per cent. of miners employed claimed compensation, as against 12 per cent. of dockers, 4 per cent. of railway men, and 3·8 per cent. of factory operatives. For diseases alone, out of a total of 10,518 cases, including all forms of industrial disease for which first payments were made during 1929, the miner claimed 8500; and out of 8143 cases continued from previous years, he was responsible for 7629. Yet, out of the total number of 7,450,112 persons employed under the terms of the Compensation Acts, the miner only claimed 930,780. After nystagmus the next most frequent disease was beat-knee, with 3406 new cases and 175 old; followed by beat-hand with 1708 new cases and 134 old. There were also claims for 458 new cases and 35 old of beat-elbow, and 316 new and 13 old cases of inflamed wrist. All these conditions were due to the way in which the miner used, or rather misused, his body while at work, and they were very different from miners' nystagmus, with its all-important psychological factor. In each, however, treatment had to aim not only at healing, but at completely restoring function. The most serious cause of accidents among miners was falls of roof, due largely to careless timbering while at work. Every colliery was called upon to provide facilities whereby such injured men could be removed to the nearest hospital. The mortality-rates experienced by coal-miners from various diseases, and from accidents, showed interesting differences on different coal-fields, and it had been observed that miners tended to be most dissatisfied with their working conditions on those coal-fields where the mortalities were highest.

In his second lecture Prof. Collis described the miners' welfare fund. This began, he said, in 1920 and depended upon a levy of 1*d.* on every ton of coal raised, which brought in about £1,000,000 a year. Since 1926 the fund had been augmented by a levy on royalties, in order that pit-head baths might be provided throughout the coal-fields. Baths of special construction were now springing up over the coal-fields, and were an advance on anything to be found abroad. They should go far to reduce the incidence of beat-knee, beat-hand, and beat-elbow, and boils in the hot mines, and should help to reduce muscular rheumatism, the great enemy of the miner.

Apart from pit-head baths four-fifths of the money from the fund was spent on the coal-field from which the levy came, and the remaining fifth was used by a central committee for purposes beneficial to the whole mining community, such as research into safety and health. A board of experts had been brought into existence, with an income of rather over £50,000 per annum, and this board carried out investigations for preventing explosions. They studied safety appliances and means for improving mechanical conditions below ground, as well as furthering research into conditions of health.

INFECTION FROM MESS UTENSILS.

MANY years ago[1] Col. C. Lynch and Lt.-Col. J. G Cumming, of the U.S. Army Medical Corps, co tended that infection from sputum-borne disea in the army was spread by dirty utensils rath than the barrack-room air, and urged the boiling mess-gear. Dr. Cumming returns to this meth in a further paper (*Military Surgeon*, reprinted i the *Jour. R.A.M.C.*, for February). To quote o of his evidences: of 21,411 civilians studied, 17,2 had their mess-gear washed at 91° C. by machine, an 20 per 1000 got influenza, while there were 103 ca per 1000 among the 4175 whose mess-gear was washe by hand at 44° C. Machine washing at 91° (195° F.) similarly reduced infection from diphtheri mumps, measles, and pneumonia.

A NEW TYPE OF LIGHT-SOURCE.

A BOOK entitled Artificial Sunlight[2] has an ope ing paragraph in the following style: "Nature beneficent—life giving—but also ruthlessly destr tive. Its eternal shower of blessings has not effac or even dimmed the edict that only the fit sh survive." When an author starts thus and contin in more or less the same strain for nearly 30 pag the reader is hardly prepared to find the caref compiled mass of data bearing upon the measurem reflection, scattering and absorption of infra-r visible and ultra-violet radiations which follows th rhetoric. The data, which are drawn from a numb of reliable sources, should be of the greatest value readers concerned in many forms of quantitati work. The final chapters are on Electric Arcs the Utilisation of Artificial Sunlight. The front piece of the book is an illustration of a new type light-source and consists of a mercury arc betw tungsten electrodes with a tungsten filament parallel with the arc. Though the arc is enclosed a bulb, it transmits ultra-violet radiation up to t wave-length 2800 Angstrom units and would appe to have claims upon the attention of radiotherapists.

ANIMAL WELFARE.

THE first volume of an annual review of wo in the cause of animals has just appeared.[3] Th University of London Animal Welfare Society, which sponsors the book, is composed of under graduate and graduate members of the Univers of London. The volume contains a series of sig articles and reviews. Mr. F. E. Hodgson surveys th history of the Parliamentary protection of anima Prof. J. G. Wright supplies a report of the Po Persons' Clinic at the Royal Veterinary College, a note on the use of narcotics and anæsthetic Various writers describe the state of animal protecti in foreign countries, including the practice in th slaughter-houses, the use of animals in sport, amuse ment, and industry, and the state of the law and publ opinion. A symposium on present-day problems includes discussion on the cruelties of the fur trade— with a list of firms where fur fabrics made of woo can be purchased—humane slaughter, the trag of diving-birds on oil-strewn beaches, and reform needed in the trapping of rabbits. The book will be of interest to all who care for animals.

Corrigendum.—Owing to a misunderstanding for which he was in no way responsible Dr. Gilbert E. Brooke was described as P.M.O., Sarawak, at the head of an article on Abolition of Bills of Health, in our issue of March 14th (p. 606). His appointment is that of chief health officer.

ADDRESSES AND ORIGINAL ARTICLES

THE NEUROLOGY OF OLD AGE.*

BY MACDONALD CRITCHLEY, M.D. BRIST.,
F.R.C.P. LOND.,
NIOR NEUROLOGIST TO KING'S COLLEGE HOSPITAL; ASSISTANT
PHYSICIAN TO THE NATIONAL HOSPITAL, QUEEN SQUARE.

LECTURE II.

Clinical Manifestations in Old Age.

In this lecture I propose to discuss the neurological mptoms and signs which are commonly encountered aged subjects. The problem at once arises whether istinction can be made between what is "normal" nd what is "pathological" in old age. At either treme the differentiation is obvious, and a contrast striking between a vigorous and active old man nd the bedridden and decrepit senile patient. The termediate stages are extremely difficult to evaluate, owever.

Létienne was bold enough to attempt a definition tween senescence or healthy old age and senility; states that in the former there are modifications the organism which must not be looked upon as sorders, while in the latter there are actual altera- ons or lesions. Therapy is impossible in the one, says, but possible in the other.

The inadequacy of this proposed definition is vious, and I believe that no useful purpose is served setting up artificial distinctions between the two ates. I propose to confine my attention to the inical manifestations in such aged individuals as e commonly seen in medical practice either in their omes or in the large special institutions.

There remains the problem of selection; which gns and symptoms shall be included in this discussion nd which omitted? Bearing in mind Hippocrates's ictum that "old persons have fewer diseases than he young, but chronic diseases never leave them" —I have decided to concentrate on the former group. propose, therefore, to omit (1) the ordinary nervous iseases of mankind which may happen to occur in ld people, and (2) the commoner cerebrovascular yndromes, such as hemiplegia, aphasia, and the like. There will remain for discussion (1) those minor lterations in neurological signs which are typical f old age, and (2) certain rare syndromes which elong more or less exclusively to the senium.

These two classes can most conveniently be escribed under various neurophysiological systems.

Sensation.

It is a common observation that in old age there may be a general diminution in the acuity of perception both as regards the special senses and also in respect of visceral and cutaneous sensation. 150 years ago Buffon wrote that in old age . . . "the head shakes, the hands tremble, the legs totter, the sensibility of all the nerves decreases, and every sense is blunted." Rolleston points out how often severe thoracic or abdominal disease exists in the aged without pain; an extensive pneumonia or peritonitis can be entirely unsuspected; gallstones and renal calculi may be passed without the ordinary colic. Dr. Earl has informed me that minor surgical operations and dental extractions can be carried out with but little pain and discomfort. The catastrophe of coronary thrombosis can take place with none of the agonising symptoms found in younger individuals.

On the other hand, subjective sensory complaints are relatively common among the aged. Thus stabbing, darting, or aching pains may be described particularly in the lower limbs. Neuralgias are common, and the intractable symptoms of tic douloureux and post-herpetic neuralgia are characteristic of old age. Dysæsthesiæ of various types are also frequent, again especially in the legs. Thus sensations of burning heat or "bursting feelings" are not rare, and at times numbness, tingling, formication, pins and needles, are described.[90] Geist referred to painful cramps in the legs provoked by movement under the term "myotalgia senilis."

Accurate objective study of the acuity of cutaneous sensibility is usually difficult, and may be impossible on account of the relative mental inaccessibility of the patient. Experience of a large series of cases, however, teaches that marked and widespread changes may occur.

The outstanding and perhaps the earliest alteration is seen in respect of vibratory sensibility. There is, with advancing years, a progressive impairment of this form of sensation, leading eventually to a total loss. This is demonstrable first at the extremities of the limbs. Thus vibratory sense may be impaired at the fingers and toes only; later it is lost at the wrists and ankles, though still present proximally.

Dr. Earl, at Tooting Bec Asylum, has found a loss of vibratory sense in 20 out of 49 consecutive patients in whom adequate coöperation was possible. In Philadelphia, Pearson [91] has examined the sensitivity of individuals of all ages to vibration, and has found that decade by decade there is a slight decrease in the sensibility over the lower extremities which becomes striking after 50 years. Many of his older patients had lost vibratory sense altogether.

It is highly probable that postural sensibility is also affected, though less frequently and to a less obvious degree. Unfortunately, the difficulties of obtaining an adequate coöperation are such as to preclude a statistical study.

Appreciation of tactile and painful stimuli is also impaired or even lost in a number of very aged individuals, though this defect is certainly less common than disorders of deep sensation. When present it is almost always found over a characteristic distribution —namely, over the hands and distal portions of the arms, and over the feet and distal portions of the legs. There is no sharp demarcation between normal and impaired sensibility, one area merging gradually into the other.

It is difficult to determine what degree of perception exists when stimuli are applied to the "normal" or proximal areas. Here again the inaccessibility raises insuperable obstacles. However, it would appear, from the common failure of emotional facial movements and gesture and the lack of protest when moderately strong stimuli are applied, that in many cases there is a relative rise in the threshold of pain sensibility, though not of cold.

This progressive impairment of common sensibility in old age is probably due to changes at all levels of the nervous system. It is likely that loss of postural and vibratory sensation can be attributed to degeneration in the long ascending tracts within the spinal cord. The common distribution of impaired touch and pain sensation suggests changes in the peripheral nerves, probably in the nature of senile or arterio-sclerotic polyneuritis (Oppenheim, Franceschi). It is possible, too, that atrophic and sclerosing alterations in the skin, subcutaneous tissue, and muscles may interfere with the sensitivity of the sensory nerve-endings. Finally, cerebral—and particularly cortical—changes may interfere with the complete and prompt recognition of proprio- and noci-ceptive impulses, resulting in a general elevation of the pain threshold, or even an indifference towards such stimuli.

---

* The Goulstonian Lectures delivered before the Royal College of Physicians of London on March 10th, 12th, and 17th respectively. Lecture I. appeared on May 23rd.

VISION AND THE VISUAL APPARATUS.

Progressive impairment of visual acuity is, of course, characteristic of advancing age, if we except for a moment those cases of myopia which improve as the years pass.

Warthin,[92] indeed, describes the three cardinal signs of senescence as sexual neurasthenia, chronic fatigue, and presbyopia. Quite apart from the results of disordered elasticity of the lens, other pathological changes may appear and further interfere with vision. Thus senile atrophy of the optic nerve (v. Stief),[93] senile choroiditis, opacities within the cornea and media, retinal arterio-sclerosis, and arterio-sclerotic retinitis may contribute to the general defect of function.

Another type of visual disorder occasionally seen in aged dements has been described by Pick [94] [95] as "senile apperception." Here we have a visuo-psychical defect belonging to the category of object-agnosia. It comprises an inability to recognise the nature of surrounding objects, although the patient can see and often describe them. The article is immediately recognised as soon as some other sense channel is stimulated. For example, one of Pick's patients was unable to recognise a burning candle until it was brought so near that the flame scorched her. A lemon or an onion was unrecognised until she smelled it. In Macdonald's case [96] the patient could not recognise a match; in the author's own words . . . "the patient could describe the shape and size, criticise the odour of the fumes, show disgust at the taste of the phosphorus, repeat the word "match," spell it, tell that it was made of wood, withdraw from the heat and sight of the blaze, and yet declare that it was an unfamiliar object, that he had never seen anything like it, and, moreover, could neither describe its uses nor name it." A milder form of senile apperception comprises a difficulty in recognising the whole of an object, especially when of large size. Thus a patient may recognise his own thumb but be unable to point to his little finger; shown a portrait, he may indicate the eyes but fail to point to the ears or mouth. This defect is best described as one of visual synthesis. The anatomical basis for such agnostic disorders lies in an atrophy, usually bilateral, of the occipital cortex. Many of the best examples are found in cases of senile dementia, but also in that presenile psychosis known as Pick's circumscribed cortical atrophy.

Numerous objective changes in the ocular mechanism occur in old age. We need mention only the more strictly ophthalmological features, such as epiphora, blepharospasm, arcus senilis.

Alterations in the pupillary reactions are important. With advancing years there is a progressive sluggishness in the response of the pupils, both to light and on accommodation, and ultimately a condition of pupillary immobility may develop. At an intermediate stage the response to one form of stimulus—namely, to light—may suffer before that on accommodation, so that the Argyll Robertson phenomenon may be demonstrable. According to Möbius,[97] the react sluggishly or not at all to acoustic and stimuli.

The pupils are usually small in the elderly, wide mydriasis scarcely ever occurs unless cat is present. Möbius found high-grade miosis in 23 cent. and small pupils in 71 per cent. of his of senile patients, and he associates this phenom with the enophthalmos and narrowed palpeb fissure common in old age.

The range of the ocular movements may interesting changes; it is common, for exam for the inward movements of the eyeballs on conv ence to become impaired and ultimately to be lo Still more often one sees an absence or impairm of the conjugate movement of upward deviation the eyeballs; lateral and downward moveme rarely suffer. Nystagmus does not occur, exc when focal lesions within the cerebellum happen be present.

HEARING, TASTE, AND SMELL.

Deafness due to intercurrent disease of the midd ear is, of course, not uncommon, but even in absence of gross aural disease some degree of impair auditory acuity is frequent. This latter is cha terised by a loss of hearing for whisper and for hi tones, together with shortened bone conducti Loss of audition for low tones appears lat Berberich [98] describes an "arcus lipoides" of drumhead analogous to the arcus senilis of the corn

The faculties of taste and smell are probably l acute, for most very aged individuals are indiffer to the quality of what they eat, provided the quant is adequate. A liking for pungent or piquant s stances is suggested by the frequent excessive use condiments. The senile dement is usually witho appreciation of flavour, and may eat filth and d without disgust. The appetite, however, does suffer in the vast majority of cases. Indeed one the characteristics of the centenarian is a voracio appetite which can be satisfied only by large an frequently repeated meals.

Apart from exceptional instances, there is characteristic diminution and loss of the sex libido.

Myotrophy.

The entire musculature tends with advancing ye to undergo involutional changes which are manifest as wasting. Probably the chief cause of this chan is to be demonstrated in the general process of sen atrophy which shows itself in the muscles as elsewher Undoubtedly, however, other factors operate, an changes in the grey matter of the spinal cord, an also in the peripheral nerves, are contributory cause Lastly, in individuals who have spent much time i athletic pursuits or have been engaged in hard manu labour, the factors of disuse and enforced inactivi participate.

A progressive and extreme wasting of the muscl advancing from one segment to another, and accom panied by fibrillation and at times by signs pyramidal disease, is a rare feature in senility Oppenheim has spoken of such cases as instances subacute and chronic anterior poliomyelitis. Tw examples of this kind in patients of 66 and 67 respec tively were described before this College by Miche Clarke in 1915.

But, in addition to the general marasmus, mo focal muscular atrophies are not infrequent in old and are probably associated with localised changes in the neurax [illegible] nus in some of the forms of senile p anied by fibrillation, may be visible in the paralysed mbs. Here there is an association with degeneration nd atrophy of the corresponding anterior horn cells.

A rarer type of focal atrophy is exemplified in asting of the shoulder girdle, which may be associated ith spasticity of pyramidal type in the lower xtremities. Here a local lesion of the middle cervical ord is predictable, and has actually been demonstrated y D'Antona [99] in one case.

Without doubt, however, the commonest site for a trictly localised atrophy is in the hands, an Aran-uchenne type of atrophy, either unilateral or bilateral, eing by no means rare. Dr. Earl has demonstrated ten times in a series of 59 consecutive male patients ver the age of 80 at Tooting Bec Mental Hospital. he atrophy shows itself particularly in the thenar minence, but the hypothenar group and the interossei re also implicated. There results a claw-deformity, o which the later development of contractures and rthritis will produce more grotesque attitudes. he motor power in the hands is impaired, especially pposition of the thumb. Electrical tests may reveal typical reaction of degeneration. Sensory changes o not occur as a rule.

An accurate history is in most cases unobtainable, ut the typical story is that of a slowly progressive ffection of the hands, often preceded or accompanied y vague pains. There is no apoplectic onset to the isability in most cases. After reaching a certain tensity, the march of the disease stops and remains nchanged for an indefinite period.

Several attempts have been made to explain this senile thenar atrophy." Marie and Foix [100] des-ribed this wasting in a number of old people, some f whom were syphilitics. Post-mortem examination as obtainable in three, and a strictly localised trophy was found in the anterior horns of the eighth ervical segments of the spinal cord with cicatricial eplacement or small cavity formation. The authors roposed the title "anterior tephromalacia" for this athological picture.

Lhermitte has studied this syndrome with great are, first in conjunction with Nicolas,[101] and later ith de Massary.[102] In his second paper, he deter-nined that the maximum spinal change lay in two laces—the dorso-lateral nucleus and the intermediary orso-lateral nuclei in the sixth and seventh cervical egments.

The explanation of the occurrence of such localised hange is problematical. An abiotrophy of those articular neurones has been suggested; some uthors have stressed the phylogenetic importance f the hand movements in man with their specialisa-ion in such acts as prehension, and have emphasised the frequency with which wasting of the small muscles occurs in nervous diseases. Lhermitte rightly dislikes speculation of this type, and suggests that an anatomical peculiarity of the arterial supply to that spinal area may account for its frequent affection.

Arthritic muscular atrophies are frequent in old age, and are seen most typically in the interossei.

REFLEXES.

From routine neurological examination of a large number of old people it becomes obvious that the state of the reflexes alters, and that the same interpretation of physical signs does not apply as in younger individuals. Thus, the tendon-jerks tend to become sluggish and are frequently lost. The ankle-jerk illustrates this point especially well; with advancing years this tendon reflex becomes more and more difficult to elicit and finally disappears. So frequently does this occur, in the absence of other neurological manifestations, that one is driven to the conclusion that absence of the ankle-jerks in old age is without pathological significance. The supinator, biceps- and triceps-jerks also become sluggish, and may disappear, but not until after the loss of the ankle-jerks. Sometimes the knee-jerk behaves in the same manner, but here again it does not disappear until long after the ankle-jerk has been unobtainable.

Möbius [103]—who alone seems to have written on this subject—found the knee-jerks sluggish or absent in one-half of his senile patients. Much more rarely the tendon reflexes may be exaggerated; this change is particularly uncommon in the case of the Achilles jerk.

This "normal" progressive sluggishness in the tendon responses is independent of local change in the fibro-muscular structures, but the jerks may also disappear from various mechanical causes. Severe and long-standing cases of paraplegia in flexion lead to widespread contractures which render the tendon responses unobtainable. Similarly, changes within and around the knee- and ankle-joints frequently prevent the elicitation of the appropriate tendon-jerk.

The superficial reflexes also change in old age. Progressive difficulty in obtaining an abdominal response is, of course, well known, and indeed this change occurs at a relatively early date. The plantar response, however, usually persists as a characteristic flexor movement throughout adult life. At times, however, extension of the great toe occurs in old age in the absence of obvious disease of the pyramidal pathway.

The well-known laxity of the urinary and rectal sphincters in old age probably depends upon weakness of the musculature concerned and not in a disorder of the nervous controlling mechanism.

Extrapyramidal Manifestations.

Among the commonest of the neurological manifestations of old age are those usually labelled extrapyramidal motor disorders. Within that term are included the so-called amyostatic phenomena which, when occurring in complete form, constitute a variety of parkinsonism without tremor.

So common indeed are these minor extrapyramidal signs that we are often inclined to overlook them in the so-called normal senium. But most of those numerous little signs and manifestations, the characteristic gestures, attitude, stance, and gait of the elderly which so obviously distinguish them from the youthful, are really manifestations of an extrapyramidal order. So the actor, in assuming the rôle of an old man, actually imitates and adopts the various components of the parkinsonian symdrome.

The truth of this statement is revealed by closer analysis of the individual factors.

An attitude of general flexion is one of the characteristics of normal as well as of pathological old age. The head and neck are held craned forward, the upper limbs are bent at the elbows and wrists, while the hips and knees are flexed. In marked cases the degree of flexion may be extreme, and may recall examples of advanced paralysis agitans. When the patient lies in bed, one often sees the neck so flexed that the head is held in the air on a so-called "psychical pillow." A flexion attitude of the hands is very common, and in extreme cases—particularly when joint changes are present—the fingers may be ankylosed into a tightly clenched fist (main en poing fermée) with the terminal phalanges either hyper-extended or else pressed tightly into the palms (main de fakir).

Although we are no doubt on safe grounds in ascribing much of the flexion attitude to a defective function of the extrapyramidal motor system, we must not overlook other factors—mostly extraneural—which play a minor part. Thus senile atrophic changes in the vertebral column, and particularly in the intervertebral discs, will contribute to the bowed stance and the reduction in stature. Ankylosing affections of the ligaments and joints are often responsible for some of the fixity of the limbs in a position of partial flexion. Indeed, advanced cases of arthritis deformans and spondylose rhizomélique, resemble a parkinsonian syndrome so closely as to obscure the differential diagnosis.

Rigidity is another common symptom in old people, especially those showing gross cerebrovascular degeneration. In typical cases this "arterio-sclerotic rigidity" as Foerster[104] named it, consists in an uniform resistance to passive manipulations, more obvious in the extremities than in the trunk, in the proximal rather than the distal segments of the limbs, in the legs more than the arms (Critchley).[105] There is often a superadded hypertonus of a quasi-volitional nature due to the patient's failure to relax as soon as his limbs are under examination.

The clinical features of arterio-sclerotic rigidity are strikingly similar to those occurring in extrapyramidal disease, but one hastens to add that changes at all levels of the nervous system, as well as in some extraneural structures, add to the sum-total of rigidity. Thus mental change, small pyramidal lesions, sclerosis of the muscles, intra- and peri-articular adhesions, all contribute in impeding passive manipulations. The extrapyramidal factor is, however, the most important.

An additional feature is demonstrable in some senile and arteriopathic cases, particularly where psychical changes are present. Thus the patient may allow his limb to be retained in whatever attitude it is placed even in antigravity positions. This symptom, known as catatonia or catalepsy, usually denotes a combination of extrapyramidal motor disease with some degree of dementia.

A third characteristic motor sign of old age consists in a general poverty of movement. That is, the individual makes as few motions as possible, although he is not paralysed, and can execute any movement at command. The patient prefers not to exert himself, as if the effort were too great. This relative immobility is exemplified in the impassive facial expression; in the infrequent blinking of the eyelids; the statuesque attitude. When the elderly person wishes to look to the extreme left or right, the eyes move first, and the head, neck, and shoulders slowly follow all in one piece. The quick nervous gestures, movements of rhetoric, of expression, and emotional display are not seen, and in their stead is a certain poise or immobility. The elderly sit for long periods without changing their position, crossing their legs, fidgeting with their hands, or gazing around.

The so-called "associated" movements under which we include with Wilson, the secondary movements, synergias, movements of coöperation, and the like, are not in abeyance as some writers have insisted, but are reduced in amplitude and rate.

The final index of extrapyramidal disease is seen in the characteristic bradykinesis or slowness of movement; senile and parkinsonian patients alike move at a rate which strikes younger subjects as unduly slow. Automatic as well as volitional actions are affected, so that the passage of the fork to the mouth at meal-times, the movement of the jaws in chewing, are just as retarded as is the deliberate execution of a movement to command.

The foregoing components of [illegible] disease—namely, flexion attitude, rigidity, poverty of movement, and bradykinesis when present in some intensity—constitute a picture of parkinsonism. But it is probable that in some degree these manifestations are present in the majority of all senile patients, if we except those who show the more obvious signs of hyperkinesis or motor agitation.

Under two distinct circumstances these amyostatic signs become so marked in the elderly as to betray themselves immediately. In the first place, arterial changes may dominate the clinical picture so that the senile individual may present the characteristics of arterio-sclerotic parkinsonism. Secondly, we may be dealing with a condition described by Jakob[106] as "senile rigidity." Here symptoms of an obvious parkinsonian type follow the development of the characteristic psychical traits of senile dementia. The pathological basis of Jakob's disease comprises a widespread senile process affecting simultaneously the cortex and basal ganglia.

The relationship of true paralysis agitans with the ageing brain is a problem which stands a little aside, but will be considered later.

Hyperkinetic Manifestations.

In contrast with the usual economy of movement in senility, symptoms of a hyperkinetic nature occupy a less important position. Under diverse conditions, however, involuntary movements may occur, differing widely in nature and complexity. They range from simple repetitive movements of the order of tremor to bizarre pseudo-volitional activities in certain demented patients.

TREMOR.

Senile tremor constitutes the commonest instance of hyperkinesis, although by no means often encountered. Its occurrence in the elderly has been noted from the earliest times, by both laymen and physicians; it is, indeed, one of the traditional stamps of old age. Despite its universal recognition, however, little study has been made either of its clinical features or of its pathogenesis.

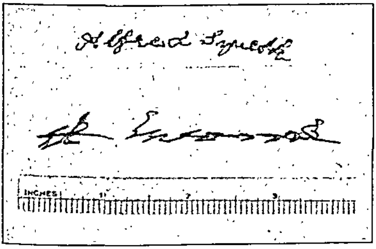
A regularly repeated alternate contraction of antagonistic muscle-groups, of small amplitude, constitutes the usual picture; there is some resemblance to the tremor of parkinsonism. Its usual rate is about 100 beats per minute. The common sites for its occurrence are the head and lower jaw, the hands, and forearms. During the waking-state the tremor may be constantly present, unless the affected segment is supported. Thus a senile tremor of the head ceases when rested against a pillow. At other times the tremor may cease spontaneously for a time, to reappear quite suddenly a moment later. The tremor is exaggerated by *fatigue* and by emotional stress; in some patients there is an apparent dependence upon the atmospheric conditions. Demange[107] refers to a patient whose tremor was inhibited by the taking of food; he was unable to commence a meal without assistance, but after taking a few mouthfuls the tremor improved so that he could finish his food alone. During sleep the tremor stops, but if the individual stirs in his sleep a tremulousness may be seen in the limbs.

The effect of volitional activity upon the tremor is variable; in the majority of cases the amplitude of the oscillations increases as soon as the limb is employed.

When the head is affected the tremor may comprise a vertical or nodding movement (*tremblement affirmatif*) or a horizontal one (*tremblement negatif*). With the involvement of the mandible there is an appearance s if the patient were constantly chewing. At times senile tremor occurs in the tongue or in the face. n the latter case there is a curious persistent grimacing, especially of the lips; one of Demange's patients was nicknamed on this account "old rabbit-face." Articulation is characteristically altered in such cases so as to produce a tremulous and punctuate type of speech.

A senile type of tremor is extremely rarely confined to the legs, and I have seen only one case in which the possibility of such a diagnosis could arise.

A man of 80 was admitted to the Hufeland Hospital, Berlin, under the care of Prof. Schuster, on account of tremor in the legs. This symptom had commenced gradually about five or six years before; it had shown itself first in the left leg, but later the opposite limb became affected, though never to the same extent. The tremor progressed slowly for a while, and then remained stationary for the last three years. Both legs are rigid, more especially the left, and the gait is spastic. When he sits down the left leg is held out in an attitude of full extension, with hyperextension of the great toe. The right knee- and ankle-jerks are barely obtainable; those of the left side are absent. Both plantar responses are of the flexor type. There is no gross abnormality in the arms or cranial nerves except for a rather lisping and imperfect articulation; no sensory changes are present. The tremor is confined to the legs, being more marked on the left side. It consists in coarse rotary movements of the whole limb, affecting mainly the thigh. The *movements* are greatly aggravated by both passive and active manipulations of the legs.



wo specimens of handwriting from patients with senile tremor. The tremulous and angular characters of the handwriting are well shown; note the absence of micrographia.

There is a striking lack of disability from the presence of senile tremor in the early stages, and even in long-standing cases the motor power is surprisingly intact. Fine manipulations of the fingers, however, soon become impaired, and the handwriting becomes grossly affected. The tremulous and irregular character of the writing resembles that seen in paralysis agitans, but differs strikingly in the absence of the characteristic micrographia.

Although senile tremor suggests at first sight the diagnosis of Parkinson's disease, the absence of rigidity, as well as gross slowness and poverty of movement, is a point of distinction. Moreover, the march of the tremor may differ in the two conditions; in paralysis agitans tremor appears in the hands before the head and jaw, whereas senile tremor may be seen first in the head and mandible, and remain localised for many years. The progression of symptoms is altogether quicker in paralysis agitans.

In a striking proportion of cases there is a family history of a similar tremor appearing in or before old age; this fact immediately suggests some association with the so-called "essential" or "hereditary" tremor which usually starts in middle age. Possibly senile tremor represents a delayed form of the idiopathic family tremor. The following cases are of interest, as suggesting that the frontier between the essential and the senile varieties is ill-defined:—

Male, aged 73, came under observation for "shaking of the hands," which had been present for about 30 years. Other members of his family were similarly afflicted; at first the tremor was but slight in degree, and it did not incommode the patient until he reached the age of 70. At this time a marked aggravation occurred, causing him to seek advice. *The appearance of the tremor differed* in no respect from that of senile tremor.

A female, aged 69, suffering from a senile tremor in the head, lips, and hands, was kindly demonstrated to me by Mlle. Gabrielle Lévy at the Hospice Paul Brousse, Paris. Symptoms had begun at the age of 50; the patient's father was also similarly afflicted since the age of 30.

A male, aged 75, had noticed shaking in the right hand for about one year. The tremor was of the typical senile variety, and there was no evidence of parkinsonism. One of the patient's brothers had had tremulous hands all his life, his present age being 71; another brother, now aged 65, had shown symptoms of paralysis agitans for 17 years. Two second cousins had also suffered from tremulous hands.

A male, aged 61, complained of tremor of the hands which had been present for five years. The characters of the movements were typical of the senile variety—despite the relatively early age of onset. An elder brother also suffered from a senile tremor, the symptoms in this case starting at the age of 70.

ATHETOSIS.

Another type of involuntary movement occasionally encountered in senility is exemplified by athetosis. Richter has directed attention to an acute form of athetosis occurring in subjects of advanced age. It is highly probable, however, that in his cases, as well as in the majority of instances, athetosis appears suddenly as the result of a gross vascular lesion; in this way athetosis appears mainly as an indication of cerebrovascular disease rather than of pure old age.

The following case exemplifies a bilateral athetosis occurring in a woman of 81—probably of arteriopathic nature:—

Female, aged 81, an inmate of an institution for some years, apparently altered physically and mentally with some suddenness five years before. She became forgetful, irritable, and restless, and was now incontinent. Both arms became "contracted" and useless. The upper limbs lie across the chest; both hands are clawed with the thumb strongly adducted across the palms. The fingers are strongly flexed, except the index fingers of both sides, which remain in a pointing position of full extension. She cannot extend her fingers voluntarily, but there is no contracture preventing passive movements. Once the fingers are straightened, slow involuntary athetoid movements appear, and gradually the hand reassumes its resting position. There is little or no defect in power in the other segments of arms, and the tendon-jerks are present. Both legs lie in an attitude of extension; there is a marked spasticity with increased reflexes and bilateral Babinski responses. Blood pressure 105; slight hardening and tortuosity of the radial arteries.

At times there occur movements of a slow "torsion" character, localised to the trunk musculature. Under the title of "the dystonic syndrome of senility," Sterling[108] has described two such cases: in the first, a woman of 69, involuntary movements gradually appeared in the abdomen and pelvis, recalling a "danse du ventre" or—as the author states—an attempt at scratching without using the hands. The term "tortipelvis" is not inapt in describing these movements. The second patient, a man of 69, developed suddenly a series of universal involuntary movements comprising tic-like contractions of the platysma; pseudo-expressive facial contortions; pseudo-spontaneous movements *of the right limbs*; choreo-athetosis of both legs, and spasmodic contractions of the tongue and left arm. In this latter case we are again probably dealing with a manifestation of vascular disease.

CHOREA.

Much attention has been directed to the occurrence of chorea as a manifestation of old age occurring independently of cerebral arteriopathy. The first case of this character was recorded in 1848 by Graves[100] of Dublin, who wrote: . . . "I think it right to mention that Dr. Ireland consulted me . . . respecting the late Mr. Dyas, a respectable apothecary residing in Castle-street, who, when 70 years old, was attacked by chorea in as complicated a form as I ever saw. The disease was very severe, and lasted many months."

It is usually described as the occurrence of generalised and symmetrical choreiform movements of gradual onset and progression in subjects of advanced age; mental changes are said to be absent, and the affection is regarded as independent of other types of chorea in the adult—particularly Huntington's disease and chronic progressive chorea.

Without doubt the term senile chorea has been applied too readily to cases with characteristic movements associated with old age. In order to make this diagnosis, one must be scrupulous to exclude: (1) cases associated with a family history of chorea or insanity; (2) cases in which the chorea has commenced in middle life and has persisted into advanced age; (3) cases of apoplectic onset—usually unilateral in their manifestations. When these criteria are rigidly applied, senile chorea is found to be a rarity.

The physical signs differ only slightly from those of Sydenham's chorea; the movements are perhaps of wider amplitude and more intractable, and tend to show themselves more frequently in the facial and abdominal musculature. In the early stages there is a hypotonus resembling that in Sydenham's disease, but in the more chronic forms a state of rigidity may gradually supervene. The "minor signs"—such as characteristic attitude of the forearms and hands—may be demonstrable at times, but I have never seen either a pendular or a sustained knee-jerk in the senile varieties.

RESTLESS MOVEMENTS.

The most complex types of hyperkinesis are those of the "psychomotor" variety. Within this category are grouped an array of diverse bizarre movements which are "spontaneous" rather than "involuntary" in character. Movements of patting or rubbing the hands together, of touching and stroking objects in the vicinity are not infrequent. There is a characteristic stereotypy in the repetitive nature of these movements. At times it is possible to determine that the movement commences as a deliberate volitional action, which is, however, perseverated long after the initial stimulus has passed (=palipraxia). The bedridden senile patient may at times be found lying with the hands outstretched as if groping or feeling for something. As soon as a person approaches the patient seizes hold of him, grasping his hands or clothing, or he may be seen clutching the bedclothes tightly, which he cannot easily be persuaded to release.

Such manifestations are rarely seen unless some degree of mental enfeeblement is present; they are physical concomitants of senile dementia rather than of pure senility. In that form of presenile psychosis, called presbyophrenia, motor agitation and restlessness are particularly evident.

In advanced cases the movements may become still more complicated. The patient may be seen parcelling up imaginary objects in bed or even transferring to the mouth any article placed in the hand (Stief[110]). A finger, or indeed any object of suitable size, placed near the lips or gums, may evoke movements of sucking and chewing. In their methods of feeding and their primitive response to various stimuli, these demented patients appear strikingly infantile. This reversion towards an infantile state is indeed seen not only in the act of feeding but in the forms of motor hyperkinesis, and in the character of their easily evoked laughter and tears. There is some resemblance also to the behaviour of the older mentally defective child or some of the restless schizophrenic types.

PATHOLOGY AND PHYSIOLOGY OF SENILE HYPERKINESIS.

We have no precise knowledge of the pathological anatomy and physiology of these various types of hyperkinesis. Senile tremor, athetosis, and chorea are all as inexplicable as the more complicated motor activities. The dearth of morbid anatomical data has not prevented, however, a wealth of speculation. There is a universal tendency towards the ascription of these involuntary movements to lesions of the basal ganglia and of the striatum in particular. Thus senile tremor is often compared with the tremor of paralysis agitans and linked with an outfall of small striatal cells. Senile chorea has been associated with a similar degeneration of the pallidal but more particularly striatal cells, together with changes in the dentatum (Jakob[111]); Wilson,[112] however, stresses the importance of changes in the post-central cortex in a personally observed case. The psychomotor types of spontaneous movement have been associated by Kleist[113] with lesions in the external pallidum and in the caudate, and he attributes their appearance to a disordered balance of function between the individual ganglia of the corpus striatum.

In this country we have always been hesitant to ascribe manifestations of an active nature to particular foci of disease, and especially to lesions in the basal ganglia. It is unlikely that striatal lesions should be responsible for such totally diverse phenomena as tremor at one end of the scale and movements of grasping and groping at the other. Theories of striatal dysfunction ignore the cortical changes which are always present at autopsy, and can frequently be suspected clinically. The demonstration of decaying or dead nerve-cells still leaves unexplained what mechanisms are actually producing the movements. Lastly, the pathological processes are too diffuse to allow one to pick out a solitary focus as the cause of a particular symptom.

There are many points of resemblance between senile tremor and the static tremor common in cerebellar disease. The nystagmoid movements of the head, neck, and limbs, their disappearance when the limb is completely supported, and their aggravation by effort recall the cerebellar titubation often seen in disseminated sclerosis. Schuster[114] has published a number of cases in which senile tremor was an early and prominent feature of a cerebellar syndrome, and where at autopsy cerebellar lesions were demonstrable.

When we compare the tracings of tremor in paralysis agitans, or of senile tremor with the curves of voluntary muscle contraction, we see—as first demonstrated by Schäfer—a striking similarity in the presence in both of fine wavy oscillations. This fact suggests that the tremor appearing in such pathological states as Parkinson's disease or senility is no more than the exaggeration of a normal manifestation of muscular contraction; this conception is in accord with the modern views on the pathogenesis of tremor as formulated by Kollarits,[115] De Jong,[116] and others. Walshe,[117] in a recent Oliver-Sharpey lecture, suggested that tremor is not a new phenomenon indicating a peculiar mode of innervation of pathological nature, but rather an emergence of a ormal cortical rhythm. The reason why this rhythm does not appear in health is problematical, and may depend upon the presence of a damping-down mechanism at a lower neuronic level; in tremor enilis and in parkinsonism this inhibitory mechanism s perhaps defective, permitting the unbridled activity of cortical impressions. The site of this ower-level control is unknown.

Cerebellar Syndromes.

It is striking how often cerebellar lesions are demonstrable at the post-mortem examination of very aged individuals, in the absence of corresponding clinical manifestations. Thus foci of softening or ocal or widespread atrophy may exist apparently without characteristic signs. Obviously, it is arguable that minor degrees of hypotonus and incoördination may have been overlooked, either through inadequate examination or on account of the patient's inaccessibility. Or the cerebellar signs may have been overshadowed by more striking coexistent pyramidal or striatal manifestations. It is doubtful, however, whether these arguments can explain away all the clinico-anatomical discrepancies.

Cerebellar symptoms, therefore, are rather uncommon in old age, but at times they are demonstrable and may even exist in marked degree. Such signs include diminution in muscular tonus, although occasionally rigidity occurs in the senile cerebellar atrophies. Incoördination of the limbs and trunk causes characteristic disturbances in the gait. The patient's efforts at walking may be accompanied by an ataxia of such severe and bizarre nature as to raise the suspicion of an hysterical basis. Tremor of the limbs, and particularly of the head, is common, and is usually much enhanced by muscular effort as well as by emotional stimuli. Nystagmus may occur, but is exceptional. Speech defects of diverse type are encountered, many of which recall the slow, scanning, explosive dysarthrias of advanced disseminated sclerosis. Schuster has published a series of cases of senile cerebellar atrophy in which the speech was inspiratory in character and unusually loud, as if the patient were being throttled; this variety is named by Schuster "the sea-lion speech." Motor power may be impaired to some degree, being most obvious in the performance of finely coördinated manipulations, and in rapidly alternating movements.

These physical signs may be present in old age, either singly or combined with other neurological manifestations, under various conditions, which may be briefly enumerated.

CEREBELLAR VASCULAR DISEASE.

Bilateral infarctions in the cerebellum will give rise to the sudden appearance of cerebellar signs affecting first one side of the body and later the other. The presence of concomitant softenings in the brain-stem—depending upon the particular vessel occluded—will modify the picture and produce cranial nerve palsies, pyramidal signs, and sensory loss.

At other times a large number of foci of vascular disease are scattered throughout the cerebrum and cerebellum, and lead to bilateral hemiplegias with added cerebellar signs. Thus arise the various "cerebellar types of pseudobulbar palsy," so ably described by Raymond and Alquier,[118] Lhermitte, Cuel, and Kyriaco, and others.

SENILE CEREBELLAR ATROPHIES.

Diffuse atrophic processes may occur involving part or all of the cerebellum, and even some adjacent structures. Three nosological subgroups may be isolated — namely, olivo-ponto-cerebellar atrophy (Dejerine and Thomas[119]); olivo-rubro-cerebellar atrophy (Lhermitte and Lejonne[120]); and delayed cortical cerebellar atrophy (Rossi,[121] Marie, Foix, and Alajouanine[122]).

The first is characterised pathologically by a loss of intragranular fibres in the cerebellar cortex, together with atrophy of the ventral part of the pons and of the middle cerebellar peduncle. No fibres are to be seen in the hilus of the olive, the medial lemniscus, or the peduncle of the restiform body. The external arcuate fibres are missing. Winkler[123] associates these changes with an affection of the neo-cerebellum.

In the so-called olivo-rubro-cerebellar atrophy there is a global atrophy of the cerebellum and of the dentate nuclei; the superior cerebellar peduncle is affected as high as the red nucleus. The olives and the restiform bodies are atrophied, but the other bulbar nuclei are intact.

In the third variety—delayed cortical cerebellar atrophy—the process is confined to the antero-superior aspect of the vermis and the anterior part of the quadrilateral lobe. A portion of the olives may also be affected. Here the distribution of the atrophy corresponds approximately with Edinger's conception of the palæo-cerebellum.

All three types are associated with a slowly progressive interference with gait, equilibrium, and coördination, accompanied at times by speech defects. Our knowledge of the symptomatology of olivo-rubro-cerebellar atrophy is at present limited to one case, but the points of similarity and of contrast between types 1 and 3 may be set out in the following Table:—

—	*Olivo-ponto-*cerebellar atrophy.	Delayed cortical cerebellar atrophy.
Familial incidence	Occasionally.	No.
Age of onset ..	Up to 60.	40–75. Average = 60.
Course	Gradual.	Gradual.
Gait	Ataxic.	Wildly ataxic.
Titubation of head	Yes.	Occasionally.
Spontaneous tremor	Yes.	—
Incoördination ..	Legs = arms.	Legs more than arms.
Asynergia ..	Yes.	Yes.
Intention tremor	Yes.	Slight.
Speech	Slow; monotonous; scanning; dysarthric: "sea-lion speech."	Slow; monotonous; dysarthric. At times scanning.
Nystagmus	Usually none.	Slight or none.
Tonus	Diminished.	Usually diminished; occasionally increased.
Vestibular functions	Normal.	Normal.
Motor power ..	Slightly impaired.	Slightly impaired.
Reflexes	Ankle-jerks often absent.	Ankle-jerks often absent. Occasionally bilateral extensors.
Cranial nerves ..	—	Normal.
Sensation	Normal.	„
Sphincters	Impaired in later stages.	—
Psychical state ..	Deterioration in late stages.	Normal.

It is obvious that the clinical differences between these two groups are very slight, and it is debatable whether any clear-cut distinction actually exists between these two disorders.

HEREDO-FAMILIAL ATAXIES OF LATE ONSET.

Although we associate the symptoms of familial cerebellar disease with the first two decades, occasionally the signs commence in the elderly or even in the aged. The importance of these rare cases is great in their bearing upon the genesis of hereditary disease in general.

An instance of the delayed appearance of neurological symptoms—largely of cerebellar character—

is seen in the remarkable family recorded by Ferguson and myself,[124] where the average age of onset was between 35 and 45. In two out of three members of Holmes's family[125] with cerebellar atrophy the symptoms started in the fourth decade. Sanger Brown's[126] ataxia also commenced in maturity. In an interesting familial affection recorded by Schuster, extending through three generations, five members first showed marks of a progressive cerebellar lesion between the ages of 50 and 60. Perhaps the most striking example is in the family recorded by Neff,[127] where 14 members belonging to four generations were affected. In 11 of these, the age of onset was between 50 and 65; in two others the symptoms commenced at 68 and 72 respectively.

Senile Paraplegia.

One of the commonest neurological symptoms in old age consists in a progressive weakness of the lower extremities with the frequent development of contractures.[128] Cases differ markedly one from another both in the degree of paresis and in the distribution and character of the hypertonus; paraplegia in flexion is the common experience; less often paraplegia in extension is seen. The state of the reflexes is variable; sensory changes may or may not be present, and the state of the sphincteric control is inconstant.

The term "senile paraplegia" is purely descriptive, and offers no clue as to the morbid anatomy. Since there is often a vascular basis to the paraplegia, it happens that analogous cases may be seen before the onset of old age; hence "arterio-sclerotic paraplegia" would be an alternative title in some cases.

As in so many other senile syndromes, changes are usually demonstrable at all levels of the nervous system, so that exact correlation between clinical and pathological data becomes impossible. At times, however, the morbid change is more or less limited to one particular region; in this way certain relatively pure varieties of senile paraplegia may be isolated. Thus one may enumerate the chief types as cortical, subcortical, spinal, or muscular.

CORTICAL TYPE.

The cortical senile paraplegias are characterised by a clinical picture resembling the following: a symmetrical or asymmetrical weakness of the legs which may be of gradual or abrupt development. Or one leg may suddenly become weak, followed after an interval by a similar apoplectic weakness of the other limb. A paraplegia in extension develops first, but later a flexion attitude may supervene. Signs of pyramidal disease are recognisable in a characteristic spasticity with exaggerated tendon-jerks, clonus, and Babinski responses. Sensory changes are typically absent, and there are no sphincteric palsies. Concomitant symptoms may include mental change; psychomotor defects in the arms of an apractic or hyperkinetic origin; movements of grasping are particularly common.

A degeneration in the longest pyramidal fibres descending from the two leg centres as the apex of the motor cortex constitutes the characteristic anatomical basis. Such a process may arise as a pure neuronic decay, independent of circulatory disturbance. This type—so often quoted as the usual cause of senile paraplegia—is actually the rarest, and, indeed, I have been unable to trace unequivocal evidence as to its occurrence in pure form. The second and much commoner cause depends upon arterial disease. The leg area differs from the rest of the Rolandic cortex in being supplied by the anterior as opposed to the middle cerebral artery. Occlusion of the anterior cerebral artery will, therefore, produce a crural monoplegia; a bilateral thrombosis will cause a paraplegia. This latter usually results from two separate strokes but occasionally, because of a congenital or acquired vascular anomaly, one anterior cerebral artery will supply the leg areas of both hemispheres. Thrombosis will, therefore, cause a sudden paralysis of both lower extremities.[129]

SUBCORTICAL TYPE.

Multiple softenings scattered throughout the white matter, internal capsule, basal ganglia, and brain-stem often result in a type of paralysis which has been termed "intracortical" or, better, "subcortical" paraplegia.

In such cases there arises a slowly progressive paresis of the legs without sensory loss. A hypertonus of mixed type is usually present, and reflex changes may occur indicating involvement of the pyramidal tracts. The sphincters may be intact, but more commonly there is "psychical" type of incontinence. Pseudobulbar and parkinsonian signs, as well as mental change, are frequently associated. Indeed this particular type of paraplegia usually forms part of a broader arteriopathic syndrome which may belong to the cadre of progressive lacunar disintegration, arterio-sclerotic parkinsonism, or démence paraplégique.

Another type of subcortical paraplegia may develop in the senile. The patient, having sustained a hemiplegia, takes to his bed; gradually extensive contractures and deformities appear which further incapacitate him, and slowly the paralysed leg loses its attitude of extension and becomes more and more flexed. Still later the opposite non-paretic leg becomes similarly affected, so that a condition of paraplegia in flexion develops. Signs of pyramidal disease are demonstrable, of course, in the hemiplegic limb only.

It is evident that these subcortical types of senile paraplegia are essentially the effect of vascular disease rather than of any primary or "senile" neuronic decay.

SPINAL TYPE.

In the myelopathic varieties of senile paraplegia the maximum, if not the sole morbid change, is situated within the spinal cord. Such varieties are rarely diagnosed during life, although specifically described by Demange[130] in 1885 as "progressive tabetic contracture."

Here the signs include a symmetrical weakness of the legs, either of gradual or abrupt appearance. Spasticity is present, chiefly of pyramidal type, and a flexion attitude usually develops. Subjective and objective sensory disturbances are frequent; wasting of the muscles with fibrillation is not uncommon. Sphincter defects typical of spinal lesions will here be present.

Two chief pathological changes may cause a spinal type of senile paraplegia. First, there may be a slowly progressive combined sclerosis of the cord, the lateral and posterior columns showing the maximum change. This process, which differs only in degree from that described in our consideration of the senile cord, may possibly result from disease of the finer branches of the nutrient vessels, leading to a chronic ischæmia. This type of change will be associated clinically with the slowly progressive paraplegias accompanied by ataxia and dysæsthesiæ and objectively by defective postural sensibility.

The other type of myelopathy depends upon sudden occlusions of the larger spinal arteries; infarcations of the cord result which cause a sudden development of signs of a transverse lesion. Pathological and clinical differentiation from cases of myelitis may be difficult.

MUSCULAR TYPE.

The fourth type of senile paraplegia often accompanies changes in the brain, cord, and peripheral nerves, but may also occur in isolated form. It is actually independent of disease of the nervous system, and consists in hardening of the muscles of the lower extremities. A senile hyperplasia of the interstitial tissue of the muscles, under the terms "progressive myosclerosis" or "senile myopathy," was originally described by Lhermitte,[131] both alone and in collaboration with Lejonne.[132] Atrophy, pigmentation, and plasmoidal regression of the muscle-fibres are found, some of which are hypertrophied. The connective tissue between the bundles, and also between the individual fibres, is enormously proliferated. Accumulations of small round cells distend the lymph spaces.

The clinical correlates of this type of change comprise a gradual stiffness and weakness of the legs, accompanied by some wasting and vague pains.[133] Examination reveals an extreme flexion contracture; passive manipulation is scarcely possible, and its attempts evoke pain. Indeed the limbs may not be extensible, even under deep anæsthesia or after death, on account of powerful contractures around the joints. The muscle bellies and tendons stand out prominently, and on palpation the muscles are hard and wooden, and are distinctly tender. Sphincteric and sensory changes are absent; the plantar responses are flexor in type; the knee- and ankle-jerks are usually unobtainable. The myosclerosis affects almost exclusively the lower limbs, and here the extensor group of muscles is affected earlier and more severely than the flexors.

In addition to the foregoing examples of paraplegia, where the severity of the symptoms actually prevents walking or standing, there are numerous minor degrees of weakness of the legs leading to characteristic disorders of the gait. Between these latter and the senile paraplegias proper there is no frontier, the differences being merely those of degree.

DISORDERS OF GAIT.

The most characteristic type of gait in old age is seen in the *marche à petits pas.* In the early stages this is betrayed by a mere loss of elasticity, some shortening of the steps, and a slight widening of the base. Such a gait may almost be regarded as characteristic of healthy old age. Later, however, the defects become exaggerated; the patient assumes a slightly flexed attitude and advances slowly by very small steps. A subjective sense of propulsion is often present. This particular gait is encountered not only in numerous cases of old age but also in the pseudo-bulbar and lacunaire syndromes. By slow gradations it passes over into a more typical parkinsonian type, with shuffling steps and loss of the movements of arm swinging, and finally into the second or subcortical type of senile paraplegia.

Cerebellar lesions have already been mentioned as causing marked interference with walking. This type of disturbance is characterised by a reeling, titubant gait, punctuated by occasional falls. There is an accompanying sense of insecurity, and the patient endeavours to maintain his equilibrium by widening his base. In the autobiographical descriptions left by Dr. Holyoke, who died at the age of 101, we have an instructive account of this type of disability, together with some interesting comments as to its causation. Writing at the age of 98, he said:—

> ". . . in walking I was apt to lose my equilibrium and sometimes to stagger like one intoxicated, particularly if I looked up to see the town clock or how the wind blew, in doing which I have several times nearly fallen to the ground; this complaint gradually increased. . . . My idea of the disease is this—I presume that we are not able to walk steadily unless the cavity of the cranium be so full as to prevent the brain from being agitated when the head is in motion. I presume also that by disease or old age the brain may be so shrunk or shrivelled as to leave such a vacuity as to allow the brain to vacillate and so produce the staggering and unsteady walking so common to persons much advanced in age. . . . May not the tottering and proneness to fall incident to age be accounted for by supposing the brain to shrivel and contract . . . so as to leave a vacuity; and may not that vacuity be supposed to contain a fluid. . . . ? Now if this fluid does not occupy so much space as the brain did, the function of the brain may not be injured, although the instability may be much increased."

It is interesting to note that at the autopsy of this gentleman an atrophy of the cerebellum was the most striking abnormality.

Eighty years later von Malaisé,[134] apparently unaware of Dr. Holyoke's note, described a peculiar ataxic gait of cerebellar type, which he associated with a senile internal hydrocephalus.

In some cases the grossly incoördinate gait suggests an element of hysteria. This suspicion is perhaps strengthened when the integrity of the motor power of the legs as tested with the patient in bed is contrasted with the great difficulty in walking. Such types of gait constitute the astasia-abasias of the aged. One must be cautious, however, before lightly assuming such manifestations as functional; it is probable that in some cases at least the defect is of an apractic character and bears no relationship to hysteria. The same qualification applies to the so-called Petrén's[135] gait, where there is a difficulty in continuing the movements of walking; after a few steps the patient feels he can go no further, but with coaxing and by dint of concentration upon the movements of the legs the patient can start again. Von Malaisé rightly disagrees with Petrén, and points out that such a gait is certainly of organic nature, and probably associated with psychical disorder.

Lastly, it must be remembered that an abnormal gait in the aged is frequently the result of disease outside the nervous system. Thus, changes in the joints and periarticular tissues are common causes of difficulty in walking in old age, as exemplified by arthritis deformans, spondylose rhizomélique, and morbus coxæ senilis.

Trophic Alterations.

The important metabolic changes occurring in old age cannot be detailed here: neither will time permit a discussion of the interesting alterations in the skin and its appendages, the endocrine organs, or the various sympathetic and vegetative syndromes met with in the aged. One trophic change only will be discussed—namely, senile obesity—in that there is probably direct bearing with a cerebral lesion.

A progressive emaciation is, of course, one of the usual accompaniments of advanced age. As Rolleston has pointed out, the fat-cells of the subcutaneous tissues may become replaced by fluid—the so-called serous atrophy—or the cells may revert to the condition of connective tissue cells. Occasionally, however, a condition of marked adiposity is encountered in the very aged, which, because of its recent development and pathological degree, merits the title "senile obesity." One must carefully distinguish these cases from those where the adiposity is of long is seen in the remarkable family recorded by Ferguson and myself,[124] where the average age of onset was between 35 and 45. In two out of three members of Holmes's family[125] with cerebellar atrophy the symptoms started in the fourth decade. Sanger Brown's[126] ataxia also commenced in maturity. In an interesting familial affection recorded by Schuster, extending through three generations, five members first showed marks of a progressive cerebellar lesion between the ages of 50 and 60. Perhaps the most striking example is in the family recorded by Neff,[127] where 14 members belonging to four generations were affected. In 11 of these, the age of onset was between 50 and 65; in two others the symptoms commenced at 68 and 72 respectively.

Senile Paraplegia.

One of the commonest neurological symptoms in old age consists in a progressive weakness of the lower extremities with the frequent development of contractures.[128] Cases differ markedly one from another both in the degree of paresis and in the *distribution* and character of the hypertonus; paraplegia in flexion is the common experience; less often paraplegia in extension is seen. The state of the reflexes is variable; sensory changes may or may not be present, and the state of the sphincteric control is inconstant.

The term "senile paraplegia" is purely descriptive, and offers no clue as to the morbid anatomy. Since there is often a vascular basis to the paraplegia, it happens that analogous cases may be seen before the onset of old age; hence "arterio-sclerotic paraplegia" would be an alternative title in some cases.

As in so many other senile syndromes, changes are usually demonstrable at all levels of the nervous system, so that exact correlation between clinical and pathological data becomes impossible. At times, however, the morbid change is more or less limited to one particular region; in this way certain relatively pure varieties of senile paraplegia may be isolated. Thus one may enumerate the chief types as cortical, subcortical, spinal, or muscular.

CORTICAL TYPE.

The cortical senile paraplegias are characterised by a clinical picture resembling the following: a symmetrical or asymmetrical weakness of the legs which may be of gradual or abrupt development. Or one leg may suddenly become weak, followed after an interval by a similar apoplectic weakness of the other limb. A paraplegia in extension develops first, but later a flexion attitude may supervene. Signs of pyramidal disease are recognisable in a characteristic spasticity with exaggerated tendon-jerks, clonus, and Babinski responses. Sensory changes are typically absent, and there are no sphincteric palsies. Concomitant symptoms may include mental change; psychomotor defects in the arms of an apractic or hyperkinetic origin; movements of grasping are particularly common.

A degeneration in the longest pyramidal fibres descending from the two leg centres as the apex of the motor cortex constitutes the characteristic anatomical basis. Such a process may arise as a pure neuronic decay, independent of circulatory disturbance. This type—so often quoted as the usual cause of senile paraplegia—is actually the rarest, and, indeed, I have been unable to trace unequivocal evidence as to its occurrence in pure form. The second and much commoner cause depends upon arterial disease. The leg area differs from the rest of the Rolandic cortex in being supplied by the anterior as opposed to the middle cerebral artery. Occlusion of the anterior cerebral artery will, therefore, produce a crural monoplegia; a bilateral thrombosis will cause a paraplegia. This latter usually results from two separate strokes but occasionally, because of a congenital or acquired vascular anomaly, one anterior cerebral artery will supply the leg areas of both hemispheres. Thrombosis will, therefore, cause a sudden paralysis of both lower extremities.[129]

SUBCORTICAL TYPE.

Multiple softenings scattered throughout the white matter, internal capsule, basal ganglia, and brain-stem often result in a type of paralysis which has been termed "intracortical" or, better, "subcortical" paraplegia.

In such cases there arises a slowly progressive paresis of the legs without sensory loss. A hypertonus of mixed type is usually present, and reflex changes may occur indicating involvement of the pyramidal tracts. The sphincters may be intact, but more commonly there is "psychical" type of incontinence. Pseudobulbar and parkinsonian signs, as well as mental change, are frequently associated. Indeed this particular type of paraplegia usually forms part of a broader arteriopathic syndrome which may belong to the cadre of progressive lacunar disintegration, arterio-sclerotic parkinsonism, or démence paraplégique.

Another type of subcortical paraplegia may develop in the senile. The patient, having sustained a hemiplegia, takes to his bed; gradually extensive contractures and deformities appear which further incapacitate him, and slowly the paralysed leg loses its attitude of extension and becomes more and more flexed. Still later the opposite non-paretic leg becomes similarly affected, so that a condition of paraplegia in flexion develops. Signs of pyramidal disease are demonstrable, of course, in the hemiplegic limb only.

It is evident that these subcortical types of senile paraplegia are essentially the effect of vascular disease rather than of any primary or "senile" neuronic decay.

SPINAL TYPE.

In the myelopathic varieties of senile paraplegia the maximum, if not the sole morbid change, is situated within the spinal cord. Such varieties are ecifically rarely diagnosed during life, described by Demange[130] in tabetic contracture."

Here the signs include a sy the legs, either of gradual Spasticity is present, chiefly a flexion attitude usually de objective sensory disturbances of the muscles with fibrillatio Sphincter defects typical of spin be present.

Two chief pathological changes may type of senile paraplegia. First, the slowly progressive combined sclerosis of the lateral and posterior columns show maximum change. This process, which differs only in degree from that described in our consideration of the senile cord, may possibly result from disease of the finer branches of the nutrient vessels, leading to a chronic ischæmia. This type of change will be associated clinically with the slowly progressive paraplegias accompanied by ataxia and dysæsthesiæ, and objectively by defective postural sensibility.

The other type of myelopathy depends upon sudden occlusions of the larger spinal arteries; infarcations of the cord result which cause a sudden

THE PATHOLOGY AND ÆTIOLOGY OF BRAIN ABSCESS.*

BY WILLIAM EVANS, M.D., M.R.C.P.LOND.,
MEDICAL FIRST ASSISTANT, LONDON HOSPITAL.

THIS paper gives the results of personal observations, and of an analysis of the records of necropsies performed between 1908 and 1925 in the Bernhard Baron Institute of the London Hospital.

The term "brain abscess" may conveniently be employed to denote abscesses in the cerebrum, cerebellum, and brain stem. The process commences with inflammatory leucocytic infiltration and softening of the cerebral substance, and ends in the conversion of a portion of the brain into a cavity containing pus. The *acute* form of abscess was found to have no distinct wall; when the pus was evacuated the abscess cavity was lined by a shaggy and ragged detritus, whilst the adjacent brain tissue was markedly œdematous, and generally presented multiple, minute and scattered hæmorrhages. The *chronic* and clinically more latent type of brain abscess was surrounded by a definite wall. Internally the wall was composed of purulent tissue, the so-called "pyogenic membrane." External to this was a layer of granulation tissue composed of various proportions of fibrous macroglia and of fibrous tissue derived from the vascular adventitia and, in some instances, from the leptomeninges. The granulation tissue was infiltrated with plasma cells, lymphocytes, and a few eosinophil leucocytes; the infiltration was continued *in the* adventitia of the vessels for a considerable distance into the surrounding brain.

Abscess content.—In the *acute* abscess this appeared as a pale yellow creamy fluid, or was red from hæmorrhage. The content of the *chronic* abscess presented a more characteristic appearance. It usually consisted of fœtid, greenish-yellow or bright green, viscid pus. In both cases microscopic examination revealed pus cells, and the causative organism or organisms.

Bacteriology.—Any of the pyogenic organisms may be present as the exciting cause. When the abscess had resulted as a complication of middle-ear and mastoid infections, the organisms present were generally multiple; staphylococci, streptococci, pneumococci, and various Gram-positive and negative bacilli were commonly found together; in some cases, however, this type of abscess showed pneumococci alone. In the abscess complicating intrathoracic suppuration, the streptococcus was frequently grown in pure culture. Similarly, the staphylococcus was usually the only organism isolated from the multiple brain abscesses that formed in a general systemic pyæmia resulting from osteomyelitis. A mould was found in one case of abscess secondary to bronchiectasis. In a number of cases the abscess content was sterile, no bacteria being discovered on examination of a stained film or by culture in different and suitable media.

Size of abscess.—In the series of 194 cases investigated, careful measurements of the abscess were noted in 168 instances. In 7 it was larger than an orange. In 5 it was linear and consequently unsuitable for comparative measurements. In 14 the size had not been noted or had been described in vague terms of "large," "small," &c. For easy comparison it is convenient to group and classify them in relation to common objects whose sizes are familiar and easily appreciated, and to which each abscess conformed in size but not necessarily in shape. Such a scheme is presented in Table I.

TABLE I.—*Classification of Abscesses according to their Dimensions.*

Numerals denote number of cases.

Size of abscess in terms of objects of familiar magnitude.	Nature of spread of the infection to the brain.		
	Direct extension.	Hæmatogenous.	Uncertain.
Larger than orange ..	6	—	1
Tangerine orange ..	25	—	6
Billiard ball	23	3	4
Golf ball	20	10	3
Walnut	20	5	1
Cherry	18	5	—
Pea	5	9	—
Pinhead	1	10	—
Allotriomorphic ..	5	—	—
Size not accurately noted	8	4	2

The data in this Table indicate that the size of a brain abscess may vary from that of a pinhead to an orange or bigger, and that the larger variety occurs with a much greater frequency than the smaller. They also illustrate that whereas the abscess that is formed as the result of a direct local spread of the primary infection tends to be of a larger size, the abscess that follows the transmission to the brain by the blood stream of infected material from a distant focus of suppuration is more commonly small. In regard to the latter group, when the brain abscess was a part of a systemic pyæmia, it had usually formed as a terminal event and was generally less or no larger than a pea. Where, however, intrathoracic suppuration in the form of bronchiectasis or empyema had given rise to the abscess, it was frequently of a large size.

The size of the abscess also bore an important relationship to its site. The size tended to vary inversely with the rapidity of onset of serious symptoms and death. Thus, an abscess having its seat in the so-called "silent areas" of the brain sometimes reached very extensive dimensions before it gave rise to symptoms sufficiently distressing to compel the patient to seek medical advice and treatment; whereas an abscess formed in the internal capsule or its immediate neighbourhood soon gave rise to a mono- or hemiplegia. This intimate relationship between site and size was further very well illustrated in the case of a cerebellar abscess. Here, invariably, the abscess was of small dimensions, for as soon as the process of suppuration had resulted in the destruction of a portion of cerebellum equal in size to that of a grape, it destroyed in its further extension important communicating fibres situated in the cerebellum, and injured the cranial nerves located in this region, and so introduced early and distressing symptoms. Further, like other subtentorial lesions it proved more potent in producing an increase in the "intracranial tension" with its concomitant ill-effects on the important centres situated in the medulla. Those entered as allotriomorphic in Table I. are abscesses which were of an irregular and elongated shape, and had been produced by the entry into the brain substance of a foreign body in the form of a spicule of bone, bullet, or portion of shrapnel.

Shape of abscess.—Most commonly the abscess was spheroidal, but in 27 per cent. of the cases in the series of necropsies investigated it was ovoid. When standing and does not really belong to the old age period.

---

* Based on a paper awarded the K. E. D. Payne Prize at the London Hospital in 1927. The sequel will appear next week.

The deposition of fat in senile obesity is universal, but there is a striking involvement of the limbs, including the most distal segments. Here the fat tends to become aggregated into large masses, which are freely mobile over the deeper tissues, and over which the skin itself is movable. Such masses are especially common over the dorsum of the hands, around the ankle-joints, and in the region of the olecranon and patella.

Morel has pointed out that obesity of this type is a frequent accompaniment of a particular senile pathological change—namely, hyperostosis of the internal table of the frontal bone. In such cases other symptoms commonly appear, some of which suggest an interference with the vegetative centres in the diencephalon. The complete Morel's syndrome includes mental deterioration, headaches, and, at times, epilepsy; disorders of sleep; polyuria; polydipsia and polyphagia; asthenia.

Senile Epilepsy.

Very occasionally attacks of typical epileptiform character make their first appearance during the senile period. The attacks may be ushered in by an aura, and are indistinguishable in their clinical accompaniments from those of genuine epilepsy. There are no paralytic sequelæ. In the particular variety described by Dr. Barber,[136] the patient, while in the fit, may cry out and behave in an excited and disorderly manner.

The causation of senile epilepsy is probably diverse; there seems to be no close association with genuine epilepsy among other members of the patient's family. In perhaps the majority of cases arterio-sclerosis constitutes the responsible ætiological factor. Minute softenings, slight arterial or possibly venous hæmorrhages, or the sudden production of a lacune of cerebral disintegration may be the immediate agent. Senile epilepsy is, therefore, better described as "arterio-sclerotic epilepsy" in the majority of cases.

Some instances of fits commencing in middle or late life are associated with the development of one of the presenile dementias. Alzheimer's disease is not infrequently characterised by recurrent attacks of unconsciousness.

B.A. = Number of cases where brain abscess was found at necropsy; F. = females; M. = males.

Sex.—The present investigation showed that the incidence of brain abscess is in no way determined by the sex of the patient; the lesion was found in males and females in equal proportion in relation to total necropsies conducted. Table II. appears to indicate that brain abscess was a commoner finding in males than in females in the ratio of 3 to 2, but the total necropsies investigated were also found to bear a similar sex ratio. This is indicated by Table III.

MOTOR ACCI… FEES

(A) Spread by Direct Extension.

In 131, or 67·5 per cent., of the cases brain abscess had resulted from direct extension to the brain of infection which had originated at a site not far removed from the brain itself. Six possible sources of infection are alluded to in this group. Of these, the middle ear and antrum were the source in 109 cases, or 83·2 per cent., and the nasal cavity and its accessory sinuses the source in 12 cases, or 9·1 per cent. The six sources will now be discussed separately.

OTITIS MEDIA AND MASTOIDITIS.

Inflammation of the tympanic cavity, with or without similar involvement of its antrum, was the cause of 56 per cent. of all brain abscesses. Amongst 10,280 necropsies otitis media was noted in 718, and in 74 of these, or 10·3 per cent., brain abscess was a complication. Only four occurred in patients under 5 years of age, whilst the majority were found in adults of 20 to 35 years.

The abscess had most commonly formed in the cerebrum, and then almost invariably in the temporo-sphenoidal lobe, but it was also frequently localised in the cerebellum. In 62 cases the abscess was cerebral; in 40 the abscess had formed in the cerebellum; in 7 cases both cerebral and cerebellar abscesses were present. For every three cerebral abscesses there were, therefore, two cerebellar. In 56 of the 62 cases of cerebral abscess it was situated in the temporo-sphenoidal lobe, and in the remaining 6 in the occipital, parietal, or frontal lobes.

It remains to discuss the path traversed and the method of spread assumed by the infection. For this purpose it is convenient to arrange the cases in four groups.

(*a*) *Purulent thrombosis of the lateral sinus.*—The infection had spread by this route in 37 of the 109 cases in which brain abscess had resulted from otitis media or mastoiditis. In 28 of these the abscess was found in the cerebellum; in only 9 in the cerebrum. The intimate anatomical relationship between the lateral sinus and the cerebellum explains the frequency with which the lesion was located in the latter. The earliest evidence of extension of infection into the lateral sinus was shown by a small nodular projection of granulation tissue adherent to the sinus wall. In the next stage observed the sinus was filled with purulent thrombus. Further extension was demonstrated in some cases by thrombosis of the cerebellar veins draining into the sinus; in these cases an abscess had already formed.

(*b*) *Osteomyelitis of the tympanic wall.*—Measurements of the roof of the tympanic cavity in a series of consecutive subjects of different ages proved it to average 1·5 mm. in thickness in adults, and in 25 per cent. it was found to be almost transparent; in children under 10, however, it was a much more substantial structure, averaging 2 mm. in thickness; it was also of a tougher consistence and not so brittle as in adults of 25 years or older. The posterior wall of the tympanum averaged 3·5 mm. and that of the mastoid antrum 3 mm. in thickness. It is not surprising, therefore, that the infection from middle-ear disease reaches the brain most frequently by osteomyelitis, necrosis, and perforation of the roof of the tympanic cavity. Of the 109 cases in which the brain abscess had followed middle-ear infection, 28 fall into this group. In 23 instances the abscess was situated in the temporo-sphenoidal lobe; it had followed necrosis of the tegmen tympani in 20 cases, and the roof of the mastoid in three. The abscess was localised in the cerebellum in five cases, the infection having spread by osteomyelitis and necrosis of the posterior wall of the mastoid antrum. A study of examples of otitis media and mastoiditis showed the following results of necrosis of the bone:—

1. The opposing part of the dura became intimately adherent to the inflamed bone and ultimately became perforated resulting in a generalised or localised lepto-meningitis.
2. The lepto-meninges became adherent around the perforation and to the underlying portion of the cortex, and a brain abscess was subsequently formed.
3. Occasionally an extradural abscess formed. Here also the infection spread inwards and formed an intradural abscess, but without causing visible perforation of the dura. The cerebral abscess was then established by infection of the lepto-meninges as in the previous instance.

(*c*) *Spread via the internal auditory meatus.*—This form of spread of the infection from the tympanic cavity to the brain only occurred in one case. The resulting abscess had its seat in the cerebellum. The sequence of events appeared to have been as follows—the suppurative process had entered the aqueductus fallopii from the middle ear by *osteomyelitis of its* wall, and extending along this canal had conveyed the infection into the internal auditory meatus; subsequently it had given rise *to a localised lepto-meningitis*, and the formation of an abscess (2 by 1·5 cm.) in the antero-external angle of the right lobe of the cerebellum.

(*d*) *Spread along adventitial spaces of perforating blood-vessels.*—In 43 cases there was no evidence of spread by any of the above methods, (*a*), (*b*), and (*c*). In these cases there was a focal inflammation of the dura and subjacent lepto-meninges, which bound the meninges to the surface of the cerebrum or cerebellum. But the abscess beneath was separated from the meninges by a zone of macroscopically unaltered cortex and medulla. The probable method of spread in those cases was extension of inflammation from the subarachnoid space along the Virchow-Robin space of perforating vessels. Unfortunately, no microscopic examination was made.

SUPPURATION IN NASAL CAVITY AND ITS ACCESSORY SINUSES.

In 12 cases the brain abscess had resulted from the direct spread of infection from suppuration occurring within the nasal cavity and its accessory sinuses. In two other cases multiple brain abscesses had followed frontal sinusitis in the one case and a purulent rhinitis complicating resection of the nasal septum in the other. These cases, however, do not belong to this section, because the method of spread of infection differed: the brain abscesses were part of a general pyæmia, and the method of spread was embolic. Suppuration occurring within the nasal cavity and its accessory sinuses is, therefore, responsible for 7·2 per cent. of all brain abscesses. It may be of significance that seven of the 12 cases occurred in subjects under 17 years of age, that is, during a period when the frontal, sphenoidal, and ethmoidal air sinuses were in the course of development. Of the accessory nasal sinuses the frontal most frequently gave rise to cerebral abscess. The frontal provided the seat of infection in seven cases; the sphenoidal sinus in four. In only one case had the infection spread from the nasal cavity. The *primary* seat of the infection need not necessarily lie in the sinus which eventually provides the path of direct extension to the brain. In 75 per cent. of the cases suppuration was found to involve more than one sinus. A consideration of the intimate anatomical relationship which each of these sinuses bear to one another, and especially the close proximity of their openings into the main nasal cavity, amply explains why it is unlikely that suppuration occurring in any single sinus will remain confined to that sinus for any length of time. When the frequency of purulent rhinitis arising from nasal polyps, deflection of the septum, &c., is appreciated, it is surprising that brain abscess does not more frequently result from the tracking of infection either to the subarachnoid space along the nerves which pass through the cribriform plates or to the dura along the veins which open into the sphenoidal venous sinus, or from necrosis of the cribriform plates. The fact that good drainage is afforded to suppuration occurring at the root of the nose appears to account for the comparative rarity of intracranial complications in such conditions. It is now necessary to consider in greater detail the method of spread of suppuration from the frontal and sphenoidal sinuses and nasal cavity.

(*a*) *Osteomyelitis of the sinus wall.*—The walls of the accessory nasal sinuses are very thin. Measurements of the thickness of the posterior wall of the frontal sinus in a series of cases showed that it seldom had a uniform thickness throughout. The maximum thickness varied from a mere line up to 3 mm.; most commonly it averaged 1·5 mm. The orbital plate of the frontal was found to be thinner, and in the majority of the skulls examined proved to be a sheet-like structure. In seven of the 12 cases spread had occurred by osteomyelitis of the wall. Such spread occurred in five out of seven cases in which the frontal sinus was the source of infection, and in only one out of four cases in which the sphenoidal sinus was the source. In one other case which demonstrated this method of spread the focus of infection was in the nasal cavity. The osteomyelitis was generally extensive in character and diffuse in its distribution.

(*b*) *Spread along perineural spaces.*—This path of infection appeared to be the one traversed in three of the 12 cases. In two of these an abscess had resulted in the frontal lobe and the source of infection was situated in the frontal sinus, whilst in the third case the abscess had formed in the temporo-sphenoidal lobe, the infection having spread from the nasal cavity via the sphenoidal sinus. In all three cases the walls of the sinuses in direct relationship to the brain were found to be free from osteomyelitis, and meningitis was the first visible step in the path of infection.

TABLE IV.—*Conditions Associated with the Formation of Brain Abscess secondary to Suppuration occurring in the Nasal Cavity and its Accessory Sinuses.*

Age.	Lobe of brain in which abscess was situated	Diameter or size (cm.).	Sinus which formed initial seat of infection.	Sinus from which infection was finally transmitted to brain.	Other sinuses affected	Method of spread to brain.
16	Fr.	3·5	N. cav.	N. cav.	Eth.	Osteomy.
13	Fr.	1	Fr.	Fr.	Eth.	,,
44	Fr.	2 & 3·5	N. cav.	Fr.	Sph.; max.; eth.	,,
15	Fr.	1·5	N. cav.	Fr.	Max.; sph.	,,
9	Fr.	2·5, 3 & 4	Max.	Fr.	—	Perin.
16	Fr.	4·5	Fr.	Fr.	—	Osteomy.
68	Fr.	4 × 3 × 2	Max.	Fr.	—	Perin.
54	Fr.	2	Sph.	Sph.	Eth.	Osteomy.
14	Temp.-sph.	3·5	N. cav.	Sph.	Eth.; max.	Perin.
45	,,	2·5	Sph.	Sph.	—	Along veins.
14	Fr.	0·8 × 0·5	Fr.	Fr.	—	Osteomy.
31	Temp.-sph.	0·8	Sph.	Sph.	Eth.; fr.	Along veins.

Fr. = Frontal; Temp.-sph. = temporo-sphenoidal; N. cav. = nasal cavity; Max. = maxillary; Eth. = ethmoidal; Osteomy = osteomyelitis; Perin. = perineural.

(*c*) *Extension along veins opening into the cavernous sinus.*—In two of the 12 cases spread of the infection to the brain had occurred along veins which drained into the cavernous sinus. In both instances the [illegible]rimary seat of the infection was situated in the [illegible] sinus. There was no evidence of osteo- [illegible] the sinus wall. Purulent thrombosis [illegible] sinus was present and the resulting [illegible]h had its seat in the temporo- [illegible] in each case associated with [illegible]gitis.

[illegible] cases the position of the resulting [illegible] found to depend partly upon the sinus affected and partly upon the extent of leptomeningitis. Thus, when the cerebral abscess had formed as a complication of frontal sinusitis, purulent rhinitis or infection of the ethmoidal air-cells and the leptomeningitis was localised, the abscess was invariably in the inferior aspect of the frontal lobe. Similarly, when the infection had spread from the sphenoidal sinus the abscess was found to occupy the temporo-sphenoidal lobe. When, however, the meningitis had extended to involve a large area of the surface of the brain, it was found that the abscess occasionally occurred at a site far removed from the sinus whence the infection had spread.

The size and chronicity of the abscess varied. When the sinusitis had remained undetected or untreated and the meningitis had remained localised, the abscess had ultimately assumed fairly large dimensions (see Table IV.), and had produced no symptoms until it had emptied itself into the lateral ventricle and had given rise to the grave and catastrophic symptoms associated with pyocephalus.

FOLLOWING TRAUMA OF SKULL.

In eight cases, or 4·1 per cent., infection had been conveyed to the brain by the introduction of a foreign body. In these the abscess had resulted from puncture-fractures of the skull. Bullet and shrapnel wounds sustained during the late war caused the abscess in five cases. No example of brain abscess was found at necropsy in 318 cases in which death had followed bruising, hæmorrhage, or laceration of the brain without puncture of the skull. A study of fractures of the skull other than puncture-fractures showed that the fracture either had healed without deleterious effects and complications or had proved fatal from severe cerebral laceration or hæmorrhage soon after the infliction of the injury. In the eight examples of puncture-fractures of the skull the initial injury had not produced instantaneous death. In each case localised meningitis had resulted, and a chronic abscess had formed. In one case, that of a child aged 13 months, an abscess the size of a billiard ball had followed a perforating wound sustained by a fall. In another case, in a child aged 8 months, a punctured wound wrought by a knife had dislodged a spicule of the internal table of the skull which in turn caused perforation of the dura. The layer of brain cortex superficial to the abscess was found to be healthy on macroscopic examination, and thus appeared to illustrate spread of the infection by the adventitial or Virchow-Robin space of perforating vessels. Of the five cases contracted during the late war three had resulted from bullet and two from shrapnel wounds. In one case the bullet was found lodged in the abscess wall; in two the abscess had formed around spicules of bone displaced by the entry of a bullet which had left the skull; in the remaining two cases fragments of bone and pieces of metal were found in the edge of the abscess. The abscess which had formed in some of these cases lay at some little distance from the seat of the bullet or piece of shrapnel, and was localised to a portion of the track along which the foreign body had travelled. The abscesses in this group were not confined to any particular lobe or portion of the brain, and their shape and outline were usually very irregular (see allotriomorphic group in Table I.).

INVASION OF BRAIN BY MALIGNANT GROWTHS.

Two cases in the series investigated fall within this subdivision. In one case the contents of the left orbit had been removed, and a retro-orbital sarcoma had been incompletely removed six months previously in a boy aged 10 years. At necropsy the orbital plate of the frontal bone was found to have been eroded by the growth, purulent infiltration of the growth had extended to the frontal lobe of the brain, and a localised abscess had formed at this site. In the other case (male aged 37 years) a purulent squamous-celled carcinoma was found in the site of a sinus which had followed a complete mastoidectomy. The growth was purulent, had eroded the petrous and squamous portions of the temporal bone, and had involved the dura; purulent adhesion of the dura to the temporo-sphenoidal lobe had resulted in the formation beneath of a cerebral abscess.

Osteomyelitis of skull.—Acute osteomyelitis of the skull was found at necropsy in 51 cases, but in no single instance could an abscess of the brain be demonstrated. Osteomyelitis of the skull, therefore, appears to be a rare cause of brain abscess.

Syphilis of the skull.—Syphilis involving the skull was found in only three cases amongst 14,534 necropsies conducted over a period of 18 years, and in these three instances cerebral abscess had not resulted. If such a combination does exist, therefore, it must be excessively rare.

(To be continued.)

SURGICAL TREATMENT OF DUODENAL ULCER.

By CHARLES A. PANNETT, M.D. LOND., F.R.C.S. ENG.,

SURGEON TO ST. MARY'S HOSPITAL; PROFESSOR OF SURGERY IN THE UNIVERSITY OF LONDON.

THE number of papers dealing with this subject which appear every year renders it strikingly evident that no completely satisfactory method of treatment has yet been evolved. That no duodenal ulcer should ever be treated by surgical measures is a belief to which few clinicians of experience now subscribe. The other extreme view—that the establishment of a positive diagnosis is an indication for surgery—is equally untenable to the logical observer who sees, on the one hand, patients with indubitable duodenal ulcer lose their symptoms permanently under medical treatment, whilst on the other he knows of many who prove quite refractory to such measures. It cannot be emphasised too strongly that, in uncomplicated duodenal ulcer, surgery should be considered in connexion with this second class of case alone. For these stubborn recalcitrant cases there are three accepted surgical operations—gastro-jejunostomy, pyloro-duodenal resection, and pyloroplasty.

The object of this paper is to record the results of my own experience, which has led me to conclude that pyloro-duodenal resection is preferable to the older and well-established operation of gastro-jejunostomy. The figures which I bring forward are based on a small number of cases. Undoubtedly in this fact resides an element of weakness. The numbers are small partly because in a university surgical unit too great specialisation is unfruitful from an education point of view, and partly because the last few years have witnessed a revival by the physicians of the alkaline treatment of gastric and duodenal ulcer, a revival which significantly shows signs of waning. Where such a complicated question as the treatment of duodenal ulcer has to be assessed, the variants are admittedly very great in number. Any accuracy gained from massed statistics is likely to be lost because very dissimilar things are accounted equal, and different standards have been applied to the several component groups. The force of this argument will be seen later.

Speaking generally, continental surgeons have been dissatisfied with gastro-jejunostomy, whilst English and American surgeons have obtained such good results that they have not been impelled to explore the value of the more radical resection methods. Thus Sherren[1] had 92 per cent. well; Walton[2] had 88·4 per cent. better; Luff, in a mass statistical investigation,[3] found 91·5 per cent. to be cured. Balfour,[4] at the Mayo Clinic in 1927, reported that of 100 doctors who had had gastro-jejunostomy performed for duodenal ulcer longer than five years, 87 per cent. were cured. In 1930 Balfour reported the results in duodenal ulcer for gastro-jejunostomy in 500 patients who had been subjected to surgery more than five years previously. He says "in 69 per cent. the relief had been either so complete that the patient had paid no attention to diet or to habits of living, or dyspepsia was so slight as to be readily controlled by simple measures." It is very striking that this is the exact percentage of cures which I reported in 1925.[5] Later on in the same paper the figure 87 per cent. again occurs as representing those who "obtained relief which they had been unable to obtain by any other means."

Comparison of Operations.

In comparing the results of gastro-jejunostomy with those of resection it is not only essential to define the term "cure" but also to utilise only series of cases treated by the same operator. In the small collection of cases reported here I have applied the word "cure" to those patients who are completely free from symptoms, do not take any precautions about diet, live normal lives, and in fact are not conscious of the process of digestion. Since I began my first assays into resection for duodenal ulcer, 122 cases have passed through my hands and been operated upon by myself. Of these, gastro-jejunostomy has been performed in 35 cases (28·7 per cent.), a Finney pyloroplasty in 2, and pyloro-duodenal resection in 85 (69·6 per cent.). That is, resection has been carried out in about 70 per cent. of patients. Gastro-jejunostomy was performed either because resection seemed impracticable owing to widespread fibrosis around, or because the ulcer was a small soft one and the larger operation appeared unjustifiable.

Mortality of gastro-jejunostomy.—Three patients died (8·5 per cent.). One was from pulmonary embolism on the seventeenth day in a man of 60. One man of 36, who had previously had a perforation and subsequent severe hæmorrhage, died within 24 hours after an anterior gastro-jejunostomy from hæmatemesis. No clamps were used at the operation, but I believe the blood to have come from the suture line. The third patient, a woman of 58 with a large callous ulcer, died on the twelfth day after operation from broncho-pneumonia. Post-mortem examinations were made in all three.

Mortality of pyloro-duodenal resection.—Amongst the 85 operations, which include the very earliest when the technique was not well understood as is the standardised operation of gastro-jejunostomy, two patients died (2·3 per cent.). The ninth resection was a woman of 47. Anterior and posterior ulcers were present. A Billroth-I anastomosis was performed. She died on the tenth day with a very rapid pulse and great pallor. A hæmorrhage was suspected, but a post-mortem examination revealed nothing but fatty degeneration of the heart. The abdominal anastomosis had healed. No signs of peritonitis were present. The other patient, the eighteenth operation of resection, was a young man of only 21 who for six years had had severe symptoms. Again a Billroth-I operation was performed to remove two duodenal ulcers. On the sixteenth day he died. Post-mortem bilateral broncho-pneumonia was present. The anastomosis had nearly healed. The length of time the operation took probably contributed to the lung complication. These are the only two deaths there have been, and since then 67 consecutive patients have had resections performed upon them without mortality.

Whilst it might not be fair to take the figure 8·5 per cent. as representing the true mortality of gastro-jejunostomy in a larger series of cases, yet it must be admitted that in the hands of the same surgeon pyloro-duodenal resection has no greater and probably a lesser mortality than gastro-jejunostomy.

Later results.—Of those patients who have been operated upon for 3½–6½ years, only 51 could be studied, for some have proved impossible to trace. Of these there are only 13 gastro-jejunostomies, of whom eight are quite well (61·5 per cent.). It must be conceded that the total number is absurdly small from which to generalise. Yet it represents my clinical impression fairly faithfully. Perhaps the figure 69 per cent. that I published some years ago, agreeing as it does with Balfour's "completely well" percentage, reflects more accurately the true state of affairs. These eight patients are absolutely well and normal individuals. Of the other five, one has only slight symptoms, one is unrelieved in any way, whilst the other three show some improvement.

The cases of duodenal resection number 38. Of these, 81·5 per cent. are absolutely well. Of the failures, mention must be made of Case 19, to whom I have referred in previous publications, for during the separation of the intestine I cut across the common bile-duct, afterwards implanting the pancreas into the open end of the duodenum. For three years he was absolutely well without symptoms, but early last year he wrote that he had had attacks of severe pain in the right side of the abdomen with jaundice. Early this year he died in another hospital. Post mortem, a gall-stone was found impacted at the entrance of the common duct into the duodenum and there was a septic cholangitis. It is not absolutely certain but probably fair to attribute the formation of gall-stones to the injury of the common duct. Of the other failures, three of the early Billroth-I operations must be mentioned in which the duodenum containing the ulcers, the pylorus, and a very small piece of stomach were removed. Case 3 had recurrence of symptoms within a year; a posterior gastro-jejunostomy has given him relief since. Case 14, a man of 49, was quite well for three years but then intractable symptoms recurred. At operation two years later a hard mass at the back of the duodenum was felt—clearly an ulcer adherent to it; an anterior gastro-jejunostomy has given him relief for the last 18 months. Case 11, a male of 43, received only temporary benefit and, although X ray investigations were twice made, no abnormality was found until four years later, when it seemed clear that he had another duodenal ulcer. This was confirmed during the performance of an anterior gastro-jejunostomy. Two months after this he perforated a gastro-jejunal ulcer. Since that time, over two years ago, he has had another perforation which he has survived. He still complains.

Deductions.

This experience corroborates that of other surgeons that, like the analogous case of the gastric ulcer, local removal is insufficient. It is necessary to take away a certain portion of the stomach as well. But even this will not certainly protect every patient from recurrent ulcer, though such an ulcer is excessively rare. Jansen[6] found in the literature 21 cases of ulcer after a Billroth-I operation: 11 of them occurred in the suture line and 10 in the duodenum. An analysis showed that most of them were due to insufficient antral resection or injury to the pancreas. A few seemed to be ulcers overlooked.

Although more recurrent ulcers have been reported after the Billroth-II operation, I have not had one in my own series, probably because more of the antrum is taken away than in the small Billroth-I resection done in my earlier cases. However, a man of 45 came under my observation who two years before had had a posterior gastro-jejunostomy for a duodenal ulcer. No relief occurred, so the pylorus was resected eight months later. Four months after this an extensive Polya resection was performed for a gastro-jejunal ulcer. Less than a year later he came under my care. He was emaciated and evidently had a large gastro-colic fistula, with fæcal vomiting and diarrhœa. At operation I was quite unable to remedy this, as the marginal ulceration had been so extensive as to lay the stomach and colon into one cavity. He died six weeks later.

No operation will cure every patient with a duodenal ulcer. Of those sufferers whose complaint is unrelieved by medical treatment 69 per cent. will be cured by gastro-jejunostomy and 81 per cent. by gastro-duodenal resection. In the face of these results I feel constrained to continue to perform gastro-duodenal resections, particularly as my figures include all the early operations where the technique was not clearly worked out and the extent of the removal necessary was unknown.

DIVIDED DOSAGE IN RADIUM THERAPY.

BY ALBERT EIDINOW, M.B. LOND.,

AND

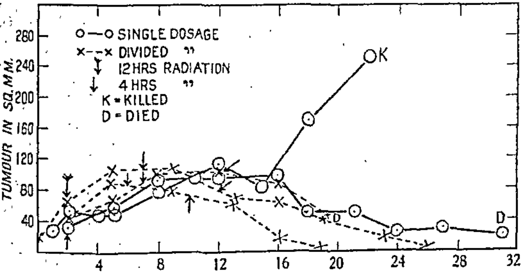
J. C. MOTTRAM, M.B. LOND.

(From the Radium Institute, London.)

THE dose of radiation required to produce an erythema of the skin cannot be expressed in milligramme-hours even when the screening, the distance, and the area of the applicator are kept constant, for the reason that fewer milligramme-hours will be required to produce an erythema when the intensity of the radiation is high than when it is low. When the intensity be reduced to a few milligrammes per square centimetre, exposures extending over several weeks will not produce an erythema. Similar results are obtained using a strong applicator by giving a number of small doses once a day or once a week. For instance, a square applicator of 60 mg. of radium spread over 4 sq. cm. and screened by 0·12 mm. of silver and 3 mm. of lead, and lead plaster (this applicator was used throughout these investigations) gives an erythema if laid on a rat's skin for 12 hours (720 mg. hours). When, however, exposures of five hours were given once a week, 13 such exposures were required to produce an erythema (3900 mg.-hours).

The Table, giving skin reactions, shows the difference *between single and divided dosage. It may be* inferred that the skin recovers from the injurious effects of the radiation between the intervals of the divided exposures, whereas during the continuous exposures there is no such opportunity for this power of recovery. The question arises, do tumours also show this power to withstand *divided dosage?*

FIG. 1.



In this and subsequent figures the number of days refers to the periods following appearance of tumours after inoculation.

SINGLE DOSES.					DIVIDED DOSES.				
Hours.	E.	M.S.	H.O.	H.G.	*3 appls. of 5 hrs. at 3 day intervals.*				
11 ..	N	N	N	N	1	N	N	21	29
12 ..	N	N	22	32	2	N	N	25	31
13 ..	15	N	21	32	3	N	N	24	27
14 ..	13	N	16	34	4	N	N	24	30
15 ..	10	N	20	27	*3 appls. of 4 hrs. at 3 day intervals.*				
15 ..	10	13	24	27	1	N	N	N	N
15 ..	?	14	20	30	2	N	N	N	N
					3	N	N	N	N

E. = erythema; M.S. = the occurrence of a moist surface; H.O. = hair out; H.G. = hair growing. The figures give the number of days after exposure (the first exposure in the case of the divided doses) on which erythema, hair out, &c., occurred. N indicates no skin reaction.

Regaud and Ferroux[1] have recently shown that whereas 4000–4500 R damages the skin over the testes of rats, and at the same time does not cause complete sterility, *5000 R* given in repeated small doses does not damage the skin, whilst complete sterility follows. Assuming that tumours will behave like the testes and present a low power of recovery, they recommend fractional dosage in radiotherapy in order to avoid damage to the skin and surrounding normal tissues.

The following experiments have been carried out to see how Jensen's rat sarcoma responds to divided dosage. Two tumours were taken of 60 sq. mm. One of these was given 15 hours Y-radiation to the radium applicator already described, the other three exposures of five hours at intervals of two days. Both tumours disappeared at approximately the same time.

Three tumours of about 20 sq. mm. were similarly dealt with. The tumour receiving the divided dosage disappeared more quickly than the two receiving the single 15-hour exposure. In Fig. 1 five tumours are dealt with. The times of radiation were 12 hours and three periods of four hours, the tumours were from 40–50 sq. mm. in area when first radiated.

FIG. 2.

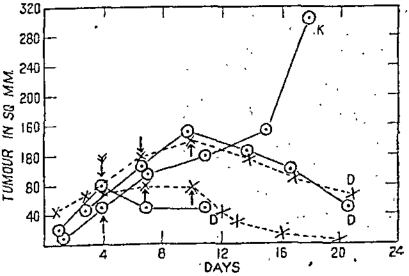


Fig. 1 shows that one of the tumours, given 12 hours, did not disappear, but after a period of retarded growth developed into a large *tumour; the other* 12-hour radiated tumour persisted for a longer period than any of the tumours which had the divided exposures. It follows that exposures of three periods of four hours at from four to five days' intervals were rather more efficient than single exposures of 12 hours in causing the tumours to regress. Fig. 2 deals with tumours which were first radiated when from 50–70 sq. mm. in area. Three were given 12 hours, and two divided dosage. *It is seen that one of the* tumours receiving 12 hours grew, otherwise there was no decided difference between the effects of a single dose and of divided dosage. Fig. 3 deals similarly with tumours from 80–92 sq. mm. in area. Here again the divided dosage is just as efficient

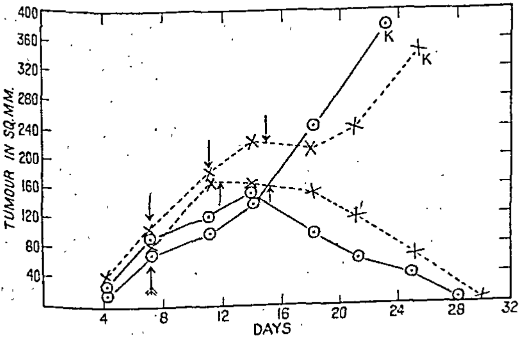
FIG. 3.



---

[1] Regaud, Cl., and Ferroux, R.: Zeit. f. Krebsforsch., 1930, xxxii., 10.

as the single dose in causing the disappearance of the tumours.

It is concluded, therefore, that Jensen's rat-sarcoma is just as sensitive to divided dosage as to a single dose within the limits of the above experiments; and that irradiating this tumour with a view to causing its disappearance, and at the same time avoiding injury to the overlying skin and normal tissues, can be accomplished more successfully by divided dosage than by a single exposure. It is clear that a much larger dose of radiation can be set free in a tumour without the production of an erythema of the skin by divided dosage than by a single exposure, and that this larger dose will have its full effect on the tumour, since its power to recover in the intervals between exposure is much less than in the case of the skin. These results strongly suggest that in the external application of radium or X rays in the treatment of tumours, divided dosage should be given a thorough trial. How much the dose should be divided and what should be the intervals of time will probably depend upon the growth rate of the tumour and on its kind, only by clinical research can this be discovered.

CLINICAL AND LABORATORY NOTES

A CASE ILLUSTRATING THE COEXISTENCE OF THE ARTHRITIC AND ALIMENTARY FORMS OF PURPURA.

By G. Eric Lewis, M.B. Camb., M.R.C.P. Lond.,
HOUSE PHYSICIAN AT THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET;
AND
G. H. Macnab, M.B. Edin.,
RESIDENT MEDICAL SUPERINTENDENT OF THE HOSPITAL.

It is well authenticated that both the forms of the anaphylactoid type of purpura may occur in the same patient. The following case, however, presents several points of clinical interest.

A girl, aged 11½ years, who had always been an exceptionally healthy child, was admitted to the Hospital for Sick Children under the care of Dr. Robert Hutchison on March 25th, 1931. She had, for six days, complained of frontal headache, of a sore-throat, and of pains in the arms and legs which had lately become more severe. On the day before admission she had vomited once.

Examination showed some swelling and pain on movement of the right elbow, of the left wrist, and of both knees. No cardiac abnormality was detected. A tentative diagnosis of acute rheumatism was made, but, on the next day, a few purpuric spots appeared on the right forearm and over both knees. The probability of the case being one of purpura arthritica was then recognised. This probability was strengthened by the facts that the platelet count was 129,600 per c.mm., that the coagulation time was 1 min. 25 secs., and that the bleeding time was 30 secs. After the first day in hospital there was no fever, and the pulse-rate remained around 120 per minute.

Vomiting was a prominent feature, two or three vomits taking place every 24 hours. On April 1st some gastric peristalsis was noticed through the very thin abdominal wall. Next day a fæculent vomit occurred. No further peristalsis was seen and a copious result was obtained after giving an enema. During the night there were two further vomits, fæcal in character, and the child became obviously more ill. Although a second enema gave a good result, the diagnosis of a high obstruction, probably due to an intussusception, was made, and laparotomy determined upon. There was no abdominal distension, but the condition of the child was critical. A blood transfusion was therefore given before the operation. A jejuno-jejunal intussusception about 4 inches in length was found. It was of apparently recent origin, and was successfully reduced. A great amount of free fluid, yellowish and slightly blood-stained, was found in the peritoneal cavity. It was proved, by subsequent culture, to be sterile. The appendix was normal, but in the intestinal wall, for its entire length, though especially numerous in the ileo-cæcal region, were many obvious sub-serous hæmorrhages, some frankly purpuric, and others circular. The whole presented a very striking picture.

After the operation progress was satisfactory, despite the appearance of some further purpuric spots on the wrists ten days later. These were transient, and convalescence has since been uninterrupted.

One of the most interesting features of the case lies in the differential diagnosis of the cause of the vomiting. This, it appears, was at first consequent upon the hæmorrhages into the wall of the gut. The later vomiting, which was fæcal, was determined by the intussusception. Another point of importance lies in the fact that, whilst it is generally taught that the diagnosis of intussusception should not be made without first attempting to exclude the presence of Henoch's purpura, yet in this patient intussusception and the abdominal type of purpura were found to coexist. Indeed, the intussusception was probably the result of a patch of bleeding into the intestinal wall.

Our thanks are due to Dr. Robert Hutchison for permission to publish this case.

SILICOSIS IN A GRAVE-DIGGER.

By Peter W. Edwards, M.B. Edin.,
MEDICAL SUPERINTENDENT OF THE CHESHIRE JOINT SANATORIUM, MARKET DRAYTON, SALOP.

The patient was a man, aged 32, who had worked as a grave-digger for the last 17 years. In 1924 he began occasional blood-spitting. There was cough and shortness of breath. In 1926 he had pleurisy, side unknown. In November, 1929, the symptoms were worse, night sweats, weight loss, and malaise supervened. In March, 1930, his doctor diagnosed bronchitis. The patient was dissatisfied, and in April, 1930, had a radiogram taken and was told he had lung fibrosis. Despite his symptoms he continued at work until October, 1930, when he was admitted to the Cheshire Joint Sanatorium gravely cachectic, with low blood pressure 75–112, and much emaciation. The symptoms were heavy cough, copious sputum, and marked dyspnœa. The sedimentation-rate was rapid. The sputum contained tubercle bacilli. The temperature was high. The chest expanded one inch. The right chest was dull, the breath sounds were weak, and there were some râles throughout and evidence of a cavity at the apex. The left lung had a moderate dull note, harsh breath sounds, and very few adventitia. The X ray screen showed that the diaphragms moved very slightly and that the diaphragmatic angles opened up poorly. The radiogram I considered to show advanced tuberculosis and pneumoconiosis. The patient died in 66 days.

Autopsy.—The pleuræ were thick and adherent at many points. The lungs felt gritty and had numerous cavities. The mediastinal glands were enlarged. Two sections of the lung were prepared by the freezing method and one by paraffin. One pathologist reported that the sections showed ordinary structure of chronic pulmonary tuberculosis, adding that the fibrotic nodules present had caseous centres and were therefore certainly old tubercles, and that "there is no evidence of fibrosis or of fibrotic nodules such as are found in silicosis. Thereafter, this pathologist said there was disagreement amongst other pathologists who had seen the slides. I therefore submitted the history, the radiograms, and the microscopical slides to Prof. Lyle Cummins, who has kindly reported as follows:—

> "The sections I have examined with much interest. To me they appear to be typical of silico-tuberculosis. Some of the lesions are fairly typical of what Irvine has called 'infective' silicosis, and others are those of a very fibrotic type of tuberculosis."

It is noteworthy that for 17 years the patient had worked as a grave-digger. Samples of the sand from the graves were found to be ordinary red sandstone. The man told me that the graves varied in depth from 7 to 13 feet, and that pneumatic drills were often employed and, though the patient knew nothing of silicosis, he considered his work very dusty, and in dry weather he and his colleagues were only able to dig for periods of 20 minutes. Pathologically and clinically the case appeared to me to be obviously one of tuberculosis and pneumoconiosis and, in view of the nature of the sandstone, probably silicosis.

MEDICAL SOCIETIES

ROYAL SOCIETY OF MEDICINE.

SECTION OF THERAPEUTICS AND PHARMACOLOGY.

A MEETING of this section was held at Cambridge on May 30th, with Dr. PHILIP HAMILL in the chair. A paper on the

Action of Avertin on the Liver

was read by Dr. E. B. PARSONS. This drug was, he said, an organic compound of bromine and such compounds were known to have a toxic action on the liver. He had attempted to study the effect of Avertin in rabbits by staining their livers for fat after varying doses of the drug. The interpretation of the findings had been difficult because of the accumulation of glycogen which tended to mask any pathological changes that might be present. He had, however, been able to demonstrate slight fatty degeneration after doses of 0·5 g. per kg. of body-weight. He did not claim that these experiments were in any way conclusive and he hoped to be able to repeat them in dogs where interpretation would be easier.

Sir FRANCIS SHIPWAY said he had now used avertin in 435 cases, including children and old people, without any bad results. In 12 of the patients the operation had been for removal of the gall-bladder, and in one case congenital cystic disease of the liver was present and there was comparatively little healthy liver tissue left. All had made a good recovery.

Sir WILLIAM WILLCOX said it was not yet known to what extent avertin was a liver poison, although it was known that bromine compounds were more toxic than the corresponding chlorine ones. It was very important to remember the part played by idiosyncrasy when drugs caused toxic damage to the liver. Atophan was a good example of this.

Cerebral Metabolism.

Dr. E. G. HOLMES read a paper on Cerebral Metabolism (by himself and Mr. C. A. Ashford). He pointed out that in order to understand the mode of action of drugs on the nervous system—*for example*, those causing anæsthesia and analgesia—a knowledge of the biochemical and physiological processes in the brain would be of great value. The present investigation arose from a desire to know whether during insulin convulsions there was any shortage of sugar in the brain. It was found that in an animal killed during insulin convulsions the glycogen and sugar content of the brain were not reduced but there was less lactic acid than normal present. It was found on further experiment that the lactic acid content of the brain was proportional to the glucose content of the blood when the animal was killed. The brain only had very small stores of glycogen and was mainly dependent on the glucose brought to it in the blood. The convulsions of hypoglycæmia were not relieved by lactic acid but were relieved by glucose, so it seemed that the conversion of glucose to lactic acid was one of the essential processes of brain activity. Dr. Holmes went on to discuss the differences between brain and muscle metabolism which his experiments showed were striking. In brain tissue, for example, there was no hexose phosphate stage in the formation of lactic acid and the rate of oxidation processes was much more rapid in all nervous tissues, being greatest in grey matter and least in nerve. He said that they had also carried out a few experiments on non-medullated nerve which seemed to show that here again metabolism was quite different, since plenty of glycogen was available. He thought that work on these lines was a necessary preliminary to an understanding of what was happening in the central nervous system, and was essential if the way in which it was affected by drugs was to be understood.

Digitalis in Toxæmia.

Dr. G. N. MYERS read a paper in which he said that the difference of opinion among clinicians about the value of digitalis in pneumonia had led him to test its action in toxæmia. The toxin used in these experiments was diphtheria toxin, and the experimental animals were guinea-pigs. A series were digitalised for varying periods and doses varying from one to three minimum lethal doses of diphtheria toxin were given. Nearly all the digitalised guinea-pigs survived and the controls died. Survival was found to depend on two factors—the dosage of digitalis and the amount of toxin injected. The toxin was next given first and the digitalis second, and it was found that the digitalised animals again survived provided that administration of digitalis was begun at once.

Strophanthus was found to have the same protective effect to a less marked degree. Ouabain, however, was found to have no protective effect at all. When the reaction of the white cells was examined it was found that there was much greater leucocytosis in the digitalised animals than in the controls. The differential count showed an absolute and relative increase in lymphocytes and the polymorphonuclears remained normal. The injection of nucleoprotein was found to affect the leucocytes in the same way but there was no protective effect. Examination of the cardiac muscle in the controls showed typical fatty degeneration, whereas the hearts of the survivors among the digitalised animals showed very little.

Dr. W. E. DIXON said that whatever the action of digitalis might be it was certainly different from that at present taught to students. It was probable that it had some physical effect on tissues which prevented toxin from acting.—Sir WILLIAM WILLCOX asked if digitalin had been tried in these experiments. —Dr. MYERS replied that it had not.

Sir HUMPHRY ROLLESTON recalled the observation that digitalis had a beneficial effect on alcoholic delirium.

Dr. HELLIER read a paper entitled

Sensitisation of the Uterus.

Pituitrin, he said, had been shown to have a more powerful action on the uterus than any other substance, but it was not yet clear how far it was responsible for the onset of normal labour. Dixon and Marshall had suggested that this was due to increased secretion of pituitrin at the end of pregnancy; other observers had suggested that œstrin was the sensitising agent. Using the guinea-pig uterus, Dr. Hellier showed that œstrin had no sensitising effect provided that a preparation free from protein was used; the results previously obtained might be due to protein rather than to œstrin. He then produced evidence to show that the factor of importance is the relative proportion of potassium to calcium salts in the fluids perfusing the uterus, and suggested that if potassium is increased relatively to calcium the uterus is sensitised to pituitrin. There was evidence, he said, to show that this was actually the case in pregnancy, and this might be the normal physiological process for the induction of labour.

Dr. DIXON said that œstrin was a hormone of comparatively simple chemical composition which had one known property, that of causing the return of the œstral cycle after spaying. Dr. Hellier's paper supported the view that œstrin has nothing to do with sensitising the uterus.

Histamine and the Circulation.

Dr. J. C. HOYLE read a paper in which he said that histamine could rapidly produce in experimental animals a condition resembling surgical shock. Very little work had, however, been done to show its effect on the pulmonary circulation and deductions from experiments carried out on one species of animal were of little value because the effect varied greatly in different species. His tracings showed that in the dog intravenous injection causes first a short preliminary stage in which the right auricular pressure rises, the pulmonary arterial pressure rises, and the vascular volume of the lung is increased; this is then followed by a longer stage in which these conditions are exactly reversed. Other tracings showed the variations produced in the dog, the cat, and the monkey. He suggested that the preliminary effect was due to the local action of the drug on the pulmonary vessels and heart; it was then carried round in the blood stream to the portal circulation where it produced a spasm of the vessels and therefore a damming-back of the blood which was the cause of the secondary effect on the pulmonary circulation.

THE INTER-STATE POST-GRADUATE ASSEMBLY OF NORTH AMERICA.

(Continued from p. 1194.)

AT the second session of this association, held on May 27th, Mr. LAWRENCE ABEL gave a cinematographic demonstration of the abdominoperineal operation for

Cancer of the Rectum.

It was important, he said, to know how to estimate the patient's chances of surviving the operation. Before coming to a decision a number of investigations should be made. The heart and lungs must be investigated in the usual way, and the cardiac energy index should be estimated, this being represented by the formula: $\text{C.I.} = \frac{\text{P.P.}}{\text{D.P.}} \times 100$. P.P., the pulse pressure, was obtained by subtracting the diastolic pressure from the systolic pressure. Any patient with a cardiac index between 25 and 75 was a good subject for operation, but over 75 the risk became serious. Any patient with a hæmoglobin percentage of less than 50, or a red cell count of less than four million, should have a blood transfusion before operation. The blood-urea should be estimated and the blood group ascertained. It was useful also to have an estimation of the blood chloride and blood cholesterol. The urine was studied by the usual tests, and by culture from a catheter specimen. In Mr. Abel's experience two-thirds of the patients who came up for advice were beyond all hope of help from surgery, but 33 per cent. were operable.

The abdominoperineal operation, he said, was the only thorough procedure, and it was fraught with less danger to the patient than any other. The abdominal portion was practically bloodless; the perineal portion demanded careful hæmostasis. The whole operation took about an hour. The complete abandonment of chloroform and the introduction of the McKesson gas and oxygen apparatus had done much to reduce mortality. After the operation it was very important to move the patient straight on to his bed in the theatre, to keep him warm by an electrically heated blanket, and to give him a blood transfusion at once. The mortality had fallen to 7·6 per cent. since the introduction of this transfusion. If a perineal excision could be performed, an abdominoperineal could certainly be performed; 77 per cent. of patients were alive and well five years afterwards. Colloid and melanotic growths had 100 per cent. mortality; operations for cauliflower growths were nearly 100 per cent. successful, while those for adenocarcinomata ranged between 60 and 70 per cent. The patients never had any trouble with the action of the colostomy opening; they had very rare accidents, if any, and needed no aperients. At the end of three months they went back to work, or any sport they liked—hunting or golf. Women had borne children after the operation. The prognosis seemed to be worse with young people.

Cancer of the Cervix.

Mr. VICTOR BONNEY gave a gynæcological talk. In answer to questions he began by describing his method of treating cancer of the cervix. The best radium workers, he said, had had 25 five-year cures among every 100 cases. The best surgical results were the same, but the surgeon's 25 cures really came from 65 cases, as that was the operability rate. The radium man treated 96 per cent. of the cases sent to him. The surgeon treated 40 more of his 100 cases with radium and got a certain number of cures in addition to his 25 operative successes. Even with Heyman's technique the results of radium at the Middlesex Hospital had been poor; admittedly it was only used for inoperable cases. Another objection to radium was that it could not be used without letting the patients know they had cancer; most of the surgeon's patients never knew. He did not use radium pre-operatively because it confused the issue. The mortality of Wertheim's operation had been immensely reduced—to 5 per cent. The operation was one that any surgeon could do, but it must be learned thoroughly. Radium could not remove the glands or the tissues on the side wall of the pelvis. The vaginal operation suffered from the same disadvantage. To compare radium and surgery was like comparing a trench-mortar with a high-velocity gun; their spheres of action were totally different. The method of election depended on the shape of the cancer area; the area of radium influence was limited, while that of surgery could be extended where necessary. Since the action-area of radium was essentially smaller than that of surgery, radium was best suited for early growths. The extent of a growth was relative to the size of the cervix; a growth would soon grow outside the limits of a small cervix.

FIBROIDS AND PROLAPSE.

He had a very poor opinion of the use of radium for fibroids. It induced an artificial menopause and atrophied the ovaries. The same thing could be done more safely with X rays. The operation was so simple and safe that it was hardly worth while to recommend even X rays. It was a retrograde step to destroy the ovaries for a bad uterus. The ideal treatment was myomectomy; it was never necessary to remove the uterus. He had removed as many as 125 fibroids from one uterus by the method of block incision.[1] The first step was to clamp both uterine arteries in the myomectomy clamp and both ovarians by ring-forceps on the ovariopelvic ligament. Then the uterus was split right down the centre from the fundus. With one finger in each cornu, a wedge was marked out on each half with the scalpel and taken right out, many of the fibroids going with it. The remaining fibroids were easy to shell out from the cut surface, and the two halves of the uterus were then united. The one drawback was the stitch line down the back of the uterus, which involved a mild risk of adhesion to the small intestine. Most myomectomies could be done entirely from the front. The whole essence of the operation was hæmostasis. Patients did very well in subsequent pregnancies. The uterus stood labour quite well, but the patient often preferred Cæsarean section to ensure the safety of the baby, as such a patient was naturally often near her menopause by the time her child was born.

Prolapse was a very variable thing with many lines of treatment, but, speaking generally, Mr. Bonney preferred Blair Bell's buttress method of anterior colporrhaphy. For the rare form—true hernia of Douglas's pouch—he had various methods: an ordinary colpoperineorrhaphy as for rectocele might be successful, but in some cases he had opened the abdomen. Vault prolapse could be remedied by amputation of the cervix and colporrhaphy, but ventrifixation was safer and surer unless the cervix had to come out anyway.

Retroversion of the vagina was very common, though never described in text-books. There was no redundance in the anterior wall, though far more than usual of the anterior wall of the vagina was seen through the orifice. Often the uterus was held up—retroposed, not retroverted—but often it went back too. The result was that the intestines lay in front of the uterus, on the bladder; the whole direction of pressure was changed. Instead of bringing pressure to bear on the rectum in defæcation, the intestines pushed back the uterus. Only ventrifixation would antevert the vagina. For elderly people with complete prolapse Lefort's operation was excellent.

MEDICO-LEGAL SOCIETY.

Sir WILLIAM WILLCOX presided at a meeting of this society held on May 28th, and Dr. NATHAN RAW read a paper on

Dangerous Drugs.

The League of Nations Council, he said, had coördinated national efforts to prevent the illicit manufacture and distribution of narcotic drugs, and the Dangerous Drugs Act, 1920, was the contribution of Great Britain to this work. The Regulations of 1928 scheduled medicinal opium; extracts and tinctures of Indian hemp, cocaine and ecgonine and their salts; morphine and its salts diacetyl-morphine (heroin), eucodal and dicodide; and any preparation or other substance containing one-fifth per cent. or more of morphia or one-tenth per cent. or more of cocaine or ecgonine; and some others. These drugs could all be obtained on the prescriptions of doctors but not otherwise, and careful records must be kept and be open to inspection.

The illicit drug traffic was enormously lucrative and the unlawful supply of dangerous drugs was very large. A great deal of opium was smuggled into Cairo from the Red Sea by nomad Arabs who made this activity their chief means of livelihood. The men at the head of the organisation were Greeks, who must have made colossal fortunes out of it. Once in Cairo, the opium, cleverly adulterated, was parcelled out among the pedlars who sold it in the coffee-houses, or transported it in bulk to one of the opium dens in the Mouski bazaar. Generally speaking, the opium traffic had been stamped out of Europe, with the possible exceptions of Berlin and Constantinople. The latter town contained three factories, two of which turned out opium and heroin at the rate of one ton per month. The normal wholesale price of opium and cocaine was, he said, about £25 per kilogramme. They were never sold in Western Europe to an addict at less than a shilling a "shot" of about 20 mg., and the drug was as a rule heavily adulterated in the first place; the profit, therefore, was usually far in excess of 1000 per cent. The "Byng broom" had swept away most of the West End night clubs which had been used by addicts and pedlars, but similar resorts were springing up in the outlying districts. The machine-gunners of the American criminal gangs were nearly all cocaine addicts. Cocaine- and heroin-taking owed their growth to the war. Wounded men had developed a craving for drugs; hospital staffs had taken to them in their world of horror, and a large synthetic production had developed to meet the demand. Germany, which had made much synthetic cocaine and heroin during the war, was a prolific source of supply, with Switzerland in second place. Much of the increase was due to curiosity and a sensuous craving for something new; to lack of hope, recklessness, neurasthenia, and the necessity to maintain the pace at work and to seek refuge from a jarring world. Moreover, young women found that "sniffing" gave them brightness and vividness.

---

[1] See THE LANCET, Jan. 24th, p. 171.

An international conference on the limitation of the manufacture of narcotic drugs was at present in session at Geneva, to agree if possible on amendments of the Geneva Convention of 1925 and to limit the derivatives of opium and coca leaves to strictly medical uses, as contemplated by Article 9 of The Hague Opium Convention of 1912. A pamphlet published by the secretariat of the League of Nations showed how failure to ratify or carry out the Geneva Convention had led to an alarming increase of the illicit drug traffic. The only effective weapon against this traffic would be combined international effort. Nevertheless, this country could be proud of the fact that its share in the traffic was comparatively small.

Sir William Collins related that Lord Brassey's Commission in 1895 had given the impression that opium, at any rate in India, was rather a good thing than a bad, and that the Indian opium trade with China was indispensable. John Morley—as he had then been—had overthrown that position and an attempt had been made to bring the Indo-Chinese opium trade to an end, but it had failed in 1917. While it had been in progress, England had been exporting large quantities of morphia to India and the Far East, but this traffic had decreased. The only way to control the spread of dangerous drugs was to draw a ring round Turkey, Persia, and China. The work of the present conference seemed to be largely invalidated by the omission of any attempt to control raw opium and raw coca. The American and the Chinese delegates had withdrawn from the conference in 1925 because no account was being taken of raw material. There was strong opposition in India to any legislation parallel to the Dangerous Drugs Act, although the British signatories to The Hague Convention had accepted responsibility for the Crown Colonies and the Dominions as well as for the Home Country. India's large export of opium to the Far East would not be forgotten at Geneva.

Aspirin and Thyroid.

Dr. Gerald Slot remarked that practising physicians also encountered the problem of addiction to hypnotics of the barbituric acid series, to thyroid preparations, and to the aspirin group. Drugs of the barbituric acid series did not bring about the same moral and physical degradation as opium and cocaine, but they were none the less very harmful. Thyroid was often taken by women who wished to get thin, and its addicts took it in enormous doses. One girl he had attended had developed argyria from the silver coating of the pills, besides the symptoms of tachycardia and swollen feet; she had been taking grs. 70 of thyroid a day. It was not uncommon to see women eat aspirin out of their handbags as though it was so much sugar. Again, although ergot-like preparations had been put on the Dangerous Drugs list, many ecbolics equally powerful or more so could be bought without restriction, such as pituitary extract and pennyroyal. The sale of drugs such as lysol and arsenic from automatic machines also constituted a great danger.

Mr. H. N. Linstead stated that chemists in some of the middle European countries produced drugs which, although not dangerous drugs, were chemically very close to them and could be easily changed into them. These basic products could be manufactured and sold without restriction. Only a Government monopoly would check this evil. Six months ago, he said, the Turkish Government had agreed to control the three factories in Stamboul which were manufacturing morphine and heroin. The amount of opium grown in India had been cut down steadily.

Dr. E. H. Griffin recalled that in the war he had purchased "paradise pills" from an Italian and had derived great benefit from them at a time when he had been sleepless. The dangerous drug menace was probably not so serious as the alcohol menace. Drug patients were invariably nice people, well turned out and well-behaved—a great contrast to alcoholics. The replacement of opium by alcohol in China had done the population great harm. We complained of a few grains of morphia from Turkey, but we dumped large quantities of whisky on the Americans.

Dr. Morgan Finucane said that, unlike most legislation, which was drafted as the result of careful inquiry, the Dangerous Drugs Act and its strict regulations had been based on hasty war legislation in America and hurriedly adopted here, chiefly because of a few notorious cases. Morphia and heroin were a great sheet anchor in chronic illness, but doctors became obsessed by the idea that they could not give them, especially to poor patients. It was quite wrong to restrict the liberty of the doctor as the Act restricted it.

Dr. Percy Spurgin pointed out that, whereas medical men now tended to restrict the giving of drugs of any kind, the sale of patent medicines had enormously increased, among them being drugs quite as dangerous as morphia and heroin if taken in the wrong way.

Mr. E. R. Bolton maintained that he had never found that the Dangerous Drugs Act had ever prevented anyone from obtaining the drugs he wanted for scientific or medical purposes.

Mr. A. A. Romain pointed out that medical men looked upon an addict as a diseased person, but the law knew no other remedy than prosecution and imprisonment.

Mr. F. D. Levy stated that in a recent case one of the girl witnesses had said that she had not known it was wrong to take these drugs. This ignorance was very widespread. He asked why the medical profession did not band together to inform the public of the law on dangerous drugs.

Sir Bernard Spilsbury suggested that, if imprisonment had the effect of curing an addiction, it might be worth while. The number of addicts in this country had greatly decreased since the Dangerous *Drugs Act.*

Mr. E. L. Turnbull said that the Home Office only did what Parliament told them to, and that to accuse them of being bureaucratic or maniacal about dangerous drugs was quite unjust. He suggested that much addiction was due to the actual repressive effect of the Act, and that if it were repealed the gain might exceed the loss.

Sir William Willcox said that this country might pride itself on taking the lead in what was an international problem.

Dr. Nathan Raw briefly replied.

MEDICAL WOMEN'S FEDERATION.

AT a meeting of the London Association of this Federation, held on May 19th, the President, Dr. LETITIA FAIRFIELD, being in the chair, Dr. MARY BARKAS spoke on the

Voluntary Mental Patient.

The main thing in the new Act about voluntary patients, she said, was that provision for their treatment was not compulsory on the local authority. Even a statutory duty was often neglected by local authorities, so that there was not likely to be any great hurry to take up a permissive activity. Unless somebody pushed the local authorities they would do nothing, and it was extremely important for all practitioners to look out for cases requiring such treatment and to see that the local authority made provision for them. Further, the Act now gave the local authority power to spend money on out-patient departments, preventive measures, research, and after-care. Again, it was the duty of practitioners to see that the money was spent.

A good deal of the hopelessness often felt about mental patients was due to the fact that they were not treated until the most favourable period for treatment had passed. Those who had worked in institutions where voluntary boarders had been taken for some time had a more optimistic outlook. If the surgeon never saw a cancer case until three years after hope of successful treatment was over, and moreover had to live with those patients until they died, he would not feel he was getting the best chance. The general practitioner should be as ashamed of letting a mental case go beyond the curable stage as of letting a case of cancer become inoperable. How far the proportion of voluntary patients increased in public hospitals depended largely on the general practitioner, who needed a great deal more insight into the personality of his mental patients. He was in a unique position for learning all about them and for catching them in an early stage. Far too many practitioners told their patients to pull themselves together when they needed to be put to bed. "Make an effort, Mrs. Dombey" was the tragedy of many mental patients.

All that voluntary patients had to do was to write to the medical superintendent and ask for admission; they could leave on giving three days' notice in writing, thus allowing time for communication with relatives and for making arrangements. The medical superintendent had to see that the patient understood these conditions; often a doctor would send up as "voluntary" a patient who was incapable of appreciating the situation. If the voluntary patient lost volition and remained without it for a month, he must be put on some other footing. In recent years the attitude of the Board of Control had altered very considerably; they now wanted a patient to be on a voluntary basis if possible—provided only that he could understand his position. It was surprising to what extent really insane people would come as voluntary patients.

SOME TYPES.

Nearly every type of mental illness could be found among voluntary patients—even acute mania and paranoia. Far more patients with delusions of persecution could be cured if they were taken in time; their delusions developed very slowly and they did not generally reach a mental hospital for 10 or 12 years after their first complaint. They came up for advice about headache or rheumatism or some other ailment apparently irrelevant to their mental state and the general practitioner should look out for them, by inquiring of patients whether they thought there was any adverse influence affecting their health. The melancholic—the patient who got depressed and felt he was no good—was very suitable as a voluntary patient. Far too often these patients were treated vaguely by the general practitioner and urged to make an effort—until at last they committed suicide—whereas the first thing taught them in a mental hospital was to go to bed at once and stop making an effort as soon as this black cloud of dullness, absence of feeling, and insomnia came down on them. The difficulty was to select those melancholics who were best treated as voluntary patients. Some of them found it very difficult to make any decision, and a decision to enter a mental hospital and stay there was beyond them. They constantly gave notice and withdrew it, and the ensuing worry prevented them from getting the needed rest. They were depressed, retarded, and full of guilt, and could usually be certified. When the decision was taken out of their hands they settled down and got better. It would have been an advantage, in Dr. Barkas's opinion, if the Act had provided that a voluntary patient, having once signed a request to enter a mental hospital, could be detained for a few months.

Another type of possible voluntary patient was the neurotic. Many of these would be seen in the new out-patient departments and in-patient provision for them was greatly needed. Whereas those in the psychotic group needed all the resources of the mental hospital, at any rate in reserve, the neurotics often needed no more than removal from home and an occasional talk, or a rest in the open air with massage, feeding up, and, above all, a little understanding affection. Many people resented the idea that these patients should come under the Board of Control, but the smaller homes might be very unsatisfactory if under no supervision. The neurotic was particularly liable to become the victim of the quack.

If general hospitals made suitable provision for voluntary mental patients neurotic patients would get the advantage of thorough physical investigation. The general hospitals were, however, short of beds, and their help would not go far. An out-patient department was essential for the neurotic and voluntary class of patient.

In reply to questions, Dr. Barkas said that the treatment of early paranoia in institutions depended on the employment of sufficient staff. Many early cases of schizophrenia and other mental illness were much better treated outside a mental hospital, and some other provision was needed for them. They needed both psychological and physical treatment—exercises and massage, for instance—and they tended, when once they got into hospital, to relapse into "just sitting." They might do well with out-patient treatment in their own homes. Some kind of social worker was absolutely essential; at least 50 per cent. of the treatment of the patient was treatment of the family.

DISCUSSION.

The CHAIRMAN pointed out that the clause relating to temporary patients had been so whittled down in its course through Parliament that it was very difficult to interpret. It was extremely rare for any patient, not hopelessly insane, to remain without volition for a month.

Dr. MILDRED CREAK emphasised the number of cases of mild melancholia treated devotedly by the practitioner, up to the day of their suicide, as neurasthenia. The practitioner's attempts at distraction were comparable to taking a patient with a broken thigh folk-dancing. She questioned whether the anxiety of the legislator to safeguard personal liberty was really in the interest of the patient.

The CHAIRMAN observed that mild and transient psychoses were far more common than was recognised. Lay people still tended to think of mental illness as a thing apart, and took any attempt to deal with it as an insult. Coroners were ready enough to attach blame to the medical profession for any slight error in physical treatment, but never mentioned the gross maltreatment of melancholia; they did not realise how easy it was to recognise early symptoms. One early manifestation sometimes encountered was extreme resistance to treatment of any kind: "I am unworthy of medical attention." The paranoiac above all other people could be moved by self-interest and could be induced to enter a mental hospital if persuaded that it was to his advantage to do so. The public mind must be disabused of the idea that the early and the voluntary patient were necessarily curable. The voluntary provision was going to be of the utmost benefit and comfort to the chronic relapsed patient. An out-patient department without in-patient beds was a useless thing. The out-patient department attached to the big general hospital and teaching school would, in her view, prove a delusion. Nor could the work depend on voluntary social service; it was astonishing that the Board of Control had not issued a warning against instituting any treatment without trained social workers.

REPLY.

Dr. BARKAS did not agree that an out-patient department without beds was useless. It might be valuable if it had attached to it some kind of occupational centre or hostel and a convalescent home. An apparently genuine neurotic might suddenly slip over into an acutely psychotic phase; it was therefore difficult to draw a hard-and-fast line between those who needed mental hospital treatment and those who could be safely treated outside. A good convalescent villa in a mental hospital was probably the best place to treat them. Every melancholic should be regarded as a potential suicide, and yet at the same time a certain amount of risk must be taken.

NEW INVENTIONS

A PNEUMOTHORAX APPARATUS.

This apparatus, which we have design[illegible] structed, is very simple to operate a[illegible]nt. to read, and can be used without [illegible] which [illegible]eumo- To do away with the operat[illegible] interferes with the apparat[illegible] thorax is being induced, [illegible] we have so designed i[illegible] that a switch is the [illegible] part which needs [illegible] handled. The [illegible] explain the ope[illegible] is a front v[illegible] a two [illegible] instrument [illegible] other [illegible] a wooden [illegible] the height [illegible] aperture the quantity [illegible] manometed into the [illegible] for cavity. The [illegible] itself shows [illegible] of marking—e.g., "Start Operation," "Intrapleural Pressure," "Air Introduction." The water-valve E is to control the flow of the fluid into the bottle and is in the centre of the switch. The other is a diagrammatic sketch of the apparatus. There are two bottles—1 and 2 kept at a constant level. All india-rubber tubes pass through the switch-ways A, B, and C, while E represents the water-valve described above. To perform the operation it is first necessary to see that the level of fluid (e.g., 1 in 80 carbolic acid) in bottle 2 is at hanero. The water-valve is then turned until a slow althougm of fluid leaves bottle 1 and enters bottle 2. the Dangtch is then turned to "start operation" and powerful or of fluid is automatically stopped. The restriction, such to the tube is then inserted into the royal. The sale o[illegible] [illegible]avity and the switch turned to "intrapleural [illegible]ure." The manometer reading having been [illegible]aken, the switch is then turned to "air introduction." The fluid will now flow into bottle 2, and air into the pleural cavity. During the operation it will be found necessary to observe the true intrapleural pressure. This can be done simply by switching back to "intrapleural pressure." At the end of the operation the switch is turned back to "start operation," and the water-valve closed (screw action). All that is now necessary is to change round the bottles and bring the level of fluid to zero, and the apparatus is ready for the next patient. The whole instrument is contained in a leather case from which it can easily be slipped out. Messrs. A. F. Browne, of York-road, London, S.E., are the makers of the apparatus.

REVIEWS AND NOTICES OF BOOKS

La collapsotherapie de la tuberculose pulmonaire.

By Michel Leon-Kindberg, Médecin des Hôpitaux de Paris. Paris: Masson et Cie. 1931. Pp. 181. Fr.22.

Étude sur le traitement de la tuberculose pulmonaire chronique basé sur de nouvelles recherches cliniques et expérimentales.

By Dr. C. M. Desvernine, des Facultés de New York, Paris et Madrid. Paris: Louis Arnette. Pp. 98.

Collapse therapy dominates the modern treatment of pulmonary tuberculosis. Sanatorium treatment is chiefly of value because a sanatorium provides the best possible conditions for carrying out collapse therapy, a staff trained in the special technique required for its successful employment, an X ray department operated by one who has made a special study of chest radiology, abundant fresh air—often lacking in a town hospital—and a duration of institutional treatment not possible in an ordinary hospital. But the sanatorium is not essential for the successful treatment of pulmonary tuberculosis whereas collapse therapy is essential in many cases. Dimly envisaged by Arnould in 1770, realised by the physiologist Carson in animal experiment in 1819, and first consistently practised by Forlanini (1888) the "patents of nobility" of artificial pneumothorax, to employ the expression of Rist, have a quite respectable antiquity.

It is only in recent years, however, and notably since the Great War, that collapse therapy has found universal acceptance and been successfully practised in the four continents. The principles upon which it depends, the methods employed in its use, the developments in chest surgery to which it has led, and the benefits to be expected from it should be realised by every medical practitioner. The seeker after knowledge in this department could not find a better guide than Dr. Leon-Kindberg, an enthusiast who never allows his enthusiasm to upset his judgment. And this admirable little book is evidence not only of his practical knowledge of his subject, but also of the breadth of the writer's mind. He is never afraid to explain "this is a little tip of my own, probably other workers get quite as good results without using it." After an introductory historical section the author devotes three chapters to artificial pneumothorax treatment. A chapter on oleothorax, concerning the future of which Dr. Leon-Kindberg does not seem to be very hopeful, precedes a short description of the surgical interventions which have been designed to supplement or replace pneumothorax treatment when the success of the induced pneumothorax has been in jeopardy through adhesions, or when an adherent pleura has prevented its employment. The practitioner who wishes to know what happens to his patient when he has been sent to a sanatorium or who wishes to be in a position to advise his tuberculous patient on the wisdom of accepting collapse therapy could not do better than read this book.

Dr. Desvernine's little book, which appears to be a continuation of a brochure published by the author under a similar heading in 1921, consists of two essays on the treatment of tuberculosis. The first deals with treatment by artificial pneumothorax and the second by specific immunity methods. In the first essay the writer suggests that the effect produced by collapse therapy is due to a variety of cellular and intercellular activities resulting in increased tolerance for tubercle antigen, and he sees in all this an interrelationship with the vegetative nervous system. The second essay consists in a short exposition of his own specific treatment by inoculation of infected guinea-pigs with autolysate of tuberculous sputum. The writer has made free and generous use of quotations from all and sundry, but the arrangement of his matter leaves something to be desired. There are several pages of bibliography.

Operative Obstetrics on the Manikin.

For Students and Practitioners. By Charles B. Reed, M.D., F.A.C.S., Associate Professor of Obstetrics, North-Western University Medical School, Chicago. Philadelphia: P. Blakiston's Son. With 254 illustrations. Pp. 134.

Since the more widespread adoption of antenatal supervision the practice of many teaching obstetric hospitals is becoming more and more restricted to normal cases and opportunities for the student to see the treatment of obstetric complications are consequently becoming fewer. Even when complications were more common the student rarely had a chance to treat them himself and we have always felt that such lack of opportunity might be made good to some extent by constant practice on the manikin. Such practice has many advantages. Procedures can be repeated as often as necessary to give the operator confidence and dexterity, and there is almost no limit to the operations that can be carried out and to the complications that can be invented. For this reason we welcome this work which the author claims to be the first on the subject in English.

The book is divided into two parts. Part I. is taken up with operations on the manikin. These are described in detail "commencing with the simplest and gradually advancing to the more difficult and dangerous." The various steps in each manœuvre are explained minutely in the text, and illustrated by numerous diagrams and pictures, so that the student with this book to guide him hardly requires supervision. Our first thought on receiving the book was one of surprise that no one had thought of producing such a work before. We feel that it should be in the hands of every teacher of obstetrics and available for every student. Its great merit is the precise and detailed directions for carrying out the various operations described so that at no point is the student left without guidance. Certain errors and omissions are noticeable. It is stated (p. 150) that for external cephalic version there is but one indication—viz., transverse presentation. "External version might be done to avoid a breech delivery but such a manouver is not called for." With this opinion we cannot agree, for in our view one of the most valuable procedures in midwifery is prophylactic external version in breech presentations. In the description of the delivery of the after-coming head in breech cases there is no mention of the value of the forceps on the head when moderate jaw and shoulder traction fail to deliver. Part II. (seven chapters) is not occupied with operations on the manikin but with other operations that could not be carried out on the manikin (such as Cæsarean section and the artificial interruption of pregnancy); and to accounts of such conditions as antepartum and postpartum hæmorrhage. Doubtless these are introduced in an attempt to make the book a complete text-book of operative midwifery, but this entire part would have been better omitted since the operations described do not properly come under the title of the book, and are more fully treated elsewhere.

We had hoped to find somewhere a description of the best kinds of manikin available and especially, seeing that the author rightly advises the use of the stillborn fœtus rather than the "puppet" as better and far more instructive, some directions might have been given on the best way of preserving the fœtuses. The "furfurol" method for this purpose is used in the Sloan Hospital, New York, and in University College Hospital, London; a fœtus treated by this method is preserved indefinitely and at the same time kept soft and flexible.

We can confidently recommend the work; the idea is original and the matter is sound.

Diseases of the Tongue.

By W. G. Spencer, M.S., F.R.C.S., Consulting Surgeon, Westminster Hospital; and S. Cade, F.R.C.S., Assistant Surgeon to the Hospital. London: H. K. Lewis and Co., Ltd. 1931. Pp. 561. 35*s*.

This book represents the third edition of Butlin's classical monograph on the tongue and its diseases, but it has been revised, altered, and rewritten to such an extent that it is actually a new work on the subject. Mr. Spencer and Mr. Cade give a good account of the many diverse affections of the tongue and mouth, but the real merit of the work lies in the attempt the authors have made to evaluate the modern methods of dealing with cancer of the tongue. This section, of course, deals largely with radium treatment, and we observe with some satisfaction that the authors have not used massed statistics, but base their opinion solely upon their personal experience. To the reader who desires information upon radium therapy from this point of view we commend this book. The authors are enthusiastic in their praise of radium, and in their belief in future improvements in its use, but are not blind to its limitations and the many failures they have experienced. The book does make the serious student feel that radium therapy is very far from being the solution of the cancer problem, though undoubtedly in certain circumstances it can accomplish more than any other means at our disposal. The book is profusely illustrated, pleasant to read, and has a good bibliography.

The Mongol in Our Midst.

Third edition. By F. G. Crookshank, M.D., F.R.C.P. London: Kegan Paul, Trench, Trübner and Co., Ltd. 1931. Pp. 539. 21*s*.

If Dr. Crookshank had belonged to another age he might have spent a happy life pricking o'er the plain in burnished armour seeking occasions for martial impact. When, after a hearty joust, he found that the lady to whose rescue he had galloped was without either personal charm or need of assistance, he would have bound his wounds cheerfully, remarking: "What matter? It is as if I had seen a damsel in distress, and anyway, it was a good fight." Such an attitude of mind is a joy to those who sympathise with it and a thorn in the flesh to those who cannot understand. In this new edition of "The Mongol in Our Midst" he reproduces the material which aroused so much controversy when it was first published in 1924, and adds to it a great deal of new matter and new photographs and a hearty reply to his many critics. His style is incisive and readable and the material of his thesis is undoubtedly stimulating. His book will be a delight to all those who like to wander in those realms of knowledge where the receptive mind can unfold to limitless possibilities while reason hesitates on the outskirts and orthodoxy turns shudderingly away. Dr. Crookshank marshals an array of facts which cannot be ignored; as he himself says, their explanation is yet to seek, but they command respect and sober reflection. No advance can be made in any direction by refusal to handle bricks which do not fit comfortably into the orthodox structure but which nevertheless remain lying about for the builder to stumble over. The bizarre and fascinating problem of the mongol is still far from solution, but nobody who is interested in it can afford to miss this book.

Die klinische und röntgenologische Untersuchung der Lungenkranken.

By Dr. Hans Philippi. Munich: J. F. Lehmann. Pp. 119. M.6.50.

This book is a short account of the usual clinical methods applied to the examination of the diseases of the thorax. Dr. Philippi describes briefly the symptomatology of respiratory disease, and then goes into a detailed description of inspection, palpation, percussion, and auscultation of the lung, covering fairly fully all the well-known ground. In the chapter on the radiology of the chest a rather large proportion of space is devoted to screen examination. Two pages are concerned with the examination of the upper respiratory tract, and a final chapter with temperature recording. The book would have been more helpful had it been possible to include more diagrams (there are only three) and a few radiograms of the normal thorax. Although various authorities are quoted in the text there is no bibliography and no subject index.

A Treatise on Light.

By R. A. Houston, M.A., Ph.D., D.Sc., Lecturer in Natural Philosophy in the University of Glasgow. London: Longmans, Green and Co., Ltd. 1930. Pp. 494. 12*s*. 6*d*.

The author does what he sets out to do, the subject matter is lucidly explained, and is illustrated by well-chosen line drawings and coloured plates. While essentially a book for the student of physics who can tackle the mathematics, it will be found useful to those who want a work of reference dealing with a very wide range of the subject of optics. The chapters on polarisation, spectroscopy, the infra-red and X rays, the eye and colour vision bear on medical science, the last-named chapter including some excellent illustrations of optical illusions. The final chapter is on the ether and relativity, and will be found to offer a very clear account of the initial need of physicists for a luminiferous ether and of their subsequent arguments that perhaps after all it is not necessary.

Altogether a book which can be thoroughly recommended.

THE LANCET.

LONDON: SATURDAY, JUNE 6, 1931.

PHYSICAL TREATMENT CLINICS.

THE big demand for treatment by physical remedies at the Clinic for Rheumatism set up by the British Red Cross Society in Peto-place proves—if proof be required—that work of this kind is badly needed. Six years ago[1] we announced the formation of a small committee on rheumatism, and we hope that the proposal of that committee, now partly realised by the Society, to establish a central demonstration clinic in London for research, treatment, and teaching is well on its way to fulfilment. To erect a medical centre with such a comprehensive programme is no slight undertaking, and cannot be immediately accomplished. Well may the directors of the Clinic confess that they have been confronted by many new problems, and that the experimental stage of the work is by no means at an end. On the treatment side it involves far closer study than has yet been given of the actions and reactions of a large number of physical procedures in the early stages of rheumatic disease. New lines of observation and research have to be mapped out. And, above all, the best available experience, from England and from other countries where rheumatic diseases prevail, has to be obtained. The medical use of baths is at present an unfamiliar field, although within the last few years diligently cultivated here and there. It would be wasteful if new groups failed to begin their work at the advanced point where these others had arrived. Moreover, in any national effort, such as that foreshadowed by the Society, the interwoven studies of treatment and ætiology must be combined with the theoretical and practical teaching which is immediately necessary for the right extension of such clinics throughout the country. Incidentally, we commend the suggestion recently thrown out that these clinics should be organised for different lines of investigation.

A year has elapsed since the opening of the Peto-place Clinic, and similar centres are being planned in other places. In these circumstances the original aims of the committee to which we have referred may well be recalled. Relying upon the experience of the Red Cross Clinic for the Physical Treatment of Disabled Officers, in 1916–1918, they suggested that the same combination of baths with other physical methods should be used, on a much larger scale, with special precautions against chill and fatigue, which nullify the effect of such treatment in rheumatic cases; also that in the proposed clinic the same close study and expert treatment should be given to rheumatic disability as was devoted at special clinics during the war to other forms of disability. Among the conditions of success laid down were careful selection of cases, close study of the reactions to heat and cold in rheumatic subjects, special investigation of selected cases, and the service of a specialist in physical methods, who should devote himself for some years to the study of rheumatic conditions. Subsequent experience has justified these proposals. The new studies of the circulation of the skin in rheumatic disease, of abnormalities of surface temperature, of defective reactions to heat and cold, of the effect of graded and local applications of heat, have gone far to explain the value of balneotherapy in these diseases. They may even be held to establish the claim that surface remedies, properly employed, are an essential part of the treatment of rheumatism. Unfortunately here, as elsewhere, the more powerful the remedy the more easily it is misapplied; the physical physician, not less than the surgeon, is in need of special training, experience, and technical dexterity.

In the development of this movement in the towns these conditions of success ought to be borne in mind. What is really new and unfamiliar in these clinics (outside the spas) is the precise use of baths, by which certain desired reactions are sought. Various forms of radiation, electricity, manipulation, are common property in the hospital and elsewhere. The essential feature in the clinic for rheumatism is the combination of balneotherapy with these other methods. The British Red Cross Society is probably right in thinking that this can be best effected sometimes in a large hospital, sometimes in an independent out-patient centre. We cannot doubt that the ruling principle will be accepted that in all departments or independent clinics where special treatment is given it must be directed by medical men highly experienced and skilful in such treatment. In a hydrological department, as the Society admits, difficulties were experienced because attendants qualified for hydrological work were not available. But if bath departments or clinics for rheumatism are to form part of the hospital and medical service, it will obviously be necessary to make arrangements for adequate training to cover the methods of treatment employed. In the case of radiology and electrology that has been already done, but at present there are no facilities in this country for post-graduate training in hydrology. We cannot allow that the solution set forth in the Society's pamphlet[2] is adequate—the stipulation that, for example, in the election of six physicians for a clinic to treat 500 persons daily "one or more of those elected should have a special knowledge of hydrology and electrology." At a bath clinic in which special treatment, investigation, and training are concurrently carried on, the most highly *specialised* medical direction is required.

We agree with the Society that a chain of well-organised clinics of this kind is greatly needed.

ANNOTATIONS

THE DANCE OF DEATH.

FOR 500 years the motif of the Dance of Death has fascinated artists, and most travellers will have seen one or other of the well-known series of pictures in situ, while quite a literature has grown up around them. But there was room for this book,[1] because the author has had an ingenious and original idea. He has written a series of interesting chapters round a collection of prints which he has made of the representations of death in art, and his learned text, which is profusely illustrated by reproductions from many of the well-known frescoes and woodcuts in which death forms a serial subject, has a special medical interest.

The figures in the Dance of Death, whether they dance or not, have certain things in common due probably to the origin of the theme as a survival of a church festival. Members of the various ranks of society, from Pope and Emperor, through the official and professional classes, down to the peasant, are depicted, each in company with a skeleton, which dances, drags, or clutches him to the grave; and the common message, whether the grim procession is painted on walls or printed in block books and incunabula, is that in the presence of death all are equal. The physician is nearly always represented in the series, and Prof. Warthin has examined the particular treatment of the doctor and manners of the accompanying skeleton in order to gauge the social position occupied by medicine in the different centuries. For this purpose he divides the pictorial displays into time periods. Of these the first two, covering the period preceding the great Holbein, witness the frescoes placed on the walls of churchyards, and the production of block books and the earliest printed books, such as illustrated prayer books. During the fourteenth, fifteenth, and sixteenth centuries it can be surmised that the physician was mounting more or less regularly in social scale as indicated by his place in the processions and the character of his clothes. But his rendering is not complimentary, for his sole professional accomplishment would appear from the pictures to be urine-gazing. Holbein mitigates the implied criticism. So many editions, copies, and facsimile reproductions of the Holbein Totentanz have been published that the beautiful drawing of the physician with his hour-glass and sleeping dog being visited by a venerable patient in company with death is familiar to everyone. Now here the physician is treated with dignity. Death holds the inevitable urine-glass, and appears to indicate the futility of any doctor interfering between him and the aged, but the doctor himself is drawn as a student and not as a quack and the detail of the open hand in expectation of a fee is omitted. Holbein had many imitators, and Dr. Warthin writes as an expert upon their work, which following the example of the master, became satirical and secular, all the religious spirit having now disappeared. The doctor, as the date changes, changes in clothes and manners, but there is not much indication that he has developed in scientific knowledge. Through the eighteenth and nineteenth centuries up till the present day artists have used the old motif as a text for new treatment. And as society became more complex the doctor was no longer given any prominent rôle in the dramatis personæ, which, to judge from Dr. Warthin's collection, is just as well for our repute, since with few exceptions, the doctor plays a sorry part in these series.

THE VIVIAN POORE MEMORIAL.

WORK is proceeding under the scheme for a memorial to the late Dr. George Vivian Poore, inaugurated by the National Homecroft Association, announced in our columns some months ago.[1] Ten rural workmen's dwellings, built on the homecroft plan near Cheltenham, are to be fitted, as nearly as possible, with exact models of the natural rural sanitation which Poore advocated; and later it is hoped to raise a small building to his memory. Prof. J. W. Scott, of University College, Cardiff, who is acting as secretary to the association and to the memorial committee, has good hope of seeing two of the models in operation this summer, probably more if funds permit. It is not without its interest that Poore's scientific results in preventive medicine should at this comparatively late date have reached a lay body such as this association, which is ready to try to raise funds to push them. Local authorities in rural areas are still doing the stupid things which Poore long ago exposed; but time has its revenges. All who are interested in Poore's work and memory are invited to the next meeting of the memorial committee, over which Dr. F. G. Crookshank will preside, to be held in Church House, Dean's Yard, Westminster, on Thursday, June 11th, at 2.30 P.M., when Dr. Scott will present a report.

THE COMMON COLD AND THE WEATHER.

IT is a matter of common observation and belief that colds in the head and other forms of upper respiratory disease are associated with wintry conditions, and it has lately been impressed upon the public that damp cold is much more likely to cause catarrh than dry cold. Dr. W. M. Gafafer[2] has made a study of the relation between upper respiratory illness and weather elements over a period of 82 weeks. The volunteers came from the Johns Hopkins University and consisted of medical students, students of the school of hygiene, and members of the common cold research staff. A second group consisted of about a hundred families living in Baltimore, selected for their intelligence, willingness to coöperate, and the presence of children. The 82 weeks were divided into two cold periods and a warm period. In the cold period there was a slight indication among the medical group of an increased tendency to colds when any one of the following weather elements fell below its ordinary level: minimum temperature, average temperature, dry bulb temperature, and vapour pressure. The maximum temperature, the temperature range, the humidity, the rainfall, the wind-velocity, the sunshine, and the atmospheric pressure seemed to have no effect on the incidence of respiratory illness. Among the family group, however, there seemed to be no correlation whatever between the upper respiratory attack-rate and the weather during the cold period. During the warm period the rise in attack-rate in the medical group seemed to be associated with a fall in minimum temperature, average temperature, temperature range, dry bulb temperature, vapour pressure, sunshine, and atmospheric pressure. In the family group the associated weather factors seemed to be minimum temperature, average temperature, dry bulb temperature, and sunshine. The conclusion of the two investigations is that changes in weather during a warm season are probably far more closely associated with colds in the head than similar changes during the cold season.

PREOPERATIVE INVESTIGATIONS.

THERE was a time when the preoperative investigation of a patient consisted in the use of the stethoscope and no more, but now there seems no end to the tests regarded as desirable before a patient may safely be handed over to the surgeon. Mr. Lawrence Abel's interesting views on this subject, set out in our last issue (p. 1191), find a parallel in those of Prof. Marcel Labbé.[1] Dr. Labbé, like Mr. Abel, insists on an inquiry into the renal and cardiac functions, with examination of blood and urine, but he also lays stress on the hepatic functions. Besides the usual search in the urine for albumin, leucocytes, and casts, and an estimation of the blood-urea, he would use the phenol-sulpho-phthalein test. He also draws attention to the significance, from the renal point of view, of the blood pressure. He is less concerned than Mr. Abel with the investigation of the cardiac system and does not mention the cardiac index, although he would have an electrocardiogram in the presence of any disturbance of rhythm. His blood tests include an ordinary complete blood count with estimation of hæmoglobin and the coagulation time, and, like Mr. Abel, he would give a blood transfusion in a case with a low red cell count. The hepatic functions occupy the greater part of Labbé's paper, and he recommends chromoscopy—the study of the elimination of coloured substances from the blood by the bile. He regards the glycosuria produced by the ingestion of glucose as an unsatisfactory index of the glycogenic function and insists on a record of the hyperglycæmic curve. This test, however, is not enough in itself for a diagnosis of hepatic insufficiency, since pancreatic, nervous, and endocrine factors are also involved. The proteolytic function of the liver must be studied; the most precise results are furnished by Philibert's method of giving amino-acids and estimating the amino-aciduria, which should not be above 3 per cent. in the normal subject. The amount of ammonia excreted rises with an acidosis, but it may be present in the absence of acidosis in the course of certain grave hepatic lesions. Errors of nitrogen metabolism may be revealed by the relationship of the colloidal nitrogen to the total nitrogen excreted. Disturbance of the proteolytic function may be shown by Fosse's method of administering urea. The blood nitrogen is considerably reduced in hepatic insufficiency, cirrhosis, and simple catarrhal jaundice. The lipolytic function of the liver is difficult to estimate; often the estimation of urinary ketose—in the absence of diabetes—reveals grave disorder of the liver. Finally, the liver should be investigated by the study of the biliary function and of the blood coagulation. In diabetics Labbé thinks that the acidosis is more important than the glycosuria; the alkaline reserve should always be studied. In the presence of any endocrine disorder the estimation of the basal metabolism must not be omitted, and there must of course be the usual routine examination of the respiratory system. It may be presumed that many of these precautions are taken only when there is doubt of the candidate's fitness. But surgeons may well wonder how they managed to achieve such a high percentage of success before the physicians and pathologists came to their aid. Perhaps they made a habit of looking at the patient.

ANATOMY AT KING'S COLLEGE, LONDON.

WORK has now begun on the new anatomy department of King's College, London, which is being constructed in two additional storeys on the roof of the existing buildings at a cost of over £60,000. Greatly increased laboratory, research, and museum accommodation will be provided. The department in future will be in close topographical association with the other biological departments of the college, and for their general use a suite of rooms for animal experimental work is being included in the new building. These extensions represent the first step in execution of the building programme set out in the centenary appeal of the college. The next will be the conversion of the old anatomy department into an extension of the chemistry department. The extension and modernisation of the medical department of the college has been undertaken to meet the needs of the large and growing pre-clinical school, which is associated on the clinical side with four of the London teaching hospitals—King's College, Charing Cross, Westminster, and St. George's.

MEDICINE IN RUSSIA.

AUTHORITATIVE statements on conditions in the Soviet republics are few and far between, and it is almost impossible to gain an accurate idea of the state of medicine in a country so vast and so obsessed by political prejudice. Nevertheless, a recent article by Dr. H. Hamperl[1] gives the impression of impartiality and confirms information from other sources. Private practice, he says, became almost extinct under the first revolutionary government, but recovered a certain degree of freedom with the end of the civil war and the institution of the new economic policy. The government, however, pressed on it more and more hardly by the expansion of its public dispensaries, and the intensive campaign against the "capitalist elements" in 1929, hastened its downfall. The medical situation in Russia and the other Soviet countries is therefore dominated by the ambitious policy of a State medical service available to all citizens (needless to say, with preference in favour of workmen and peasants and their dependants) operating through hospitals, sanatoriums, and ambulant clinics, and the problem is the provision of sufficient doctors to staff the new establishments. The number of medical practitioners available is estimated to be 44,500 and the Five-Years' Plan includes the training of 37,500 more. The teaching facilities are naturally inadequate and it cannot be easy to find additional teachers to order. Moreover, Dr. Hamperl says, the students are selected exclusively from the working classes and are given only from one to three years' pre-medical instruction, so that by the time they approach their medical course they are not in a position to profit by the ordinary lecture system. The authorities have therefore been obliged to institute the "seminary" system of instruction in small groups, the members of which pass on the instruction to the remainder. The course of instruction has, follow up the babies who attend the welfare centre during the first year of their life.

[1] Bull. et Mém. Soc. de Méd. de Paris, May 8th, p. 316.

[1] Wien. klin. Woch., April 10th, p. 483.

The speech clinic has now been working for 18 years, and the number of admissions is increasing. The fathers' and mothers' centre has moved into an enlarged building where there is scope for new ventures, bigger nurseries, and an open-air roof garden, while the old informal atmosphere is maintained.

TO BOOK LOVERS.

Messrs. Sotheby are announced to sell shortly, in the New Bond-street auction rooms, London, two rare books which have direct interest for the medical profession as well as the bibliophile. The first is a translation of Ulric von Hutten's "De Morbi Gallici Quæstione, &c.," published in 1539, the translation being entitled "Of the Wood called Guaiacum that Healeth the French Pockes." Guaiacum had been introduced into Europe by the Spaniards some 20 years before, although the action of the resin was not known till later. Von Hutten's treatise was written shortly after his famous epistolary satires on theologians and was translated by Thomas Paynel and published in London by one, Thomas Berthelot. The disease referred to is, of course, syphilis, which we called after the people from whom it was introduced into Britain, just as they named it after the Italians who, in turn, blamed it on to the Spaniards. The other book is rarer, probably, for it is thought that but two other copies exist, one in England and one in America. It is a small paged octavo volume by Dr. John Caius, and was published in 1552 in London by R. Grafton. The name of it is "A Boke, or Counsell against the Disease commonly called the Sweate, or Sweatying Sicknesse." This is Caius's famous treatise on a remarkable epidemic, which exists in the form of an English translation only, save for these rare examples. It may be added that the lot preceding Dr. Caius's book is a copy of the first edition of Sir Thomas Browne's Pseudoxia Epidemica, 1646, which is much less rare than the other two books, though fully as interesting from the medical aspect.

A TREATMENT FOR CARBUNCLE.

THE carbuncle is the prototype of indolently progressive inflammation, and is seldom seen at its worst in young persons, since their defensive mechanisms are active enough to lead to early and brisk suppuration. Treatment may reasonably aim, therefore, at increasing general and local resistance, and for the past four years a method has been tried in Prof. Bier's clinic in Berlin which is intended simply to amplify the local reaction to infection, which is assumed to be deficient in such cases. The immediate object is to produce an active capillary hyperæmia, and for this purpose a pure solution of arnica is used, prepared in ampoules and sold under the name Arnusit. W. Gerlach,[1] who reports on the results, points out that the injections must be made into healthy tissue in the vicinity of the infected area, and not into the carbuncle itself, which is already so poisoned that it cannot respond normally. For the same reason it is unnecessary to surround the lesion with a ring of injections, and this moreover would employ too large a bulk of a drug poison. Very minute doses prove sufficient, and they are given subcutaneously at least a hands-breadth away from the zone of inflammation. A burning pain follows but can be controlled to some extent by pressure with the finger. No further injection is given for 24 hours, by which time, as a rule, the artificial hyperæmia has disappeared. The treatment is then repeated as often as may be necessary. The number of injections required depends on the stage at which they are begun, and it occasionally happens that six or eight are needed before suppuration occurs. Meanwhile, it is said, the symptoms are obviously controlled. Pain and fixation disappear almost at once, and the patient feels better. The symptoms soon return however; the temperature rises, and in 24 hours the bluish periphery of the carbuncle assumes a ruddier tint, which is regarded as evidence of acceleration of the more acute stage. The same phenomena are provoked by the second and third injections, if required, but no case appears to have needed more than eight injections in all. An increased tendency to small local hæmorrhages at each change of dressing will usually be noted and need not be feared; it springs from an activated blood-supply and is easily controlled by pressure. A further local manifestation of the protective response is the development of superficial pustules near the carbuncle, while marked general sweating is a common sign of recovery. Healing of the lesion is sometimes associated with a local itching which is in striking contrast with the pain caused by the slightest pressure on an untreated carbuncle. Gerlach claims that if the case is treated in its early stages, before necrosis has begun, the whole process remains localised and subcutaneous, and the pus is evacuated through a pea-sized opening, so that the scar is subsequently invisible. The best local dressing is a moist compress of diluted arnica in normal saline. Furthermore he says that large boils mostly involute after one or two injections, and cases of lymphadenitis, bursitis, and superficial cellulitis can be similarly aborted.

It will be noted that the treatment here described bears a resemblance to the use of setons, formerly much in favour.

Mr. D. P. D. Wilkie, professor of surgery in the University of Edinburgh, is acting as director of the surgical professorial unit at St. Bartholomew's Hospital during the first fortnight in June. He takes over the duties of Prof. Gask and also lectures to the students. Each year an exchange of this kind is made, and the experiment has been notably successful.

To celebrate the centenary of the Harveian Society of London a meeting will be held at St. Bartholomew's Hospital at 3 P.M. next Thursday. At 3.15 P.M. Dr. Raymond Crawfurd will deliver an oration on the Place of Medical Societies in the Progress of Medicine. Exhibits of interest in connexion with Harvey will be on view in the library from 4.30 P.M.

AT the annual general meeting of the Research Defence Society, to be held at 11, Chandos-street, W., at 3.30 P.M., on Wednesday next, Dr. H. H. Dale, F.R.S., will deliver the fifth Stephen Paget memorial lecture. His subject will be the Effect of Research on Curative Medicine.

EAST END MATERNITY HOSPITAL.—Dr. W. H. Oxley, hon. medical officer, reports that "booked cases" have numbered 10,366 during the last five years. Of these only one healthy mother died as the result of childbirth. Six others who died "were seriously ill before labour commenced with some disease quite apart from pregnancy, which either entirely caused or contributed to the fatal result."

SPECIAL ARTICLES

PATIENTS' WAKING HOURS IN LONDON VOLUNTARY HOSPITALS.

REPORT BY A SUBCOMMITTEE OF KING EDWARD'S HOSPITAL *FUND FOR LONDON*.[1]

THE management committee of King Edward's Hospital Fund for London, having received from the distribution committee the report of a subcommittee on the subject of patients' waking hours, resolved that the report be circulated for the consideration of the hospitals concerned, in the hope that it may assist the hospitals, so far as their different circumstances may permit, to fix an hour not earlier than the time suggested in the report.

The attention of the Fund's visitors was explicitly directed last year to a series of questions grouped under the general heading "Comfort of Patients." One of these questions dealt with the hour at which patients are awakened in the morning, and the distribution committee asked for a special report on it.

The replies of the visitors were accordingly referred by the distribution committee early in 1931 to a subcommittee consisting of Mr. Walter Spencer (chairman), Dr. Morley Fletcher, Mr. Eardley Holland, and Sir Harold Wernher, and their reports are summarised below:

The hours of waking are summarised, for the different groups of hospitals, in the table in an appendix. This table gives the following results, classified under the earliest hour mentioned by the *visitors*:—

(*a*) 4, 4.30 or 4.45 A.M.	4 hospitals.
(*b*) 5 or 5.15 A.M.	40 „
(*c*) 5.30 or 5.45 A.M.	22 „
(*d*) 6 A.M.	44 „
(*e*) 6.30, 6.40 or 6.45 A.M.	8 „
(*f*) 7 A.M.	6 „
(*g*) Average of teaching hospital group	5.55 A.M.
(*h*) Averages of other general hospital groups	5.10 to 5.35 A.M.
(*k*) Averages of special hospital groups	5.30 to 5.55 A.M.

Amongst the hospitals where the hour is after 6 may be specially mentioned the Middlesex, where the recent change of hours has drawn a good deal of attention to the general question. The male patients are awakened at 6.30 and the female at 6.45.

Extra-Metropolitan Hospitals.

The general conclusions drawn from replies from 63 large general extra-metropolitan voluntary hospitals are as follows:—

1. That the day nurses in the majority of cases come on duty at 7 A.M.

2. That the night nurses in the majority of cases go off duty from 8 to 8.30 A.M.

3. That the time on duty of the night staff overlaps the time on duty of the day staff in the majority of cases from one hour to an hour and a half.

4. Work begins in the wards in 45 instances before 6 o'clock and in 18 instances at 6 o'clock or later.

5. The interval between the beginning of work and breakfast varies from 0 to 2¼ hours. The great majority of hospitals allow from 30 to 60 minutes.

6. The interval between the beginning of work in a ward and the visits of the honorary medical staff varies in those hospitals in which the honorary staff visit in the morning from 3 to 6½ hours. The majority allow 4 to 5 hours.

7. With regard to the extra staff required (i.e., for waking at 7 A.M.), the various opinions expressed reflect the difficulty involved in estimating the effect on staff whenever a load factor is increased sharply and for a limited period.

L.C.C. Hospitals.

The subcommittee also had before them a published report, dated November, 1930, by the Central Public Health Committee of the London County Council on the question "whether any, and if so what, medical or other advantages accrued to the patients of the Council's hospitals from being awakened before 6 A.M." The report states that in 10 of the 28 hospitals previously under the guardians, waking was at or before 5; that in 9 it was at 5 or later; and that in 9 it did not begin till 6. The Central Public Health Committee now propose that, so far as practicable, no patient should be awakened, except in special circumstances, before 6 A.M.; that the hospitals below that standard should be raised up to that standard as and when staff should be available; that the change should be gradual; and that the matter should be further considered in a year's time.

Items of Early Morning Work.

In considering the necessities of hospital work and the welfare and comfort of the patients there are other matters to be taken into account besides the actual hour of waking; and in these, also, there are differences in the procedure at different hospitals.

The various processes that have to be carried on throughout each ward include, for instance, the use of urinals and bed-pans, the washing of the patients and the making of the beds. The time-table has also to provide for the serving of food, which may consist of breakfast only, or of early tea first and breakfast later.

As this procedure has to be gone through with every patient in turn, much time is taken up. In arranging the hour when these processes must be finished, a sufficient interval must be left between breakfast and the light mid-morning lunch. Moreover, the washing, &c., for the patients who are dealt with last must be completed in time for the first visits of the medical officers. This, in the experience of the subcommittee, usually means by about 10 o'clock, though a good many of the returns from the extra-metropolitan hospitals mention an hour as early as 9. In calculating from this the time when work must be begun for the patients who are dealt with first, it is often the practice to decide on an official hour, but to arrange for work to be begun before that hour with such of the patients as happen to be awake.

Within the limits thus determined, the order of the different processes may vary. At some hospitals the patients are washed before breakfast, at others breakfast comes first. Sometimes as many as possible of the patients are washed before breakfast, and the rest afterwards. Sometimes early morning tea is served immediately on waking, and breakfast an hour or so later, after all the washing is done.

Another factor in the time-table is the division of the work between the night and day nursing staffs, and the hours when the night nurses go off duty and the day nurses come on. There is an overlap usually of from one hour to an hour and a half.

Suggestions.

The question is much more complicated than it might seem at first sight to those who think only of the actual hour of waking.

It is certainly a question on which the King's Fund, if it takes action at all, would only do so after consultation with the hospitals concerned. Nevertheless, the subcommittee have formed definite opinions on some points and consider that these may well be made the subject of consultation.

It has been shown that, in the London Voluntary Hospitals, 6 o'clock is at present the official hour of waking more often than any other hour.

There is also a good deal of evidence that hospitals which have already made a change to 6 o'clock from some earlier hour, or which would be prepared to consider the possibility of such a change as a practical question, would nevertheless regard the difficulties in the way of the adoption of so late an hour as 6.45 or 7 as insuperable.

---

[1] London: Geo. Barber and Son., Ltd. May, 1931. 6*d*.

After taking these facts into account, and after having also considered the varieties of practice in the other matters mentioned in this report, the subcommittee are of opinion :—

(1) That, unless there is some exceptional and adequate reason to the contrary, the most suitable hour for the waking of patients is 6 o'clock ; bearing in mind the fact that, in a hospital, work closes down for the night long before the hour at which the patients are accustomed to go to bed when at home.

(2) That, while the adoption of any later hour would probably require an addition to the nursing staff, a change to 6 o'clock on the part of most of the hospitals which now have an earlier hour could probably be effected without any material increase of staff or expenditure.

(3) That, at some of the hospitals where the present hour is exceptionally early, it may well be impossible to change to 6 o'clock without increase of staff, but that nevertheless in those hospitals a change is so desirable that the question should be considered.

(4) That breakfast should be served as soon as possible after the hour of waking ; and that work involving the disturbance of the patients before breakfast should be limited as far as possible to what is necessary for their comfort.

(5) That, whatever the official hours may be, no patient should be washed before having either breakfast or early morning tea.

(6) That the rules and the practice should be such as to avoid as far as possible any noise in the wards before 6 o'clock.

AUSTRALIA.

(FROM OUR OWN CORRESPONDENT.)

ROYAL AUSTRALASIAN COLLEGE OF SURGEONS.

THE King has approved of the prefix "Royal" for the Australasian College of Surgeons. The college is an Australian and New Zealand organisation, and its chief objects are to improve the standards of surgery and of surgical training and research. To further these objects and to assist Australasian graduates who cannot afford the time and expense involved in a visit to England for the purpose, the Royal Australasian College of Surgeons has arranged with the Royal College of Surgeons of England that the primary Fellowship examination of the latter shall be held in Australia. The first examination will begin in Melbourne on August 11th.

The aims and functions of the Australasian college are similar to those of the English college, and a close association has arisen between the two. A gratifying expression of this is the fact that the council of the Royal College of Surgeons of England is presenting a mace to the Australasian college. The president of the Royal College of Surgeons, Lord Moynihan, will visit Australia early in 1932 to present the mace. That Lord Moynihan will personally present the mace is naturally regarded as a special honour for the Royal Australasian College of Surgeons. The mace, which is an exact replica of one given as a mark of royal authority to the English college is being designed and executed by Omar Ramsden, of London. It will bear the arms of the English college, the arms of the Australasian college, which have recently been granted by the College of Heralds, the arms of Australia, and the arms of New Zealand. Special permission has been granted by His Majesty for the use of the orb and cross in the design of the mace.

Lady Syme and her children have given the Royal Australasian College of Surgeons £2500 to form a research endowment fund in memory of the late Sir George Syme, the first president. The interest derived from this amount will be applied to foster surgical research, particularly in diseases common in Australia. The results of the research work will be presented in an annual memorial oration, called the Syme oration, which will be delivered at the general meetings of the college. Lord Moynihan has consented to give the first Syme oration at the time of the presentation of the mace to the college.

THE MATERNITY ALLOWANCE.

A sum of £5 is payable to every mother in Australia in respect of each parturition resulting in the birth of a viable child whether such a child be born alive or dead. The legislation to effect this payment was enacted by the parliament of the Commonwealth of Australia in October, 1912. The mother must be a native of the Commonwealth or intend to settle permanently therein. No payment is made in the case of an aboriginal or an Asiatic. Some idea of the financial responsibility of this legislation may be gauged from the fact that for the year ending June 30th, 1929, the total expenditure including administration was £661,520, of which the cost of administration absorbed £16,627. Analysis of these claims showed that 87 per cent. of the cases were attended by medical practitioners. The bonus is claimed by almost every mother in Australia irrespective of her social or financial position. The originators of this scheme hoped that it would increase the birth-rate or at least arrest the decline ; that it would diminish the maternal and infantile mortality, and render a difficult and dangerous period in women's life safer, and thus conduce to the national welfare. A review of the results from 18 years' experience of this legislation shows that the Australian birth-rate is steadily declining. No marked alteration has been effected in the puerperal death-rate. The lowest that has been attained was for 1915 with a rate of 4·27 per 1000 births. The figure for 1929 was 5·1. There has been a slight reduction in the infant mortality-rate which for 1929 was 51 per 1000 children born. It is considered, however, that a more important factor has been the establishment of baby health centres and the more widespread application of modern methods of infant management. An interesting and not unexpected result is that the proportion of maternity cases that have been attended by a doctor has considerably increased. At the inception of the scheme 65 per cent. of mothers were so attended, but in 1929 this figure had increased to 87 per cent. It is a discomforting fact that the maternal mortality-rate has not been thereby reduced.

Endeavours have been made by the federal committee of the British Medical Association in Australia to have the maternity bonus revised, and for the money thus set aside to be utilised for the establishment of more maternity hospitals, antenatal clinics, and infant welfare centres ; and for the provision of help for mothers and expectant mothers in necessitous circumstances. Another suggestion that has been made is that the payment of the bonus should be conditional on the attendance of the mother for antenatal examination at monthly intervals, either by her own practitioner or at clinics established for the purpose. These suggestions, however, have not received parliamentary approval, and the only inscription on the Statute Book was in 1926 when the word "Asiatic" was omitted from the list of those to whom no payment is to be made and the word "Alien" substituted. It would seem that the bonus, as a public health measure, is not giving value for the financial burden incurred. The original idea was not conceived by an obstetric mind. It seems that it was primarily a vote-catching device, and now the measure is so popular with the people that no government is sufficiently strong-minded to interfere with it. No qualification is placed upon how the payment is to be expended and instances are not wanting of its being utilised in keeping up the payments on the pianola while skilled nursing and medical services are neglected. The bonus has been termed "the recognition of motherhood" and it is looked upon in general as a rebate on taxation paid at a time when the arrival of the stork with his long bill has caused a temporary difficulty in the family budget.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

THE GERMAN SURGICAL CONGRESS.

AT the annual congress of the German Surgical Association, Prof. Victor Schmieden (Frankfort) presided, and in his inaugural address spoke against increasing specialisation in surgery. He announced that the discord existing since the war between the German Surgical Association and the International Surgical Association has now been resolved, so that German surgeons will be in a position to take part in the proceedings of the international organisation. He thanked Prof. Erwin Payr (Leipzig) and Prof. F. de Quervain (Basle) for their services in this connexion.

The first official subject of discussion, operation on peripheral nerves, was introduced by Prof. Hermann Küttner (Breslau). He said that in nerve injuries a certain reserve is advisable, for complete function may be restored after five to six months, even if the electrical reaction of degeneration has already appeared. Following suture of nerves function often returns after several weeks, and sometimes even after a year or 18 months. Neurolysis should be performed only in late cases. In paralysis of the facial nerve anastomosis of the facial with the hypoglossal nerve is recommended, but late suture of the injured facial nerve gives good results too. Severe pain may be produced by neuroses, callus, cicatrices, and foreign bodies. Injection of a 70 to 80 per cent. solution of alcohol is often ineffective against such pain, whilst higher percentages may injure the motor paths. Injections of formalin are preferable. In discussing more radical methods he described section of the posterior roots as being uncertain, and advocated section of the anterolateral columns.

The second official theme was operation for Graves's disease, introduced by Prof. Ferdinand Sauerbruch (Berlin). He spoke of the nervous causes of the disease as a sequel of strong psychic trauma. The result of operation depends on the pre-operative preparation of the patient. He recommended administration of iodine, after Plummer's method, for eight to ten days, and said that this has much contributed to the decrease of post-operative mortality. Prof. Paul Morawitz (Leipzig), speaking from the point of view of the physician, pointed out that vasomotor neuroses, Graves's disease, and thyrotoxicoses cannot always be distinguished. The treatment has become more and more a surgical one. Iodine therapy without subsequent operation is of doubtful value. Of a series of patients treated by radiotherapy 50 per cent. improved, 25 per cent. failed completely, and in no case was complete cure observed. Severe cases with exophthalmos do not become quite healthy even after operation, though able to work again. Prof. Paul Sudeck (Hamburg) recommended total removal of the thyroid gland in malignant goitre, its function being replaced afterwards by a continuous administration of thyro-iodine tablets.

Dr. Barthels (Leipzig) stated that stricture of the rectum is often caused by lymphogranulomatosis inguinalis, a venereal disease common especially in the tropics. Rectal diathermy is better than the formation of an artificial anus or irrigation of the rectum. In severe cases high resection must be performed. Dr. Bircher (Aarau) reported on his results of resection of the left vagus nerve in cases where the existence of gastric ulcer is presumed. Acidity was reduced to a quarter by the operation. In gastric ptosis resection of the sympathetic nerves to the pylorus and duodenum was recommended.

PROSECUTION FOR ARTIFICIAL ABORTION.

Discussion on the legality of artificial abortion has begun afresh because of the arrest, at Stuttgart, Wurtemberg, of a medical man and a medical woman on a charge of performing this operation in some hundreds of cases without sufficient medical indication. The police seized the books of the accused so that the names of the patients became known, and they were compelled to give evidence before the police judge. The accused did not deny the facts, but stated that they had performed abortion not to get money, as was alleged by the prosecution, the fees having been extremely low, but for social reasons. The patients were held to be unable to bring up healthy children in a proper way. The medical man had given the certificates, while the medical woman had performed the operation, which in no instance had done any harm. The man was after some time released on bail, but the woman was held in custody until she began a hunger strike, when she also was released. The prosecution of both practitioners has stirred up public opinion, the more so because they are members of the communist party, and the question has rapidly become political. Meetings have been held to protest against the prosecution, and at these the accused have explained their views. In articles in the general and the medical press the question is being discussed from every point of view. The public trial, which will be held in Stuttgart, is likely to be sensational.

DEAFNESS AFTER TRICHINOSIS.

In Stuttgart a year ago cases of trichinosis resulted from the consumption of bear's ham in a restaurant.[1] In one of the patients, who was conveyed three weeks later to the hospital in a somnolent state with sharp muscular pains, total deafness developed, without giddiness and without nystagmus. Otological examination showed that a toxic neuritis of the acoustic nerve was present. The patient was discharged two months after the poisoning, but did not recover her hearing.

---

[1] THE LANCET, 1930, i., 937.

UNIVERSITY OF SHEFFIELD.—The chair of medicine at Edinburgh University has been offered to Dr. Albert Ernest Naish, F.R.C.P., who is at present lecturer on medicine at Sheffield. Dr. Naish has accepted the offer.

PUBLIC HEALTH SERVICES

A YEAR OF HEALTH IN SCOTLAND.

THE year 1930 was a peculiarly difficult one for the Scottish Health Department on account of widespread unemployment and the recent changes in local government. The approved societies have had to face a loss of income from their present members and the loss of the normal inflow of new young members, as well as increased outgoing for health insurance. The continuance of unemployment much longer on the present scale would create an anxious situation. The only good result of the unemployment that can be set against the suffering it has caused is the improvement and extension of public works that many local authorities have been persuaded to undertake to relieve the distress. The second annual report of the Department of Health[1] regrets that there has not been similar progress in town and regional planning. Only 11,056 houses were built during the year, which means that the output of new houses for the working classes has done little more than keep pace with the year's depreciation of old buildings, and there is still a shortage of 100,000 houses. The Housing (Scotland) Act, 1930, is, however, being well received by the local authorities, and there is evidence of a comprehensive and vigorous housing programme for the next three years. Reference is again made to the Edinburgh Town Planning Scheme, which differs from the ordinary scheme in that its object is to preserve and protect the features of an area already built up. Seven town councils passed resolutions during the year to prepare schemes for the unbuilt parts of their areas.

Local authorities have been active on water-supply and drainage schemes during the year. In July and August the Health Department issued inquiries as to the state of the water-supply in various districts, and a scrutiny of the replies showed that in many areas there was no margin for future extension and that in some the supply was not above suspicion; there has been considerable improvement. Energetic measures have been taken to prevent the pollution of rivers, and to improve the methods of refuse-collection and disposal. The Education (Scotland) Act, 1930, conferred power on local authorities to supply certified milk to school-children out of the education funds. An investigation into the effect of a daily ration of milk on 10,000 children in 67 Lanarkshire schools showed a definite increase in both height and weight over the controls. These two events gave the tubercle-free milk industry a valuable advertisement. The annual reports of veterinary inspectors under the Milk and Dairies Act provided an opportunity for ascertaining the number of tuberculous cattle in the country; the figures showed that 0·35 per cent. of cattle examined during 1929 were tuberculous. This, of course, is not the whole picture but, even after making allowance for additional factors, the figures are reassuring. An increased demand for tubercle-free milk would help towards the eradication of tuberculosis by the producers themselves.

Maternity and Child Welfare.

The past year has been one of consolidation and reorganisation rather than of extension. It is hoped that the correlation of the services for the pre-school child with the services provided by the educational authority will ensure a continuous care of the child from infancy to adolescence. The schemes for maternity and child welfare are based on home visitation, and at the end of 1930 there were 122 whole-time and 478 part-time health visitors in this service. There are two training institutions for these women in Scotland, and 45 new nurses were trained during the year. At the end of 1930 there were 202 centres for the medical examination of mothers and children, for instruction in the general hygiene of maternity and childhood, and for cookery and sewing demonstrations. The maternal mortality-rate for the five years ending 1929 was 6·6 per 1000 but, owing to different methods of classification, the statistics for Scotland are not strictly comparable with those for other countries. Of the total births during the year 1929 about one-half were attended by doctors and one-third by midwives, while one-sixth occurred in maternity institutions. A few local authorities provide home helps, and their service is much appreciated. The Central Midwives Board for Scotland have had under consideration a proposed addition to their rules, requiring the midwife to notify the local authority when a patient has not accepted her advice to consult a medical practitioner or attend a clinic during pregnancy. This arrangement has worked very well in Dundee for some time. The infant mortality-rate was 83 per 1000 births; there was a big increase in infant deaths at the end of the year, mainly due to respiratory trouble during foggy weather. Up to that time the conditions in the country had been favourable to a low mortality-rate. The spring epidemics of measles and whooping-cough were mild.

The pre-school death-rate (between the ages of 1 and 5) was 10 per 1000, the commonest causes of death being pneumonia, measles, and whooping-cough. Although there has been an improvement in recent years, children entering school are still found to have defects which might have been avoided or ameliorated by adequate supervision in the pre-school period. Mothers have learnt the importance of regular care for the infant, but have not yet realised that it is just as important for the toddler. Scotland hopes to solve the problem of her pre-school child by the education of parents; by the development of existing services of home visitation, centres, nursery schools, and day nurseries; and by the extension of the school medical service to provide for medical inspection of pre-school children at the time when the older members of the family are inspected.

A review of the medical inspections of school-children shows that on the whole children are better clothed and cleaner and suffer less from malnutrition, rickets, and defective teeth than they used to. The improvement is more pronounced in leavers than in entrants. One of the most striking testimonies of progress comes from Ayrshire, where the percentage of children with sound teeth has risen from 31·5, in 1925–26, to 56·5.

Hospital Services and Notifiable Diseases.

An outstanding problem before the new authorities is the improvement of the poor-law hospitals, which, with a few exceptions, are definitely below modern standards in construction, equipment, and staffing arrangements. A general movement towards raising the standards of medical treatment of the sick poor is anticipated, and the department hopes that the improvements will be carried through in coöperation with voluntary hospitals, universities, and other interests.

---

[1] H.M. Stationery Office. 1931. Pp. 214. 3s. 6d.

The tuberculosis death-rate continues to fall: the figure for 1930 was again a record—88 per 100,000. The greatest relative improvement in both pulmonary and non-pulmonary forms has taken place in both sexes at ages under 15. The accommodation in approved institutions is now about 5000 beds, and there was no increase in this number during the year.

There was a severe outbreak of small-pox in Aberdeen during the summer, but apart from this there was no small-pox—even of the mild type—in the country. There was considerably more enteric fever than usual, and in some cases the source of the outbreak could not be traced. The Dumfriesshire outbreak, affecting 61 persons, was eventually attributed to a careless farm servant, whose fæces were infected with the bacillus, and a faulty field-drain from the farm lands in close proximity to faulty joints in the pipes leading from the springs to the reservoir tanks.

In 1926 60 beds at the Stobhill Hospital, Glasgow, were set apart for cases of encephalitis lethargica recommended by the Department. This accommodation has always been full and the waiting list long. Last year, therefore, the arrangement was terminated and the local authorities were invited to provide beds for their own cases. The Department expects that this will result in a considerable increase in the number of beds available.

Scientific Work.

During the year a Scientific Advisory Committee was appointed to assist the Department in applying the results of scientific research to the details of public health administration and in promoting such medical investigations as come within the sphere of the Department and of the local authorities. It is hoped that this committee will bring before the Department and the local authorities such discoveries as are of immediate application and the directions in which new knowledge should be sought.

Important developments have taken place in the arrangements for certification of the blind. In 1929 the Glasgow joint committee established a central clinic where persons claiming to be blind were examined by two ophthalmic surgeons. To regularise the position throughout the country the Department have recommended the establishment of similar clinics in other centres, and proposes to convene a conference of ophthalmic specialists to consider a standard form of medical certification.

ACCOMMODATION IN PUBLIC MENTAL HOSPITALS.

WARNING BY THE BOARD OF CONTROL.

THE Board of Control has sent a memorandum to local authorities pointing out that the demand for treatment without certification is likely to increase as the facilities of the Mental Treatment Act become more widely known. At the same time the shortage of mental hospital accommodation generally has become acute, and will oblige many authorities to consider what steps should be taken if they are to maintain a reasonable standard of efficiency and progress. Though there may be no increase in the incidence of mental disorders, the number of persons under care continues to rise because the total population and the average age of the population are both increasing.

There is now hardly any margin of accommodation in the public mental hospitals. On Jan. 1st of this year there were only 27 hospitals with ten or more vacant beds on the male side, and 19 with ten or more vacant beds on the female side. Thus, there are almost no unoccupied beds the use of which authorities can obtain by contract with other authorities; moreover, the practice of taking beds on contract, though useful in special circumstances, is strongly to be deprecated if it involves sending patients so far from their homes as to make visiting by their relatives prohibitive by the expense.

The standard of accommodation laid down by the Board is regarded as a minimum standard based on long experience, and a departure from it would be injurious. Overcrowding is not only bad for the patients' mental and physical condition, but imposes unnecessary strain and may involve danger for the nursing staff. Local authorities will, therefore, have to consider increasing the accommodation for mental patients, and there are two main ways in which this can be done—viz., either by redistribution of patients among the various types of institutions now under the control of the authority, or by the provision of new mental hospitals.

As regards redistribution there are four possible alternatives:—

(1) The utilisation of beds in public assistance institutions for the quiet chronic cases or senile cases, whose condition does not necessitate treatment of the kind that can only be given in the relatively more expensive beds of a mental hospital;

(2) The removal from mental hospitals of mental defectives who can be far more economically provided for in poor-law premises or in mental deficiency colonies;

(3) The granting of leave of absence on trial and boarding out, or discharging suitable patients to the care of relatives or friends;

(4) The provision in connexion with an existing mental hospital of an admission unit and convalescent villas where these do not already exist. In this connexion it is pointed out that every mental hospital, whether full or not, should have this accommodation, which has become imperatively necessary in view of the provisions made for the treatment of voluntary and temporary patients under the Mental Treatment Act.

The second main alternative is the construction of new mental hospitals, and the Board point out that there will be some authorities who will find themselves compelled before long to build such institutions. Local authorities which have no right of ownership in any mental hospital and which, therefore, have to secure by contract beds for patients for whom they are required to provide accommodation, are particularly concerned with this aspect of the question. As the shortage of accommodation generally becomes more acute, notices terminating existing contracts are being given, and some authorities will have no alternative but to make provision themselves.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED MAY 23RD, 1931.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 111; scarlet fever, 1381; diphtheria, 824; enteric fever, 37; pneumonia, 910; puerperal fever, 47; puerperal pyrexia, 103; cerebro-spinal fever, 56; acute poliomyelitis, 7; encephalitis lethargica, 10; dysentery, 10; ophthalmia neonatorum, 88. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on May 26th-27th was as follows:—Small-pox, 160 under treatment, 8 under observation (last week 200 and 8 respectively); scarlet fever, 1223; diphtheria, 1420; enteric fever, 13; measles, 181; whooping-cough, 417; puerperal fever, 32 (plus 11 babies); encephalitis lethargica, 180; "other diseases," 152. At

St. Margaret's Hospital there were 15 babies (plus 3 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 1 (0) from enteric fever, 28 (4) from measles, 4 (1) from scarlet fever, 22 (8) from whooping-cough, 21 (1) from diphtheria, 47 (8) from diarrhœa and enteritis under two years, and 54 (6) from influenza. The figures in parentheses are those for London itself.

One death from small-pox reported for the month of April was provisionally assigned to Market Bosworth R.D., Leicestershire. West Hartlepool reported the only death from enteric fever. Only 3 deaths from meningococcal meningitis occurred in London. Six deaths from measles were reported from Leeds, 3 each from Liverpool and South Shields. Liverpool reported 3 deaths from whooping-cough. Diphtheria claimed 6 victims at Liverpool, 2 at Bootle. Diarrhœa was credited with 7 deaths at Manchester, 4 at Liverpool, and 3 each at Wolverhampton and Birmingham. Birmingham reported 7 deaths from influenza, Manchester 5, Stoke-on-Trent 4, Bristol and Barnsley each 3.

The number of stillbirths notified during the week was 301 (corresponding to a rate of 43 per 1000 births), including 46 in London.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lt. M. Barton to be Surg. Lt.-Comdr.

The following appointments are notified: Surg. Lts. L. J. Corbett to *Royal Oak*, and S. Jenkinson to *Lupin*.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Sub-Lt. A. J. W. Beard to be Surg. Lt.

Surg. Lt. D. M. Craig is appointed to *Warspite*.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. G. Ormrod retires on retd. pay.

Lts. J. J. O'Dwyer and S. R. M. Mackay to be Capts.

Lt. (on prob.) T. M. Corcoran is confirmed in his rank.

A. Macdonald to be Lt. (on prob.) and is secd. under the provisions of Art. 213, Royal Warrant for Pay and Promotion.

ARMY DENTAL CORPS.

Lts. A. K. Inglis, W. McD. Birse, W. P. Baxendine, and N. I. Macmillan to be Capts.

TERRITORIAL ARMY.

Capt. E. J. B. Sewell, from R.A.V.C., T.A., to be Lt.

D. B. Purves (late Cadet Offr., Edinburgh Univ. Contgt., Sen. Div., O.T.C.) to be Lt.

ROYAL AIR FORCE.

R. N. Kinnison is granted a Short Service Commission as a Flying Officer for three years on the Active List.

RESERVE OF AIR FORCE OFFICERS.

Flight Lt. R. F. T. Grace ceases to be employed with the Regular Air Force.

INDIAN MEDICAL SERVICE.

Lt.-Col. F. J. Kolapore retires.

Lt. H. N. Dewan relinquishes his temp. commn.

GUY'S HOSPITAL: ANNUAL REPORT FOR 1930.—Last year the record number of 12,249 in-patients were treated, an increase of about 450. Their average stay was approximately 17½ days, as compared with 18 days in 1929; the average number of beds in daily occupation was raised from 553 to 563. The report regards these improvements as "visible proof of skilful medical attention and studied organisation." The average weekly cost of each in-patient was £4 15*s.* 8*d.*, a fractional reduction. There were 123,791 new out-patients; they cost an average of 8*s.* 1*d.* each, an increase of 5*d.* The rate of mortality again moved downwards, being 4·8 per cent. for all patients and 3 per cent. for surgical cases; these are the lowest recorded figures. There were 9120 administrations of a general anæsthetic, exclusive of 6618 administrations in the dental department. For five years past income has failed to meet expenditure, and in 1930, for the second time in that period, the year's deficiency exceeds £20,000. Less than one-third of the annual expenditure of nearly £200,000 is provided from endowments. That income is slowly rising, as are payments by patients, but voluntary gifts are apparently stationary, while legacies, fluctuating widely from year to year, seldom form an important feature in the year's budget.

GENERAL MEDICAL COUNCIL.

PRESIDENT'S ADDRESS.

AT the opening of the 133rd session of the Council on June 2nd, Sir DONALD MACALISTER referred to the loss to the Council and the science of medicine from the death of Prof. Lorrain Smith, representative of the University of Edinburgh; to the death of two former members of the Council, Dr. James Alexander Adams and Prof. David Hepburn; and to the honour bestowed on Sir Ashley Watson Mackintosh, representative of Aberdeen.

RECIPROCAL RELATIONS.

"The Privy Council," said Sir Donald, "have informed us that, in consequence of recent rearrangements with *self-governing Dominions* empowered to enter into independent agreements with other countries, it may be necessary to revise the terms under which, pursuant to the Medical Act, 1886, His Majesty in Council ensures to 'the registered practitioners of the United Kingdom' reciprocal privileges of practising abroad. The matter is still under consideration, but it will probably involve the revision of the somewhat diverse conditions now governing medical reciprocity both with foreign countries and with the overseas portions of the British Empire. The Union of South Africa, and the Province of Manitoba, in particular, desire that modifications in the scope of the reciprocal privileges they offer to practitioners on our Register should be contemplated in this country. Correspondence on the subject is still proceeding.

"In regard to Indian qualifications, I am able to report only that the Bill for the establishment of an All-India Medical Council, to supervise and guarantee the standards of medical education throughout that country, is still in process of drafting. It is not yet ready to be submitted to the Indian Legislature. Meanwhile, questions incidental to the general subject are calling for prompt consideration and solution, and suggest that the need for central legislation is not becoming less urgent."

PHARMACY.

"At the instance of the Government, a Poisons and Pharmacy Bill, which has passed the House of Lords, is now before the House of Commons. It gives effect, with certain amendments, to the recommendations of the recent Departmental Committee, of which I was a member, for the better regulation of the profession of pharmacy, and of the definition and classification of poisons by the aid of a statutory Advisory Board. On this Board, under the Secretary of State for Home Affairs, the General Medical Council, as the body concerned with the issue of the British Pharmacopœia, is to nominate a member. I was invited, as your President, to attend at the Home Office a conference on the Bill between the authorities and representatives of the medical profession. Explanations were given and suggestions were considered on the scope and effect of the several clauses, as bearing on medicine, and I think I may say that when the conference rose, its members were reassured that the proposed legislation was in the public interest, and free of risk to the efficient practice of medicine in any of its branches.

"The Secretary of State has communicated to the Council certain proposed new regulations, amending those of 1928 concerning dangerous drugs, and exempting from their purview certain preparations containing one of these drugs in negligible proportions. This exemption will be for the convenience of the prescriber, without giving rise to any danger to his patients."

EDUCATIONAL CURRICULUM.

In pursuance of the report of the Joint Education and Examination Committees, Sir Donald said he had written to the Minister of Health calling attention to the desirability of making further accommodation available for the teaching of practical obstetrics to medical students. The Minister had sent a sympathetic reply, which had been referred to the Joint Committee, which had been considering this subject and the place of preventive medicine in the medical curriculum.

In 1922 the Council issued revised recommendations on the course of study and examinations to be required of candidates for degrees or licences in dentistry and dental surgery. These had been generally followed by the licensing bodies, but it appeared that certain expressions in the recommendations were so ambiguous or ill-defined that widely varying interpretations had been put upon them. A need had thus arisen for greater uniformity of standard in reference to the requirements for dental qualification, particularly as regards such general subjects as anatomy, physiology, pathology, medicine, surgery, hospital practice, and the like. It was, said Sir Donald, the duty of the Council, under Section 22 of the Dentists Act, 1878, to seek and to procure precise information "as to the course of study and examinations to be gone through to obtain" dental certificates and licences, "and any person or persons deputed for this purpose" by the Council "may attend and be present at any such examinations." The Dental Education and Examination Committee reported that in their opinion the time had come to make detailed inquiry into the working of the Council's recommendations, and that for this purpose the Council should now authorise the appointment of one or more deputy-visitors of the dental examinations.

OVERSEAS STUDENTS.

The Committee on Foreign and Colonial Students had brought into operation the method approved by the Council last November for dealing with applications from students from the United States for permission to pursue medical study in British schools. A regular interchange of evidence and certificates between the American authorities and the Council had been arranged, and the information forwarded from America had been singularly definite and helpful. It had enabled medical schools and licensing bodies to check and decide upon applications with full knowledge of the qualifications and eligibility of candidates for admission, and had been welcomed by deans and other authorities on this side. It had also contributed to a better international understanding between the medical bodies in the two countries, and to the maintenance of the standards of medical education.

COMMITTEE WORK.

The Pharmacopœia Committee had received an encouraging report on the progress made by the Pharmacopœia Commission in the drafting of the new British Pharmacopœia. The draft text was being printed, and proofs of a considerable portion had been received. But much remained to be done, and it was now doubtful whether the hoped-for issue of the new volume could be completed this year. The audited accounts for 1930 showed that the finances of the Council as a whole, in spite of heavy expenditure on the visitation and inspection of examinations, and on the preparation of the new Pharmacopœia, were in a satisfactory condition, and the anticipated surplus had been restored.

PROPOSED ENLARGEMENT OF THE COUNCIL.

The Representative Body of the British Medical Association had forwarded an expression of their opinion that the time had come for the addition to the Council of a fifth representative of the registered medical practitioners in England and Wales, and the request that the Council should take appropriate steps to this end. Section 10 of the Medical Act, 1886, said Sir Donald, empowered the General Council to represent to the Privy Council ". . . that it is expedient to confer on the registered medical practitioners resident in any part of the United Kingdom the power of returning an additional member to the General Council." One such application was made in 1909, and was granted by the Privy Council in August *of that year, and they were informed that this application* did not exhaust the powers of the Council under Section 10 (c). The General Council must decide the question itself. Under Sections 6 and 9 of the Medical Act, 1858, it could not delegate the application to the Branch Council for England or the Executive Committee.

The President also alluded briefly to the forthcoming centenary of the Leeds School of Medicine, to the duties of medical practitioners in regard to cremation, and to the large entry on the Register of new practitioners (1490) and medical students (1792), the numbers being the highest for some years.

At the conclusion of his address a vote of thanks was proposed by Sir Holburt Waring and seconded by Sir Norman Walker. The appointment of Dr. Sydney A. Smith as representative of the University of Edinburgh was announced. The Council then passed to the consideration of disciplinary cases.

HUGHLINGS JACKSON MEMORIAL FUND

FURTHER *subscriptions to this fund have been* received from Dr. Willoughby Lyle, Dr. W. R. Bett, Mr. Holmes Spicer, Dr. J. A. Arkwright, Dr. Foster Kennedy (New York), Dr. Percy Smith, Mr. R. R. James, Dr. H. L. Tidy, Dr. Batty Shaw, Dr. Nathan Raw, Dr. F. J. Nattrass, Sir J. Herbert Parsons, Mr. Ernest Clarke, Dr. Donald Core, Dr. Hinds Howell, Dr. G. M. Griffiths, Dr. F. L. Golla, Dr. Bernard Hart, Dr. Seymour Davies, The Osler Club, and Prof. Otfrid Foerster (Breslau). The fund now amounts to nearly £900, towards the £1200 required.

BIRMINGHAM CRIPPLES' HOSPITAL: ANNUAL REPORT. Although there was last year an increase in the number of patients, many of the cases required shorter treatment, particularly among the children. The annual report points out that this improvement is to a great extent attributable to those voluntary organisations which have roused public opinion so that health and education committees throughout the country are pledged to see that adequate arrangements exist in their areas for the orthopædic treatment of children. The general improvement in public health services also has made for the earlier ascertainment and consequent earlier treatment of the cripples. The waiting-list is, however, longer than ever. Patients paid £3388, often in small weekly instalments. The income was £30,153, which came within £747 of the expenditure.

OBITUARY

SIR HERBERT WATERHOUSE, M.D. Edin., F.R.C.S. Eng.,

CONSULTING SURGEON TO CHARING CROSS HOSPITAL.

THE death of Sir Herbert Waterhouse on May 23rd deprives the medical profession of a well-loved surgeon and clinical teacher whose name had been associated with the Charing Cross school for more than 30 years. Until the spring of last year, when he was the victim of a motor accident, he had always enjoyed the best of health. He was walking near his own door when two motor vehicles in collision drove on to the pavement and pinned him against the railings, causing injuries which rendered him unconscious for over two hours and, as the sequel showed, inflicted damage on his spine. He made a good recovery and was able to enjoy his usual fishing holiday in the late autumn. But early in the present year he developed symptoms of spondylitis in one of his lumbar vertebræ which crippled and disabled him. Death came suddenly as the result of pulmonary embolism.

SIR HERBERT WATERHOUSE.

[*Photograph by Thos. Fall.*

Herbert Furnivall Waterhouse was born in London in 1864, the son of the Rev. C. J. Waterhouse. He received his medical education in the University of Edinburgh, where he graduated M.B., C.M., with distinction in 1887, and two years later as M.D. when his thesis was awarded a gold medal. After graduation he served as house surgeon in the Royal Infirmary, Edinburgh, and a year later as house surgeon to Sir William Macewen in the Royal Infirmary, Glasgow, an experience to which he always looked back with satisfaction. His academic standing in his own university and in its social life was recognised by his election as President of the Royal Medical Society. After taking the F.R.C.S. Eng. in 1890, he entered the medical school of Charing Cross Hospital as demonstrator of anatomy in 1890, and a year later was elected on the staff as assistant surgeon. The remainder of his professional life was given whole-heartedly to this school and hospital: to the school as lecturer on anatomy 1897–1901, and as dean 1901–1906; to the hospital as assistant surgeon 1891–1903, as surgeon 1903–1929, and thereafter as consulting surgeon. His other chief hospital interest was as surgeon to the Victoria Hospital for Children, Chelsea, of which he was a zealous officer for many years.

Waterhouse's influence upon surgery at Charin Cross was great, and his work there was an inspiratio to many a student to take up the practice of surger in earnest. It was, indeed, a well-founded boast tha three of his house surgeons had been appointed t the surgical staff. As a surgeon, writes Mr. Norma Lake, he was rapid and dexterous, impatient of dela and incompetence, quick to distinguish the usefu from the valueless innovation, sometimes ove enthusiastic, always brilliant, and, as a corollary o such a temperament, with little capacity for sustaine interest or tedious hackwork. He was largel responsible, through a paper published with W. S Fenwick in 1910, for the introduction into thi country as a routine of the iodine method of ski preparation. Only those who remember how irksome and complicated were the methods previously i use will appreciate the immense saving in time and material the newer method brought about. Some years before this, while in Germany, he had carried out fruitful research on streptococcic infections o the peritoneum and the importance of the *locu resistentiæ minoris.* It was in diagnosis, however, that his talents best appeared. Trained in the older clinical school, before the radiologist and biochemist could give much help, he had developed what for lack of complete analysis we still have to call surgical instinct. Those who worked with him could relate many cases in which an apparently astounding diagnosis was made only to prove correct on the operating table, or where a refusal to operate, upon no obviously sufficient grounds, was followed shortly afterwards by the patient's death from some inevitable cause which surgery could not have prevented. Another of his pupils, Mr. Jennings Marshall, writes of his intensely practical faculty of fixing on the essential and conclusive, and disregarding the inessential. The same power made him a superb abdominal surgeon particularly in acute cases—in these his results were unrivalled. His was always the direct, straightforward method; he had mastered the secret of knowing when to stop. For anything tedious or involving finicky attention to detail he had little patience, nevertheless in vital points of operative technique he was meticulous and his work was neat and quick. It was a great pity he could not be induced to place on record his rich clinical experience, for there is no doubt that he could have written in an arresting manner and with a freshness of viewpoint given to few.

As a teacher of both systematic and clinical surgery he excelled. His lectures, always full of anecdote, were for that very reason well remembered long after more formal teaching had faded into uncertainty. Yet, Mr. Lake adds, it will be not so much for his abilities as a surgeon and teacher that he will be long remembered as for the enthusiasm he was able to inspire in others and for the helpful encouragement he gave to his juniors. His popularity rested upon more than his abounding geniality; it depended primarily upon a deep-seated appreciation of his abilities, of his enthusiasms, even of the occasional inconsistencies which rendered his personality the more attractive, and of his unstinted help to all those who found themselves in difficulties whether technical, tactical, or ethical. Very few teachers and chiefs, Mr. Marshall says, can have had more influence in getting the best out of his subordinates and in spurring them on to effort; indeed, if Sir Herbert had made up his mind on a certain course for one of his men, there was little peace until this was adopted. His help was available, however, far more than in a professional sense, and to all whom he had taken under his wing he was guide, philosopher, and friend, prepared to smooth out troubles and bothers. He was constantly being appealed to for advice and help, and as constantly acting as peacemaker.

During this period of his life Waterhouse was a member of the council of the Royal College of Surgeons and of its court of examiners; he examined in surgery at the Universities of London, Manchester, Birmingham, and Liverpool. These were to him not mere duties; he took pride in the academic successes of the candidates. He was also President of the Clinical Section of the Royal Society of Medicine. Early in the war he became associated with a remarkable enterprise. Queen Alexandra, hearing that the Russian Army was deficient in hospital equipment, appointed a committee to collect funds for a hospital to be sent to Russia to assist the army on the Eastern front. This Anglo-Russian Hospital was put under the charge of Lady Muriel Paget as organising secretary, Dr. Andrew Fleming as commanding officer, and Waterhouse was appointed the principal surgeon. The unit proceeded to Petrograd in December, 1915, where with the help of Russian doctors and nurses the hospital was started in the wing of the Grand Duke Demetri's palace with accommodation for about a hundred patients. In the following summer a field hospital was also commissioned and sent to the front attached to the Imperial Guards and under the command of the famous General Brusiloff. During the summer this hospital took part in his attack on the Austrian Army, which was so successful that nearly 400,000 prisoners were captured. The difficulties experienced by the organisers of the hospital were enormous, and it was due to Waterhouse's experience and discretion that they were to a large extent overcome. One of his surgical colleagues writes: "Always cheerful and hopeful under the worst conditions he gave encouragement to everyone around him. With the able assistance of Dr. Fleming the hospital created a good impression and soon became popular. Waterhouse was recognised as a surgeon of outstanding ability. Speaking French fairly fluently and in time acquiring a certain amount of the Russian language, he was an admirable chief in a very fine unit. To the Russian wounded he was always sympathetic and they accepted his advice without hesitation." He remained with the hospital for about a year, most of the time in Petrograd, after which he returned to England because he found that there was not enough work in Russia. Largely as a reward for his services in this hospital he received a knighthood.

In his later years Sir Herbert Waterhouse became closely associated with the work of the Medical Defence Union of which he had been a member since 1894. He was elected a vice-president in 1922 and president in 1925. The council of the Union, in making itself widely representative both of important medical schools and of the manifold specialties, had increased in numbers to such an extent that under a weak chairman its meetings might have become protracted and inefficient, but in managing the discussions Waterhouse showed the tact and decision required to cut short irrelevance without ever unduly pressing his own view. Everyone with a well-considered point to bring forward got a fair and courteous hearing and knew that he would get it. And his conduct in the chair was only a small part of Waterhouse's value to the Union. In constant conferences with the officers, in frequent personal interviews with such members as might be receiving the advice and assistance of the Union, in arranging for the best expert evidence on behalf of members attacked in the courts, and in whole-hearted devotion to every aspect of the Union's work, including that of finance, he expended time and energy ungrudgingly. True he took a never-ending delight and interest in the work, but none the less the whole profession owes his memory a debt of gratitude for labours which have benefited directly or indirectly all who practise medicine.

Amid these various professional interests Sir Herbert Waterhouse took an equally keen interest in other aspects of social life and enjoyments—e.g., in his relaxations as an angler and in the friendships which he formed with those of literary, journalistic, and theatrical tastes at the Savage Club, where his loss will be deeply felt. In 1892 he married Edith Florence, daughter of J. G. Harker, of Middleton, St. George, Durham. Lady Waterhouse died in 1929, and he is survived by two daughters.

HENRY JOHN BLAKESLEY, F.R.C.S.Eng.

Mr. H. J. Blakesley, who died on May 16th at the age of 73 years, was consulting surgeon to the Leicester Royal Infirmary. A student of Queen's College, Birmingham, and University College, London, he qualified in 1880 and went to Leicester as assistant medical officer to the Leicester and Rutland Asylum. Surgery was, however, from the first his aim and he gave up asylum work for general practice, with appointments as surgeon to the Provident Dispensary and the Wyggeston Hospital. In 1889 under the tutorship of the late Mr. Charles Stonham he took the F.R.C.S. Eng. and joined the surgical staff of the infirmary. After serving his time as assistant and full surgeon, instead of retiring from public work he accepted charge of the male clinic for venereal diseases. Here his attention to detail and kindly sympathetic manner attracted a large number of patients, of whom but few defaulted. Dr. Christopher Rolleston writes of the disappointment which he felt that so few of his colleagues availed themselves of the extensive material available for study in the clinic, but when practitioners did come they were sure of a welcome and ample opportunities of acquiring clinical and manipulative skill. He was specially interested in the technique of the treatment of syphilis. Most of the injections of "606" were given by him or under his direct supervision. He adhered to the gravity method which implies much expenditure of time, and had remarkably few cases of dermatitis or jaundice. As regards gonorrhœa, he applied tests of cure of a stringency rarely found elsewhere than in America or Germany. Colonel Blakesley died, Dr. Rolleston adds, as he had wished, in the hospital and wards he loved so well, quite suddenly without anguish, loved and respected by all.

WILLIAM DOBINSON HALLIBURTON,
M.D., F.R.C.P.Lond., F.R.S.,

EMERITUS PROFESSOR OF PHYSIOLOGY, KING'S COLLEGE, LONDON.

Prof. Halliburton, whose death on May 21st was announced in our last issue, will be remembered as one who helped to build medicine firmly on a basis of exact science. In days when chemists who were alive to the biological bearings of their science were much rarer even than the physiologists working on the chemical side of theirs he, like Gamgee in Manchester, upheld in London the importance of the chemical study of physiology, in the years just before the organic chemists led by Emil Fischer began systematically to explore biological fields, and before physical chemistry had come to be a specialised science or its biological applications been appreciated. His book on chemical physiology marked an era. It kept alive through dark laborious years the fire that has blazed up since so brilliantly, and no one in England had greater cause for pride in the justification of the faith to which he devoted his life. Physiology in England owes a debt to Halliburton which the Physiological Society has endeavoured to convey in the affectionate esteem with which it has regarded him for more than 40 years.

William Dobinson Halliburton was born in London on June 21st, 1860, the son of Thomas Halliburton, of Upper Norwood. He was educated privately and at University College School, under the headmastership first of T. Hewitt Key and then of H. W. Eve. In October, 1877, he entered University College as a science student, later transferring to the study of medicine and graduating B.Sc. in 1879, M.B. in 1883, and M.D., qualifying for the gold medal in 1884. He then held several resident posts at University College Hospital, but was soon diverted by the teachings of Burdon Sanderson and Schäfer into the attractive byways of physiology. He had been Sharpey physiological scholar at University College and in 1885 was awarded the science research medal and the Fellowship of the College. In 1887 he became assistant to Schäfer in the chair of physiology, a post which he resigned three years later when he succeeded Gerald Yeo in the corresponding chair at King's College. During this period he was also lecturing on physiology at the London School of Medicine for Women.

PROF. HALLIBURTON.

[*Photograph by Elliott and Fry.*

At King's College (in the words of his successor, Prof. R. J. S. McDowall) Halliburton gathered round him a number of able investigators—Brodie, Locke, C. J. Martin, Rosenheim, Da Fano, to name but a few—and many men now most distinguished clinicians were his pupils. He came particularly in contact with Ferrier and Mott, and there is little doubt that in some part this association was responsible for his making a special study of the chemistry of nervous tissues. It is interesting to remark that it was his researches, and those of Rosenheim in his laboratory, which led to the discovery that cholesterol might contain as impurity ergosterol, in which we now know vitamin D is developed under the influence of ultraviolet light. In these researches there is an untapped mine of knowledge still to be drawn upon in the interests of medicine. His biochemical laboratory—improvised in a corridor, and the first in London—rapidly became the Mecca to which large numbers of young biochemists came for instruction and inspiration. His early work was largely in relation to the biochemistry of the proteins of muscle and blood. For this work he was made a Fellow of the Royal Society in 1891. In the nature of things many of his discoveries have passed from current knowledge, but they will ever stand as essential stepping-stones in the advance of knowledge of the subject. He did not, however, confine himself strictly to biochemistry. With W. E. Dixon he carried out researches on the cerebral circulation and the cerebrospinal fluid. He was one of the founders of the Biochemical Society, of which he was the only honorary member.

Of Halliburton's relations within the College, something was told at the memorial service by a former colleague, Prof. E. Barclay-Smith. There was never, he said, a more devoted friend, a more loyal supporter of King's than Halliburton. Service to the college was his life and in many ways he was the life of the college. All who knew him will agree that he simply radiated sympathy, gentleness, and kindness. He was never known to speak unkindly of or to a colleague. In the many meetings over which he presided he would often listen with the utmost patience to a colleague with whose opinion he might differ, but never by look or word would he give pain to his opponent. For many years he served as dean of his faculty and from the day that Halliburton admitted a student he had the supreme gift of making that student feel that the dean was his friend, his confidant, his ever ready and constant help in time of trouble.

As a writer the name of Halliburton has become a household word in medicine and its allied sciences. Although he did all his writing with his left hand there is no internal evidence that his pen did not always run freely. The text-book of physiology which now bears his name has had a truly remarkable career. It was in 1848 that William Senhouse Kirkes, with the assistance of James Paget, brought out a handbook of 705 pages, expanding and revising the treatise by Johannes Müller then in vogue. The volume was (in a reviewer's words) lucid, precise, plain, and practical, and for 52 years and 13 editions it was associated with St. Bartholomew's Hospital and editors such as Savory, Morant Baker, Vincent Harris, and Klein. In 1896, on the advice of Sir William Gowers, Mr. John Murray asked Halliburton to take it over and under his guidance another 13 editions appeared in the next 21 years. Six more editions brought up the total number of copies issued to more than 125,000. And the book remained, as it started, lucid, precise, plain, and practical. No other medical text-book has shown such perennial youth and vitality. But Halliburton's greatest work was undoubtedly the Text-book of Chemical Physiology and Pathology which first appeared in 1891, a volume of 874 pages with 104 illustrations. The title was "chemical physiology" rather than "physiological chemistry," for it was Halliburton's aim to deal with the subjects from the point of view of their function in the body rather than from that of their chemical relationship one to another. This book became at once the vade-mecum of all who were trying to solve the problems of pathology from the side of chemistry. In his Essentials of Chemical Physiology he was successful in compressing into one handy volume all

CORRESPONDENCE

ADEQUATE TREATMENT OF SYPHILIS.

To the Editor of THE LANCET.

SIR,—Colonel Burke, in his article on this theme in your issue of May 23rd (p. 1127), assesses my influence on current practice in the treatment of syphilis much too highly. I have never flattered myself that any reader would accept my dicta without question, and have tried always to present the evidence with the argument so that the reader could form his own judgment. I have no wish to engage in a polemic with Colonel Burke, and write now only in order that the issue between those who advocate the practice of giving mercury or bismuth in the same course, and those who advocate first the administration of a course of arsenobenzene, then a course of mercury or bismuth, and so on, may be made clear. In both schools are workers whose opinions command the greatest respect, and I would ask the reader not to judge solely by what is said by either Colonel Burke or myself, but to refer to the original papers from which we have derived our evidence.

With regard to the respective merits of our different plans of treatment, apart from the question of neuro-recurrence, perhaps it would be best to reserve judgment until the results of the League of Nations analysis of case records has been published, and I would confine the issue here to whether or not the administration of arsenobenzene preparation alone in the first course of treatment of an early case of syphilis conduces more to the settlement of *Sp. pallida* in the central nervous (including the meningo-vascular) system, than does the practice of ensuring during the first course that mercury or bismuth is more or less constantly in circulation. I have presented evidence that it does in an article published in the *Practitioner* for February, 1931 (of which, so far as the supply will permit, I shall be glad to send a reprint to anyone interested), and in other publications, including No. 132 of the M.R.C. Special Report Series. Alurralde and Sepich, in a paper summarised in *Bulletin of Hygiene* (1930, v., 77), attributed the great increase in frequency of neuro-syphilis in Buenos Aires to the exclusive, or almost exclusive, use of arsenobenzene preparations. Against Colonel Burke's suggestion that the difference between his experience and that of Moore and Kemp in respect of neuro-recurrences may be due to his use of bismuth instead of mercury, and to the use of "606" by Moore and Kemp, is the fact that very many thousands of soldiers were treated during the war by a course of "606" and mercurial injections, and this admittedly inadequate according to present-day standards, yet the cases of clinically manifest neuro-recurrence discovered in them afterwards was negligible (see *Brit. Jour. of Venereal Diseases*, April and July, 1925).

Colonel Burke quoted an extract from Moore and Kemp's article in which it was stated that "it is absolutely unsafe to permit a patient with primary or secondary syphilis to pass a single day without the influence of a treponemicidal drug." This appears to me to favour the concurrent use of mercury or bismuth with the arsenobenzene preparation during at least the first course, because the experimental evidence is that even "606" is excreted so quickly that when it is used alone the patient is not under the influence of a treponemicidal drug for some days in each week of a course. The argument seems to apply with greater force to "914," the excretion of which is much more rapid than is that of "606," but perhaps Colonel Burke has evidence that stabilarsan is excreted more slowly. Colonel Burke states that there is no difference between our two lines of treatment in respect of clinical neuro-recurrence. This is true, but in Report No. 132 I suggested that for every case presenting clinical signs of neuro-recurrence there must be a number with only changes in the cerebro-spinal fluid, and in my other article I quoted some results of examinations of cerebro-spinal fluid by R. Bernard, which, so far as they go, support this view.

I am, Sir, yours faithfully,

Eccleston-square, S.W., May 30th. L. W. HARRISON.

To the Editor of THE LANCET.

SIR,—In reference to Dr. Tytler Burke's article may I make some comment on the section headed Therapeutic Economy. In the first place, any estimate of the value of a treatment of sero-negative primary syphilis must be based on a consideration of the blood and cerebro-spinal fluid five to ten years after infection in cases where reinfection is practically excluded. Dr. Burke has not observed his cases long enough, or adequately enough, to make more than an estimate of probable cures, and so his claim for 100 per cent. cures cannot be admitted. Colonel Harrison has made no such claim of 100 per cent. cures.

In the second part of this section Dr. Burke claims that his course has an efficiency index of 92, as compared with 79 for the St. Thomas's course. These numbers are based on computations and theories, about which may I put forward the following observations:—

(1) The relative therapeutic—i.e., spirochæticidal—value of a compound, although it very roughly varies with the chemotherapeutic index, does not do so in a mathematical manner, or, at any rate, this has not been shown. A much sounder mathematical expression of therapeutic value would be obtained by giving the inverse of the average time of disappearance of spirochætes from a lesion on exhibiting a standard therapeutic dose of the compound. Thus, supposing a dose of 0·011 g. arsenobenzene per kilo causes disappearance of spirochætes from a lesion seven days after infection in one day, and a dose of 0·006 g. per kilo of bisoxyl produced disappearance in similar cases in four days, then the chemotherapeutic value of arsenobenzene would be 1, and that of bisoxyl 0·25, instead of 0·5 (according to Dr. Burke's theory).

(2) A course cannot be judged on the intensity of therapeutic action taken as the average intensity per course, since some—e.g., Colonel Harrison—prefer a maximum intensity during the first three weeks with a long stretch of slighter intensity instead

---

(Continued from previous page.)

that would be likely to help the student or young practitioner in his approach to medicine from the biochemical side. Of special interest further were his Croonian lectures on the biochemical side of nervous activity, delivered before the Royal College of Physicians in 1901. In 1916 Halliburton was asked by the Physiological Society to take over the editorship of *Physiological Abstracts*, which in his hands became firmly established as a periodical of international importance.

of an even course of moderate intensity during a shorter period (Dr. Burke).

(3) According to Dr. Burke's theory a dosage of 0·45 g. stabilarsan per week is equivalent in spirochæticidal action to one of 0·6 g. per week, or, one supposes, of 0·9 g. per week. Each is considered to be one therapeutic unit. There can be few who had experience of the relative efficiency of large and small doses of salvarsan who would dream of accepting such an opinion.

(4) Dr. Burke's theory, although it apparently stresses the time factor, makes no real distinction between the heavy bombardment of spirochætes in a period of 48 hours or so by the intravenous arsenobenzols, and the continuous slow-fire of the bismuth over a period of a week or more. Good generalship demands a suitable combination of bombardment and slow-fire which is unrepresented by the figures in Dr. Burke's scheme.

All these considerations lead me to believe strongly that an evaluation of net therapeutic efficiency cannot be made by any very simple scheme, and also that Dr. Burke's scheme is definitely unsound.

I am, Sir, yours faithfully,

HOWARD ALLEN,

Assistant Medical Officer (V.D.), St. Thomas's Hospital.

May 29th, 1931.

To the Editor of THE LANCET.

SIR,—Dr. Burke is protagonist of what he calls the alternating regimen in the treatment of syphilis. He supports his arguments by an analysis of some 136 cases of sero-negative primary cases who have completed this alternating regimen, which he considers necessary to cure an early case. Most clinicians will be unable to accept an opinion based on so small a number of cases observed for an inadequate period. Further, in sero-negative primary syphilis it is well known that a small quantity of either arsenobenzol or bismuth is sufficient to produce an apparent cure. While I am averse to entering into a controversy on the relative merits of different forms of treatment, because many different methods are effective in attaining a cure, there are statements in Dr. Burke's article which, though plausible, have not been proved. There are also many statements which are not in accord with my clinical experience.

In our work here extending over a period of 17 years, the incidence of complications following on "concurrent treatment" with arsenobenzol derivatives in combination with bismuth or mercury has been extremely low. Some individuals are intolerant of arsenobenzol and bismuth preparations no matter what scheme of treatment is adopted. There are many factors which enter into the production of intolerance other than the drug(s) employed—e.g., septic foci, alcoholic indulgence. The periods of rest from treatment which Dr. Burke seems to deprecate are not provided to allow the patient to recover "from the toxic effects of the remedial agents administered." Experimental work and clinical experience show that arsenobenzol, bismuth, and mercury are cumulative in their effect and that a certain amount of the drug is not immediately absorbed but is stored in the tissues. The temporary rest from treatment allows the tissues to use up or eliminate the residue deposited in them.

Dr. Burke makes reference to nephritis as a common manifestation of intolerance in concurrent treatment. In our experience of close on 40,000 injections per annum it is one of the rarest complications. The production of Wassermann-fast cases is stressed as an argument against concurrent treatment. In cases of sero-negative syphilis, which Dr. Burke quotes, Wassermann-fast cases should be unknown. In generalised syphilis, with active florid lesions, a quite undue prominence is often given to Wassermann-fast cases; they are, in our experience, very rare if the patient is treated on the concurrent method. Dr. Burke's statement on "the mode of action of arsenobenzol compounds and of bismuth" is merely postulating a theory. There is no accepted scientific proof that bismuth, when injected into the body, produces a toxalbumin. The weight of experimental evidence tends rather to suggest that the mechanism of the action of bismuth is essentially similar to that of mercury, and is dependent on the ease with which the Bi-ions become dissociated, the latter being responsible for the spirochæticidal action. There is no proof that, as in the case of the arsenobenzol compounds, complex oxidation products, which are spirochæticidal, are produced. Clinical evidence also points to bismuth and mercury acting in a similar manner both in the production of toxic symptoms and in their therapeutic effects. Dr. Burke's statement that "mercury is inefficient and a mere waste of time" is not in accord with the experience of most clinicians. In conjunction with arsenobenzol it has resulted in a cure of many cases of syphilis, and in cases of late and latent syphilis there is still ground for thinking that it has a place in the therapy.

Under the heading of Therapeutic Economy Dr. Burke's attempt to calculate the theoretical efficiency of any one drug is misleading. No mathematical formula can take into account (1) the individual resistance of the patient, (2) the virulence of the infection, and (3) the many intercurrent factors such as focal sepsis, the behaviour of the patient, intercurrent illness, &c., which influence the course of the disease. The chemotherapeutic indices which Dr. Burke chooses to adopt for the respective drugs are arbitrary figures; there is no evidence, based on the treatment of human syphilis, to substantiate them, and animal experimentation is not always a reliable guide. No account is taken of the stimulation of natural immunity by the arsenobenzol preparations.

The success of treatment depends, in our opinion, more on a study of the needs of each individual patient and how far one caters for these needs. The same applies to defaulting from treatment. It is not so much how long a patient is asked to attend; it is more the power of the medical attendant to impress on him the need for continuity of treatment.

In his attempt to make out his case Dr. Burke has collected a series of assumptions and from these he lays down dogmatic rules of treatment. But what scientific proof is there:—

(1) That "606" has a greater traumatic toxic effect on nervous tissue than "914" and so predisposes to neurosyphilis?

(2) That mercury is inefficient and a mere waste of time?

(3) That the figures which he gives as the chemotherapeutic index for arsenobenzol compounds, bismuth, mercury, tryparsamide, &c., are applicable in human syphilis?

(4) That arsenobenzol compounds and bismuth act on the same "productive mechanism of the body" in the same way, or, even if we admit that they do so, that this mechanism is ever exhausted when reasonable therapeutic doses of each is given?

There is undoubted clinical evidence in support of the synergistic effect of drugs in other fields of medicine, and I fear that the tone of Dr. Burke's contribution will lead to confusion in the minds of readers who do not appreciate that many of his statements are mainly theory and not accepted *clinical* facts. It is possible to standardise a laboratory test; it is not possible, nor it is advisable to try, to standardise the treatment of a disease. There is the recognised necessity of treating the patient rather than the symptoms.

I am, Sir, yours faithfully,
DAVID LEES, M.B., D.P.H., F.R.C.S.,
Edinburgh, June 2nd, 1931. F.R.C.P. Edin.

THE CLEAN MILK PROBLEM.

To the Editor of THE LANCET.

SIR,—Many of us who are interested in the milk problem are much in sympathy with the letter of Dr. Stenhouse Williams and agree with it up to a point. While the work he cites on the nutritive side is interesting, nothing is said as to the weight of evidence on the other side, and my remarks "I do not think that its opponents have demonstrated, when efficiently performed, that it (i.e., pasteurisation) does any material damage to any known nutritional factor in milk, but the last word has not been said on this side and our knowledge is admittedly incomplete" are a fair statement. The recently issued Memorandum of the Ministry of Health[1] puts it much stronger and states as regards pasteurisation "Milk so treated appears to retain its valuable food properties practically unimpaired." But by all means let us have more studies of the nutritional values of different types of milk.

When Dr. Williams asks that any new legislation shall ensure the progress of the production of a clean milk which is free from disease it is not clear for what he is asking. My proposals advocate giving powers to the larger urban areas only to permit efficiently pasteurised milk or milk from herds certified free from tuberculosis and produced under cleanly conditions to be sold. The second group is surely what Dr. Williams wants to encourage. He evidently fears that the alternative provision of pasteurised milk will not encourage their multiplication. Here I do not agree, but in any event, their numbers are negligible now, except in the Reading area, and their rate of increase is of the slowest. If Dr. Williams and his colleagues can demonstrate the inferiority of pasteurised milk, that will be an excellent impetus to their production.

Behind these points is the old contention that any widespread system of pasteurisation will put back the clock as regards the production of clean milk. I think this is a probable and undesirable result and the evil should be minimised so far as possible. The operations of my proposals in their restricted and controlled form will do a good deal in that direction. The real answer, however, is to put the question—What is the alternative? Are we to continue indefinitely as at present with extensive infection of the milk-supply by tubercle bacilli, with no constructive scheme operating for the elimination of tuberculosis amongst our dairy cattle, with the risk and the actuality of milk-borne outbreaks of infectious disease (such as the extensive Hove-Brighton outbreak), with enormous numbers of bacteria as the normal contamination of our milk, with the agricultural interests failing to coöperate in the enforcement of the Milk and Dairies Order and indeed often actively retarding its enforcement, and with a material proportion of our milk-supply pasteurised by methods which are both undisclosed and unreliable in their operation? Dr. Williams will no doubt reply that there have been great improvements. There may be in the Reading area, and we all admire the magnificent educational and scientific work done by him and his colleagues there. Unfortunately it does not apply to the country generally, and does not affect the truth of the above statement. Like him, I should prefer to see provided a clean safe pure milk-supply without any heat treatment: but it is not in sight.

The large urban areas have no efficient means of safeguarding their milk-supply, and in view of the continued failure of the agricultural side to put their house in order, it seems reasonable to give them the opportunity of protecting it in the way I have indicated. I welcome measures to extend the number of herds free from tuberculosis and believe that financial assistance to that end is wise and necessary. With encouragement it should be possible to assure that an appreciable proportion of the milk sent to our cities is from such herds.

I am, Sir, yours faithfully,
May 26th, 1931. WILLIAM G. SAVAGE.

APLASTIC ANÆMIA.

To the Editor of THE LANCET.

SIR,—The interesting case of aplastic anæmia recorded by Dr. W. J. Fenton and Dr. A. Turner in your issue of May 30th (p. 1188) prompts me to call attention to the possibility of keeping patients suffering from this condition in good health for long periods by repeated transfusions. The case of a patient of mine, now aged 36, who is still alive and active six years after the onset of the disease, is recorded by Dr. R. Stewart-Harrison in the April number of the *Guy's Hospital Reports.* His blood picture is that of aplastic anæmia with a very low white count, and his hæmoglobin percentage has been as low as 23. The gastric secretion is normal, there is no glossitis, occult blood is absent from the stools, and there are no nervous symptoms. Very large doses of liver, stomach, and iron have no effect. The patient has, however, been kept in sufficiently good health to carry on his duties as a bank manager by means of regular transfusions, which maintain his hæmoglobin percentage between 70 and 90. On one occasion, as a result of eight transfusions given in 18 days, his hæmoglobin rose from 60 to 101 per cent. He has had 109 transfusions of a full pint since 1927, and so long as he continues to be transfused about once a fortnight there seems no reason why he should not remain in good health and full activity.

I am, Sir, yours faithfully,
New Lodge Clinic, May 31st. ARTHUR F. HURST.

APPARATUS FOR ARTIFICIAL RESPIRATION.

To the Editor of THE LANCET.

SIR,—The apparatus for the prolonged administration of artificial respiration described in the last issue of THE LANCET strikes me very forcibly as being an elaboration of an apparatus I saw at the White City in the period between 1904 and 1910. I cannot say the precise year. A fishery exhibition was in progress, and this apparatus was in charge of a venerable clergyman, who was interested in fishing companies and fishermen generally. It consisted of a plate glass case with a hole in one end, closed partly by a rubber collar; it had an air pump attached to the other, by means of which air could be pumped into the case. There was a specially made Japanese

PARLIAMENT

NOTES ON CURRENT TOPICS.

REASSEMBLING OF PARLIAMENT.

THE House of Commons reassembled after the Whitsuntide recess on Tuesday, June 2nd.

HOUSE OF COMMONS.

TUESDAY, JUNE 2ND.

Mortality Ages in British India.

Mr. Freeman asked the Secretary for India the average age of mortality, at the last known date, in British India.—Mr. Benn replied: No exact figure can be given, but in 1928 (the latest year for which materials for calculating are available) the average age was about 23 years.

Medical and Public Health Services in India.

Mr. Freeman asked the Secretary for India what percentage of revenue raised in India was spent on the maintenance of medical relief and public health services.—Mr. Benn said that for the year 1929–30 the gross revenue of British India (central and provincial) was 2,27,26,48,308 Rs. and the gross expenditure on medical and public health was 6,61,95,450 Rs., the percentage of gross revenue being 2·9.

Butter and Public Health Regulations.

Capt. Peter Macdonald asked the Minister of Health whether there was any examination of butter imported into Great Britain for sale; and what were the general regulations governing the sale of butter.—Miss Lawrence replied: The answer to the first part of the question is in the affirmative. Butter which is exposed for sale may be seized and destroyed if found to be unfit for human consumption. Samples are taken by officers of the local authorities under the Food and Drugs (Adulteration) Act and the Sale of Butter Regulations, and the vendor is liable to prosecution if there is evidence of adulteration.

Colonel Ruggles-Brise asked the Minister of Health if he would ascertain the conditions under which consignments of butter now reaching this country from Russia were produced; whether those conditions conform to the conditions required in this country; and whether he would cause samples of the butter from Russia to be analysed on arrival.—Mr. Greenwood replied: As at present advised, I do not consider it necessary to make the inquiry suggested. Imported butter is subject to examination on arrival in this country under the Food and Drugs (Adulteration) Act, and the Imported Food and Preservatives Regulations. Samples of recent consignments of Russian butter have been found on analysis to be genuine and I am having further samples examined bacteriologically.

MEDICAL NEWS

Society of Apothecaries of London.

At recent examinations the following candidates were successful in the undermentioned subjects:—

Surgery.—T. F. Davies, Guy's Hosp.; O. L. Matthews, Univ. Coll. Hosp.; C. F. Vieyra, St. Mary's Hosp.; and V. M. White, London Hosp.

Medicine.—T. F. Davies, Guy's Hosp.; B. N. Halder, Univ. of Durham; and T. L. O'C. Ryan, Univ. of Edinburgh.

Forensic Medicine.—G. I. Benjamin, Madras Medical Coll.; A. N. Coondoo, Calcutta Medical Coll. and Univ. of Durham; T. F. Davies, Guy's Hosp.; B. N. Halder, Univ. of Durham; A. E. Mathews, St. Mary's Hosp.; S. Ramarao, London Hosp.; L. B. Reeves, King's Coll. Hosp.; D. N. Ryalls, Univ. of Sheffield; H. W. Toussaint, St. Mary's Hosp.; and M. R. Tuteur-Samuel, Universities of Freiburg and Manchester.

Midwifery.—M. Belo-Zercovsky, London Hosp.; T. F. Davies, Guy's Hosp.; W. B. Mattar, St. Mary's Hosp.; T. L. O'C. Ryan, Univ. of Edinburgh; M. R. Tuteur-Samuel, Universities of Freiburg and Manchester; and C. F. Williamson, Univ. of Birmingham.

The following candidates having completed the Final Examination, have been granted the diploma of the Society entitling them *to practise Medicine, Surgery, and Midwifery*:—G. I. Benjamin, T. F. Davies, and A. E. Mathews.

Society of Medical Officers of Health.

Fever Hospitals Medical Service Group.—At the annual meeting of this group, at 1, Upper Montague-street, London, W.C., on Friday, June 12th, at 3.15 P.M., a paper on State Control of Therapeutic Substances will be read by Mr. Percival Hartley, D.Sc., of the Standards Division, National Institute for Medical Research. Visitors are invited.

Hunterian Society of London.

The Society's Medal.—The next award of this medal will be made in 1932, and is open for competition to all general practitioners of Great Britain, Ireland, and the Channel Islands. The medal will be given for the best essay on some medical subject chosen by the writers, and essays must reach the hon. secretaries on or before Dec. 31st, 1931. The president and council have decided that the medal shall be of gold and not of silver as heretofore. The rules governing the award may be obtained on application to the secretaries, Dr. D. C. Norris, 14, City-road, Finsbury-square, London, E.C. 1, and Mr. Andrew McAllister, 79, Wimpole-street, W. 1.

Local Government Medical Officers.

The annual meeting of the Association of Local Government Medical Officers of England and Wales (formerly the Poor Law Medical Officers' Association) will be held on Thursday, June 11th, at 6 P.M., at the Holborn Restaurant with Sir Arthur Newsholme, the President, in the chair. It will be followed by an informal dinner at 6.30 P.M. Any local government medical officer who wishes to be present should inform Mr. Frank Greenwood (the hon. treasurer), Bank Chambers, 150, High-street, Stoke Newington, London, N. 16.

Australian and New Zealand Medical Association in England.

The summer dinner of this association will be held at the Trocadero Restaurant, Piccadilly-circus, on Friday, June 12th, at 7.45 P.M. for 8 P.M. Mr. T. P. Dunhill will preside, and Dr. F. N. Kay Menzies will be present as the official guest of the association. All medical visitors from Australia and New Zealand, whether members of the association or not, are invited to be present. The hon. secretaries, Mr. E. T. C. Milligan and Mr. Philip Jory, may be addressed at 26, Queen Anne-street, W.1.

Medical Tour in France.

The twenty-fourth Voyage d'Études Médicales to the watering-places of France will take place this year in the western Pyrenees in the second and third week of September, under the leadership of Prof. Paul Carnot and Prof. Maurice Villaret. The party will assemble on Sept. 8th at Capvern. The principal places to be visited are Bagnères-de-Bigorre, Gavarnie, Cauterets, Lourdes, Argelès, Pau, St. Jean-de-Luz, Biarritz, Hossegor, Dax, Arcachon, Bordeaux (Faculty of Medicine and the Hospital), continuing along the coast to Royan where the tours ends on Sept. 20th. Further information may be had from Madame Juppé-Blaise, Federation of the Health Resorts of France, Tavistock House (North), Tavistock-square, London, W.C.1.

Medical Diary

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Tuesday, June 9th.—8.30 P.M., Disease in Children. Paper. Prof. A. Calmette (Paris): B.C.G. Immunisation of Infants. Epidemiology and State Medicine. Medicine. Pathology. Members of these Sections are specially invited to attend. A luncheon will be held in honour of Prof. Calmette at the Café Royal, Regent-street, London, W, at 1.15 P.M. Application should be made to Dr. A. G. Maitland-Jones, at 1, Wimpole-street, W.

Wednesday.—Surgery. Annual Provincial Meeting at the Manchester Royal Infirmary. Operating sessions. 4.30 P.M., Tea. 4.45 P.M., Cases and Specimens will be shown.

Friday.—5 P.M., Ophthalmology. Annual General Meeting. Election of Officers and Council.

HARVEIAN SOCIETY OF LONDON.

Thursday, June 11th.—3 P.M., (at St. Bartholomew's Hospital), Centenary Celebrations. Oration by Dr. Raymond Crawfurd on the Place of Medical Societies in the Progress of Medicine.

PADDINGTON MEDICAL SOCIETY.

Tuesday, June 9th.—9 P.M., (at the Great Western Royal Hotel, Paddington), Dr. G. de Swietochowski: Medical Ideals and Practice.

MEDICAL SOCIETY OF INDIVIDUAL PSYCHOLOGY, 11, Chandos-street, W.

Thursday, June 11th.—8.30 P.M., Discussion on the Treatment of Sexual Impotence by the Methods of Individual Psychology.

SOCIETY OF MEDICAL OFFICERS OF HEALTH, 1, Upper Montagu-street, W.C.

Friday, June 12th.—3.15 P.M., Annual meeting of Fever Hospitals Medical Service Group. Mr. Percival Hartley, D.Sc.: State Control of Therapeutic Substances.

RESEARCH DEFENCE SOCIETY, 11, Chandos-street, W.

Wednesday, June 10th.—3.30 P.M., Annual General Meeting. Dr. H. H. Dale, F.R.S.: Effect of Research on Curative Medicine. (Paget Memorial Lecture.)

OPTICAL SOCIETY.

Thursday, June 11th.—8 P.M. (at the Imperial College of Science and Technology, Imperial Institute-road, South Kensington, S.W.), Sir John H. Parsons, F.R.S.: Young's Theory of Colour Vision. (Thomas Young Oration.)

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.,

Tuesday, June 9th.—5 P.M., Prof. M. J. Stewart: Precancerous Lesions of the Alimentary Tract. (Second Croonian Lecture.)

Thursday.—5 P.M., Prof. Stewart. (Last Croonian Lecture.)

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

Monday, June 8th, to Saturday, June 13th.—Medical Society of London, 11, Chandos-street, Cavendish-square. M.R.C.P. special evening lectures at 8.30 P.M. Tues., Dr. R. A. Young: Empyema and its Treatment. Fri., Dr. B. T. Parsons-Smith: Cardiovascular Syphilis.—Mount Vernon Hospital, Northwood (by train from Baker-street, Metropolitan, or "Rickmansworth" bus leaving Oxford-circus at 1 P.M.), Mon., Demonstration on Radium by Mr. Duncan Fitzwilliams at 2 P.M. No fee.—Central London Throat, Nose and Ear Hospital, Gray's Inn-road, Tues., Demonstration on Throat, Nose, and Ear Cases by Mr. Lowndes Yates at 5 P.M. No fee.—Chelsea Hospital for Women, Arthur-street, S.W. Special Course in Gynæcology. Mornings and/or afternoons.—Hospital for Diseases of the Skin, Blackfriars-road, S.E. Afternoon course. Tickets from the Fellowship of Medicine.—Royal Free Hospital, Gray's Inn-road, W.C. Fri., 5 P.M., Demonstration. Antenatal Treatment and Diagnosis.—Further particulars from the Fellowship of Medicine.

CHARING CROSS HOSPITAL MEDICAL SCHOOL POST-GRADUATE COURSE.

Sunday, June 7th.—10.45 A.M., Mr. L. G. Brown: Post-operative Treatment of Mastoidectomy. 11.45 A.M. Dr. C. K. J. Hamilton: Some Common Disorders of the Newly Born.

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith, W.

Monday, June 8th.—10 A.M., Gynæcological Ward Visit, Genito-Urinary Operations, Skin Department. 11 A.M., Surgical Ward Visit. 2 P.M., Surgical Ward Visit. Medical, Surgical, Eye, Gynæcological Out-patients.

Tuesday.—9.30 A.M., Operations. 10 A.M., Medical Ward Visit, Dental Department. 11 A.M., Throat Operations. 11.30 A.M., Surgical Clinical Demonstrations. 2 P.M., Medical, Surgical, Throat Out-patients, Operations, Medical Ward Visit.

Wednesday.—10 A.M., Medical Ward Visit, Children's Medical Out-patients. 2 P.M., Medical, Surgical, and Eye Out-patients, Gynæcological Operations. 4.45 P.M., Venereal Diseases.

Thursday.—10 A.M., Neurological Department. 11.30 A.M., Treatment of Fractures. 2 P.M., Medical, Surgical, and Eye Out-patients, Genito-Urinary Department. Operations.

Friday.—10 A.M., Medical Ward Visit, Skin and Dental Departments. 12 noon, Medical Lecture. 2 P.M., Medical, Surgical, and Throat Out-patients. Operations.

Saturday.—9 A.M., Throat Operations. 10 A.M., Medical Ward Visit, Surgical and Children's Medical Out-patients.

NATIONAL HOSPITAL, Queen-square, W.C.

Monday, June 8th.—12 noon, Dr. Greenfield: The Cerebrospinal Fluid. 2 P.M., Dr. Riddoch: Out-patient Clinic. 3.30 P.M., Dr. Symonds: Acute Encephalitis and Encephalomyelitis.

Tuesday.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Dr. Adie: Retrobulbar Neuritis.

Wednesday.—2 P.M., Dr. Martin: Out-patient Clinic.

Thursday.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Dr. Walshe: Cerebral Tumours (2).

Friday.—2 P.M., Dr. Adie: Out-patient Clinic. 3.30 P.M., Dr. Carmichael: Birth Palsies.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE, Keppel-street, Gower-street, W.C.

Tuesday, June 9th.—5 P.M., Sir George Buchanan: International Hygiene.

Wednesday.—5 P.M., Mr. A. T. Pike: Town Planning.

Friday.—5 P.M., Sir Thomas Legge: Industrial Poisonings.

INSTITUTE OF PATHOLOGY AND RESEARCH, St. Mary's Hospital, W.

Tuesday, June 9th.—5 P.M., Prof. J. S. Haldane: The Problems of Silicosis.

CITY OF LONDON MATERNITY HOSPITAL, City-road, E.C.

Thursday, June 11th.—5 P.M., Mr. Arnold Walker: The Importance and Treatment of Hæmorrhages in Pregnancy.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

Tuesday, June 9th.—3.15 P.M., Mr. McNeill Love: The Differential Diagnosis of Abdominal Emergencies.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION, St. James's Hospital, Ouseley-road, Balham, S.W.

Wednesday, June 10th.—4 P.M., Dr. C. E. Lakin: Demonstration of Medical Cases.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C.

Friday, June 12th.—4 P.M., Mr. W. A. Mill: Acute Suppuration in the Middle Ear.

UNIVERSITY OF BIRMINGHAM.

Tuesday, June 9th.—3.30 P.M. (at the General Hospital), Prof. Wynn: Chronic Lung Disease.

Wednesday.—4 P.M. (in the Large Theatre of the Medical Faculty, Edmund-street), Sir Hubert Bond: Some Correlations between General and Psychological Medicine. (Third lecture.)

Friday (at the Queen's Hospital).—3.30 P.M., Mr. Douglas Marsh: The Significance of Hoarseness.

Appointments

Rycroft, B. W., M.D., Ch.B. St. And., has been appointed Honorary Ophthalmic Surgeon to East Ham Memorial Hospital.

Births, Marriages, and Deaths

BIRTHS.

Crowe.—On May 30th, at Beech House, Headingley, Leeds, the wife of W. Nigel Crowe, M.B., B.S., of a son.

Horsfall.—On May 30th, at Shempston, Cheam, the wife of Dr. T. M. M. Horsfall, of a son.

McFadyean.—On May 24th, at Herne Hill, the wife of Kenneth McFadyean, M.R.C.S., of a daughter.

McKendrick.—On May 27th, at Blackwood, Mon., the wife of William McKendrick, M.B., Ch.B., of a son.

Payne.—On May 21st, at Sussex Lodge, Colchester, the wife of Dr. W. F. Payne, of a son.

MARRIAGES.

Taylor-Jones—Corbett.—On May 27th, at St. Paul's, Herne Hill, Thomas Henry Edward Taylor-Jones, M.R.C.S., L.R.C.P., to Dorothy Amy Corbett, of Knowle.

Vernon—Wolfenden.—On May 30th, at St. Mary's Church, Netherbury, Dorset, James Anthony Vernon, M.R.C.S., L.R.C.P., to Eileen Mary, only daughter of the Rector of Netherbury and Mrs. Wolfenden.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages and Deaths.

Central Association for Mental Welfare.—A course for officers of local authorities and local associations for mental welfare engaged in the ascertainment and supervision of defectives will be held in London from August 29th to Sept. 10th. It will be supplemented, where desired, by a week's practical experience under a trained worker in the provinces. Particulars may be had from the hon. secretary of the association at 21, Buckingham Palace-road, London, S.W. 1.

NOTES, COMMENTS, AND ABSTRACTS

THE NATIONAL COUNCIL FOR MENTAL HYGIENE.

THE second biennial conference of this council was held at the Central Hall, Westminster, from May 27th to 29th. The chair at the first session was taken by Miss **SUSAN LAWRENCE**, M.P., and the subject of discussion was

The Human Factor in International Problems.

Dr. J. R. **LORD** defined the human factor as the play of moral sentiments and higher emotional reactions, the exercise of habitual self-control and the possession of the cardinal virtues; that which made a man recognise his obligations to his fellow-men, and realise that reason and self-control were as necessary for his own sake as to avoid injury to others. The biological mission of mental hygiene was to curb or modify those factors in man's nature which were racial survivals of the time when he had not developed the higher social sense. War undoubtedly had an immoral, psychopathic origin, and one of the first functions of mental hygiene was to prevent war. He would suggest three slogans for the movement. The first was "to think internationally." Mental hygiene was international in that it was a necessity to all men, and, successfully planted in the home, it spread thence to dominate the psychology of multitudes. The reign of peace throughout the world depended on the cultivation of mental hygiene. A healthy national mentality did not look for war. To raise the level of activity and knowledge of mental hygiene throughout the world was the soundest way of establishing good feeling among the nations. The second slogan was "the necessity to disarm the mind." At critical moments of international understanding the reason and intellect must not fail. Happiness depended absolutely on the ability of people to feel normally, think rationally, and act properly. The discontent of the masses was an expression of the grave tension which existed between subjective needs and the outward possibility of satisfaction. The best outlet was culture, which ought not to lag painfully in the train of economics and industrialism, but should have the first place in the ordering of daily life. The aim should be to control not only nature, but human nature. Old conventions, customs, and values would need to be challenged; moral codes would need to be recast and positive elements supplemented; the emotions and their significance in behaviour would need to have an equal place in education with that devoted to the intellect. Mental hygiene had a great mission in eliminating emotionally driven handicaps to the exercise of conciliation, reason, and common sense. The third slogan was "fidelity to truth and duty." Mental hygiene must direct its efforts to dealing effectually with the emotionally unbalanced or criminally disposed section of the public, which was a source of danger to both national and international peace.

THE "INTERNATIONAL MILIEU."

Prof. A. **ZIMMERN** said that internationalism was inseparably connected in most people's mind with peace; the natural inference was that the international milieu was a sphere from which strife, conflict, and maladjustment had been banished and in which harmony prevailed. As a matter of fact, international relationships were for the great majority of people not normal but abnormal. Very rare were those who could lead a normal life, unconscious of malaise and maladjustment, in an international community. The very abnormality of the international milieu tended to deter the mentally healthy from associating with it, and the field was occupied by those who were not normal anywhere, and therefore felt more assurance, and passed muster more easily, in surroundings where nobody was quite himself. Thus the idyllic paradise of romantic sentiment, seen from the inside, revealed many of the characteristics of the sanatorium. There was no such thing as an international society or an internationl community. A national gathering was a real society; an international one was a mere collection of individuals who found themselves in the same room and contrived to pass the time without impinging on one another's angles. The expedients resorted to by resourceful hosts in such circumstances were generally based on appealing to the greatest common measure of the gathering. The greater the diversity, the more primitive would be the level at which the common measure would be found. Thus a gathering of all the nations might find itself submitted to an atmosphere recalling the forced geniality of a "pleasant Sunday afternoon." It followed that international public opinion was equally non-existent. The individuals who composed the international milieu continued in their new surroundings to maintain their habitual attitudes, and their natural instinct was to emphasise rather than diminish their national-mindedness. To hold one's own in the international milieu, to give a lead to opinion there, needed more than a small measure of the divine spark. An important consequence of the absence of international public opinion was a relaxation of social control. As an instalment of the millennium the League of Nations was bound to cause disillusionment. It was not an ideal, but a reality, and was the reverse of romantic. One of its greatest services was in bridging the gulf between romance and reality which had hitherto so greatly impeded the sober discussion of international problems.

THE NEED FOR AN INTERNATIONAL CULTURE.

Mrs. **NEVILLE ROLFE** pleaded for the reinterpretation of religions. International progress seemed to be based on a common recognition by different people of similar moral and social values based on sufficiently strong emotional and intellectual sanctions. This had applied in the Greek city states and the Roman Empire and to a lesser extent in the Holy Roman Empire, but, in the main, international agreements before the nineteenth century had been based on "the tie of common funk," and had shown very little cognisance of matters concerning the welfare of the general population. A survey of the subjects on which international agreement had been reached before the late war and of the records of the League of Nations showed that coöperation could first be obtained between divergent peoples on matters that concerned the fundamental principal human instincts, that social progress depended on a common sense of social values, and that social values were intimately bound up with the religious and ethical outlook of a people. The conventions on traffic in women and on slavery had been ratified by all those countries where individual liberty had a social value, but in a matter like obscene publications differing social values immediately raised a difficulty. In China it was indecent to kiss; the natural nudity of Africa could be obscene in Europe; the deratisation of a ship would involve a Hindu in grave sin on account of his abhorrence to taking life. For real international progress there must be an international culture. The current values accepted by the followers of the four main religions differed profoundly, but few people realised how continually and how considerably religious tenets had been and were being reinterpreted in the light of increasing scientific knowledge. To develop an international culture, therefore, the first step was a wider diffusion of modern science, particularly biological science.

At the next session the chair was taken by Sir **Hubert Bond**, and the subject was

The Human Factor in Crime.

Mr. C. C. **Roberts**, of the Howard League, said that crime had no single source, that there was no natural will to crime, and that every evil had a cause. Society was at last beginning to realise that the responsibility for its criminal classes rested on itself, that no criminal was impossible to treat, and that pure punishment was of little value. He suggested that prisons should be run on the assumption that each criminal was a case requiring individual treatment and different medicine to effect a cure. There should be a progressive form of imprisonment, giving him back more and more of his lost independence and leading him back to everyday life.

Dr. W. A. **Potts** said that the crime itself was often of little importance compared with the human factor. Sometimes the cause was a disorder of physical health, but it was more often a disorder of the mind. To put a mental defective on probation was no help to himself and might be dangerous to the community and put an unfair burden on the probation officer. The aim of the magistrate should be to find out what made the offender act as he did; not what could be done to him but what could be done for him. The cause could not be found out by an interrogation in court. Before inflicting punishment the authority must be certain that the case was a suitable one for punishment, that the offender understood why he was being punished, and that he had not already been punished enough before coming to court. To elucidate the human factor in crime, study must be made of the parents, the home, the school, the means of recreation, the life's work, and the offender himself and his reaction to these factors.

Mr. H. E. **Norman** (Secretary, National Association of Probation Officers) said that crime, although anti-social, was not necessarily anti-human; it was rather the effort of the individual to find expression for his human desires without proper regard for the interests of society. In attempts to control crime the community was apt to forget the potency of the human egoism which constituted its driving power. It was doubtful whether the stifling of the ego by an overbearing will of greater power could ever fall within the area of mental health. In the old days the only object of treating crime was to protect the community, but now, when society desired to ensure by every reasonable means that the delinquent should be converted to normal standards of behaviour, it was doubtful whether the retaliative penal system could ever be satisfactory. The first rational step was to study each individual offender's point of view, and this demanded patient and skilled investigation which should be conducted without close association with punitive treatment. Since the anti-social character of crime was closely associated with intense emotions, the simplest and most effective channel for reformation was through those same emotions where the hurt had first begun. Skilled exploitation of the human factor of the individual delinquent was irresistible, economical and practicable, but it called for very skilful training of the social worker, since the services of the medical psychologist were too expensive as a routine treatment. The probation system offered a framework for such an organisation and for the only practicable method of reformative treatment of crime.

At the next meeting the subject for discussion was "The Human Factor in Industry." The chair was taken by Sir Harry Goschen, and the speakers were Air-Vice-Marshal Sir David Munro, Mr C. J. Bond, Mr. W. H. M. Jackson, and Miss F. A. F. Livingstone.

Dean **Inge** took the chair at the discussion on

The Human Factor in the Social Services.

Dr. H. **Crichton-Miller** said that all human relations were conditioned by hereditary factors, and that without a eugenic ideal any programme of improvement was necessarily of limited scope. If a child had inherited a difficulty of adjustment it was important to make his process of education not more difficult but more easy. The excellent process of "hardening" must be adapted to the individual child's capacity of response and assimilation. One of the chief curses of civilisation was standardised education for the child of insufficient educability. The principals of schools would be well advised to examine not only the candidate but also the parents. In the modern mechanised community there was more need than ever before for the careful selection of the worker in relation to the work. There was ample and incessant evidence that Western civilisation was making a very limited success of monogamy. Marital discord, which had hitherto been concealed owing to pressure of religion, authority, and public opinion, was now being made manifest. The tremendous increase in the transmission of ideas meant that human personality was being devaluated in relation to social existence. Civilised man was becoming a creature of second-hand ideas, dictated opinions and preformed judgments. He had less freedom of thought than he had had for many generations. Modern education was not succeeding in neutralising the detrimental effects of civilisation. Thus there was a great call for better education in all human activities: vocation, marriage, and social relationships.

Dr. **Isabel Wilson** discussed the underlying motives of the social worker. He was often, she said, quite consciously motivated by the desire to save others what he himself had suffered. Others might be quite unconscious of this identification. The value of work based on identification was its single-hearted earnestness, and the danger was its narrowness and disregard of other claims. A certain type of worker went on unsparingly and unceasingly because he was afraid to stop; a long, idle holiday was the cure. The sense of inadequacy or of guilt might link the worker's mental conflict with his work. A certain type of social work was done in order to give a comfortable feeling of usefulness or charitableness to one aware of being otherwise purposeless or uncharitable. The work might be good, but so long as it soothed a man's conscience he was unlikely to deal faithfully with the rest of his life. Another personal tendency was that of seeking self-glorification through work. These motives should always be taken into account, in order that the worker might make the best of himself, and the organiser might realise the great stores of energy available in deep-lying motives. The slow progress of international social service depended on certain personal factors: the limitation of human experience and of human intelligence and the stability of racial type.

Miss **Camilla Wedgewood** urged the value of traditions in guiding social progress, provided that they were not allowed to act as an insurmountable barrier in the path of social evolution. They were a check on violent changes, and a unifying factor. Traditions differed from history in being idyllic conceptions of the past and giving a sense of dignity to a people. They were thus a powerful factor in preserving social cohesion and building up and fortifying the conscience and self-respect of the individual.

The final session, under the chairmanship of Sir **Percy Nunn**, was devoted to a discussion of

The Human Factor in Education.

Prof. J. E. **Marcault** said that the new individuality made itself felt at every step, especially in the claim of the new generation for its right to personal experience. Education strove nowadays, not so much to hand on the common culture of the social group to all children, as to bring to its realisation of expressive creativeness that which was individual and unique in the child. The all-important factor in education was the dynamic flow, and the measure of concentration of diffusion of the conscious dynamism was the measure of the individual itself. Psychology discovered the individual; education had to educate it by applying the new psychological ideas. There was no need to be afraid of individualism. The education of the concentrated self could not be unsocial, for that self had been at all times the creator of all social relations and values, and was the creator of still more universal relations and values in the present. In educating the individual child we educated that which was universal.

Sir BENJAMIN GOTT said that the human factors in a child's education should teach the child: (1) that he must live and earn his living; (2) how to get the best out of life and use leisure to the best advantage; (3) how to maintain a healthy body; and (4) the responsibility of democratic government. Teachers and parents should see more of each other, and boys and girls should be taught together. The teachers should be carefully selected and should then be allowed plenty of freedom to deal with the child's special abilities and predilections.

Dr. F. C. SHRUBSALL said that much depended on the human factor in education. The seeds of many ills were sown by human agencies in the first years. The human element began with the child itself, whose inborn mental and physical traits were the fundamental datum line. A knowledge of the possibilities of the inherited pattern would be helpful to the teacher as well as to the psychotherapist. The child learned by suggestion, and was more affected by the feelings of those around him—as expressed in their actions and attitudes—than by their words. While uniform treatment, whether good or bad, could produce good results, changeability undermined the character before it was formed. The best form of punishment was to allow the child to suffer the inevitable and suitable consequences of its fault. The child learned most from contact with fellows of about his own age, and the only child among grown-ups therefore suffered great disadvantages.

AN IMPOSTOR.

LETTERS of a begging character are being sent out from an address in Dublin to prominent persons, claiming assistance on the ground of the writer being a doctor and suffering from a war injury, both of which statements are false.

Vacancies

For further information refer to the advertisement columns.

Aberdeen Royal Hospital for Sick Children.—Hon. Medical Officer.

Accrington Victoria Hospital.—Hon. Anæsthetist. Also H.S. £150.

Albert Dock Hospital, Connaught-road, E.—Res. M.O. At rate of £110.

All Saints' Hospital, 91, Finchley-road, N.W.—H.S. At rate of £150.

Barnsley, Beckett Hospital and Dispensary.—Res. Surg. O. £300.

Birmingham Ear and Throat Hospital, Edmund-street.—H.S. At rate of £150.

Birmingham and Midland Eye Hospital.—Res. Surg. O. £150.

Blackburn, Royal Infirmary.—4th H.S. £150.

Bolingbroke Hospital, Wandsworth Common, S.W.—Hon. Physician for Diseases of Children.

Bootle General Hospital.—H.P. At rate of £150.

Brighton, Hove and Preston Dispensary.—Dist. M.O. Also Hon. Phys. for Ditchling Road Dispensary.

Brighton, Royal Sussex County Hospital.—Cas. H.S. £120.

Bury St. Edmunds, West Suffolk Hospital.—Locum Asst. for Path. Laby.

Cancer Hospital, Fulham-road, S.W.—H.S. At rate of £100.

Canterbury, Kent and Canterbury Hospital.—H.P. and H.S. Each at rate of £125.

Chesterfield and North Derbyshire Royal Hospital.—Cas. O. At rate of £200.

Connaught Hospital, Walthamstow, E.—Res. H.P. At rate of £100.

Derby, Derbyshire Hospital for Sick Children.—Res. H.S. and Res. H.P. At rate of £150 and £130 respectively.

Derby, Derbyshire Royal Infirmary.—Ophth. H.S. Also Cas. O. Each at rate of £150.

Doncaster Royal Infirmary.—H.S. At rate of £175.

Dorset C.C. Education Committee.—School Dentist. £450.

Dreadnought Hospital, Greenwich.—H.P. and H.S. Each at rate of £110.

Durham, County Council.—District Tuber. M.O. £500.

Durham County Council and Chester-le-Street U.D.C.—District Tuber. M.O. and M.O.H. £800.

Essex Administrative County.—Asst. County M.O.H. £500–£600.

Exeter, Royal Devon and Exeter Hospital.—Res. Sen. H.S. £250. Also Res. H.S. and H.S. to Spec. Depts. Each at rate of £150.

Gloucester, Gloucestershire Royal Infirmary, &c.—H.S. At rate of £120.

Hampstead General and N.W. London Hospital, Haverstock-hill, N.W.—H.S. and H.P. Each at rate of £100.

Hospital for Sick Children, Great Ormond-street, W.C.—Part-time Jun. Cas. O. At rate of £150.

Hospital for Tropical Diseases, Endsleigh-gardens, W.C.—H.P. At rate of £150.

Hove Hospital, Sackville-road.—Res. M.O. £150.

Hull Royal Infirmary.—3rd H.S. At rate of £150.

Ilford Borough.—Asst. M.O.H. £600.

Indian Medical Service.—Commissions.

Inverness, Royal Northern Infirmary.—H.P. At rate of £100.

Ipswich, East Suffolk and Ipswich Hospital.—Cas. O. £120.

King's Lynn, West Norfolk and King's Lynn Hospital.—Jun. H.S. At rate of £125.

Lancaster Royal Infirmary.—Jun. H.S. £130.

Leeds, Gateforth Sanatorium.—Res. M.O. £450.

Leeds, Herzl Moser Hospital, Leopold-street.—R.M.O. £100.

Leeds Hospital for Women.—H.S. At rate of £50.

Leeds, St. James's Hospital.—H.P. and S. At rate of £200.

Liverpool Psychotherapeutic Clinic, 56, Bedford-street North.—Part-time Med. Reg. £150.

London, Female Lock Hospital, 283, Harrow-road, W.—H.S. at rate of £150.

London University.—Examinerships.

Manchester Babies' Hospital, Burnage-lane, Levenshulme.—Sen. and Jun. Res. M.O.'s. At rate of £125 and £50 respectively.

Manchester Ear Hospital, Grosvenor-sq., All Saints.—H.S. £150.

Manchester, Royal Children's Hospital.—Sen. M.O. for Out-patients' Dept. £300.

Maudsley Hospital, Denmark Hill, S.E.—Sen. Asst. M.O. £650.

Middlesex C.C., Redhill Hospital, Edgware, and Park Royal Hospital, Willesden.—2 Res. Asst. M.O.'s. Each £400.

Miller General Hospital, Greenwich, S.E.—H.P. and H.S. Each at rate of £125. Also Out-patient Officer. At rate of £150.

National Hospital for Diseases of the Nervous System, Queen-square, W.C.—Hon. Asst. Radiologist.

Newcastle-on-Tyne, Royal Victoria Infirmary.—Two Jun. Surg. Regs. Each £150.

Newport, Mon., Royal Gwent Hospital.—Jun. Res. M.O. £135.

Nottingham City Infirmary.—4th Res. M.O. £350.

Nottingham General Hospital.—Cas. O. At rate of £200.

Oldham Royal Infirmary.—H.P. and Cas. O. Each at rate of £175.

Oswestry, Shropshire Orthopædic Hospital and Agnes Hunt Surgical Home.—H.S. At rate of £200.

Plymouth, South Devon and East Cornwall Hospital.—Asst. Pathologist. £650.

Poole, Dorset, Cornelia and East Dorset Hospital.—Hon. Orthopædic Surg.

Princess Louise Kensington Hospital for Children, St. Quintin-avenue, North Kensington, W.—H.S. At rate of £100.

Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.—Res. Anæsthetist. At rate of £100.

Queen's Hospital for Children, Hackney-road, E.—Res. M.O. At rate of £200.

Rhondda U.D.C.—Temporary Asst. M.O., &c. £500.

Rotherham Hospital.—Cas. H.S. £150. Also Sen. H.S. £200.

Royal Free Hospital, Eastman Dental Clinic, Gray's Inn-road, W.C.—Res. H.S.

Royal National Orthopædic Hospital, 234, Gt. Portland-street, W.—Asst. Reg. Surg. for Country Branch, Stanmore. £350.

Royal Northern Hospital, Holloway, N.—H.S. At rate of £70.

St. Mary's Hospital, Institute of Pathology and Research, Paddington, W.—Research Studentship. At rate of £200.

St. Peter's Hospital for Stone, &c., Henrietta-street, Covent Garden, W.C.—Clin. Assts.

Salford Royal Hospital.—H.P. and H.S. Each at rate of £125.

Scunthorpe and District War Memorial Hospital.—2nd Res. Surg. £150.

Sheffield Children's Hospital.—H.P. and Third Res. M.O. At rate of £100 and £80 respectively.

Sheffield, Jessop Hospital for Women.—Three Asst. H.S.'s. Each at rate of £100.

Sheffield Royal Infirmary.—H.S., Ophth. H.S., Asst. Aural and Ophth. H.S. Each at rate of £80.

Southampton County Borough.—M.O.H. &c. £1250.

Southampton, Royal South Hants and Southampton Hospital.—Res. H.P. and 2 H.S.'s. All at rate of £180.

Stockport Infirmary.—H.S. £175.

Stoke-on-Trent, Longton Hospital.—H.S. £120.

Swansea General and Eye Hospital.—H.P. £150.

Surrey County Council.—Asst. M.O. £600.

Warwick County Mental Hospital, Hatton.—2nd Asst. M.O. £450.

Western Ophthalmic Hospital, Marylebone-road, N.W.—Jun. Non-Res. H.S. At rate of £100.

West London Hospital, Hammersmith-road, W.—H.P. and two H.S.'s. All at rate of £100.

Willesden General Hospital, N.W.—Hon. Clin. Asst. to Surgical Out-patient Dept.

Windermere, Ethel Hedley Orthopædic Hospital for Crippled Children.—Res. H.S. £150.

Woking and District, Victoria Hospital.—Res. M.O. At rate of £100.

Woolwich and District War Memorial Hospital, Shooters Hill, S.E.—H.P. At rate of £100.

York, The Retreat.—Sen. Asst. M.O. £400–£500.

LONDON CLINICAL SOCIETY.—The sixth annual Macalister lecture of this society will be delivered at the London Temperance Hospital on Tuesday, June 16th, at 9 P.M., by Major Richard Rigg, whose subject will be Medicine and the City Guilds. All medical practitioners are invited and may bring friends.

ADDRESSES AND ORIGINAL ARTICLES

THE PLACE OF MEDICAL SOCIETIES IN THE PROGRESS OF MEDICINE.*

BY RAYMOND CRAWFURD, M.D. OXF., F.R.C.P. LOND.,
CONSULTING PHYSICIAN TO KING'S COLLEGE HOSPITAL.

WE are gathered here to celebrate the centenary of the Harveian Society of London, and we are honoured by the presence of representatives of the sister society of Edinburgh, founded in 1782, and of that of New York, founded in 1905. The occasion may be not inopportune for considering some features of the life-history of medical societies in Great Britain.

Three Harveian Societies.

Human activity, in so far as it is enduringly fertile, is not the chance product of a few creative minds, but is conditioned by its antecedents and environment and tends to express the dominant tendencies of the time. Thus the Harveian Society of Edinburgh was born of a demand that found expression in various ways in the last quarter of the eighteenth century for the democratisation of medical knowledge. Phœnix-like it arose out of the ashes of an older Æsculapian Society, membership of which had been exclusive and limited to Fellows of the Royal Colleges of Physicians and Surgeons. The Harveian Society opened wide its doors not only to such Fellows, but also to medical graduates, neighbouring practitioners, and the naval and military medical services as well. The Scotch genius for conviviality seems to have asserted itself in the constitution of this society, as it kept in the forefront of its programme the cherishing of friendliness among members of the profession, and the degrees conferred by it included "Doctor of Mirth and Social Joy" and "Doctor of Merriment." So this society was true to Harvey's injunction as to the importance of cherishing actively the spirit of good fellowship as an assurance of usefulness and stability.

The Harveian Society of London was launched on its career of enduring prosperity at a time when educational reform was alive and active in every branch of intellectual activity. In London in little more than a decade University College, King's College, and the University of London came into being. Medical societies had already spread from their first metropolitan homes in Edinburgh and London to the provinces, and in 1819 a further tendency to decentralisation within the growing metropolis had declared itself in the foundation of the Hunterian Society, for the benefit of the medical profession in the East End of London. The purpose of this Harveian Society at its birth was to do the same for the West of London, for it should be remembered that in 1831 the centre of medical activity was not as now in Harley-street, but in the district adjacent to the British Museum.

One important function of medical societies has been to provide a medium for the conveyance of fresh knowledge from the centre to the periphery of the profession. Scientific discoveries tend to be minted in minds concentrated at the centre, but it is by the minds of the multitude of practitioners scattered throughout the country that the golden coins gain extensive currency. The flow of fresh knowledge has thus been mainly centrifugal, and very little in the reverse direction, for the country practitioner is more directly concerned with the art of medicine, which is individual and incommunicable, while the science of medicine is catholic and susceptible of ready transmission. A notable exception, however, to the general rule was Jenner's work on vaccination, a piece of scientific work that was readily practicable only in the milieu of a rural practice; while later still from the genius of Manson, Ross, and others, we at home have learnt that the highest scientific achievements may be compassed in the outposts of our far-flung empire. At its foundation this society declared its purpose to be "to promote a free communication and, whenever practicable, a demonstration of facts and inferences relating to all departments of medicine, regarded both as a science and an art." Here then was a common meeting ground for the exponents of both the art and the science of medicine and this throughout its hundred years of existence has been its peculiar cachet.

The Harveian Society of New York was founded in 1905: its avowed purpose was to convey to the medical profession generally, by means of lectures delivered by experts in different branches of medical science, knowledge gained by experimental investigation in the laboratory. It was felt that such knowledge was liable to be buried in specialised publications that were not readily accessible to the general practitioner. Anyone who is familiar with the annual volumes in which these lectures are published cannot fail to recognise the great measure of success that has attended this high endeavour. This society then is the natural corollary of the rapid growth of experimental research that has been an outstanding feature of twentieth century medicine.

Functions of a Society.

This brief outline of the activities of these three Harveian societies affords some indication of the various ways in which medical societies have aided in the diffusion of knowledge by the agency of discussions, papers, lectures, exhibition of patients and specimens, demonstrations and the printing of proceedings, but it does not cover the whole ground, for some societies have enlarged the scope of their transactions, so as to include reviews of books and abstracts of articles of scientific value, the usefulness of which to medical men can hardly be overrated, while others have added the manifold amenities of a well-organised library.

The *diffusion* of knowledge has been the primary, but by no means the exclusive purpose of medical societies, for the methods adopted for the active diffusion of knowledge cannot fail to have some share both in the *acquisition* of existing knowledge and in the *creation* of new knowledge; the larger and more affluent medical societies have indeed lent themselves to the acquisition of knowledge only in a less degree to its diffusion. In the acquisition of knowledge books and periodicals necessarily play an important part, and to this end not a few societies have provided their members with libraries, the most highly systematised of which have already attained a very high degree of utility and excellence.

The creation of new knowledge can in the nature of things form only a very limited part of the activities of a medical society as such. It is true that the intercourse of fertile minds does give birth to new conceptions and these in turn engender others, and this constitutes a creative act, but the experimenter, who would commune with nature, must needs enter his chamber and be still, and his chamber is the laboratory not the meeting house. So, too, fruitful observation postulates the presence of the objects to be observed in a suitable milieu, and in the case of morbid material, living or dead, that milieu is the hospital or its clinical equivalent.

---

* Address at the Centenary Celebration of the Harveian Society of London at St. Bartholomew's Hospital on June 11th, 1931.

If we trace back the development of medical societies to its source, we find that the earliest were concerned at least as much with the acquisition and creation as with the diffusion of medical knowledge; the more restricted function has been gradually evolved. Both Bacon and Harvey have left us a picture of the constitution and scope of the society, to which they would have entrusted the future of medical science. Each of these men was a typical product of the spirit of an age that had its roots in the Reformation; each was a champion of the scientific scepticism that, with the emancipation of the human mind from the tyranny of authority and dogma, sought by means of observation and experiment to find a rational basis for the interpretation of physical phenomena.

Bacon's Plan.

Bacon believed that science might be immensely advanced if the whole civilised world could be linked up into one scientific federation for the creation and dissemination of knowledge, and his allegorical picture of Salomon's house in the ideal commonwealth of Bensalem represents the organisation by which he would make his idea effective. His college was to consist of 36 Fellows, half of whom were to be engaged in the acquisition and recording of all existing knowledge of discoveries and inventions from every conceivable source in all parts of the world; the other half, in six groups of three each, was to be engaged in the devising, directing, executing, and recording of new experiments. Such was to be the guiding personnel of his visionary college, of which the equipment was to be on the most lavish scale. If to-day some master-mind were to fashion a scheme by which all scientific societies, covering every branch of science, should be amalgamated into one colossal institute, if he were to give each professor a free hand to construct, equip, and staff his department on the most lavish scale the professorial mind could conceive, with the addition of an unlimited secretariat and foreign correspondency, the whole directed by an all-wise and all-embracing Research Council, we should still have but a pale exemplar of Bacon's House of Salomon.

It might appear that Salomon's House has but a slender claim to figure in the lineage of the medical society of to-day, but such is not the case, for there is indisputable evidence that it had a direct and important influence in promoting the foundation of the Royal Society, and further evidence that the earliest purely medical societies did consciously adopt as their model certain features that had been tried and approved in the constitution and procedure of the Royal Society. Bacon did not even differentiate medical science from the general corpus of natural philosophy, nevertheless he did include it, and made abundant provision for the acquisition and creation of new knowledge, while leaving the discoveries to be their own advertisement. Though Bacon and not Harvey is thus the true progenitor of our Royal Society, that great corporation has flourished not in the leading-strings of Bacon but by the free and independent pursuit of the method and practice of Harvey. That its birth was delayed until Bacon had been dead 36 years and Harvey was in his grave, was again an accident of the times brought about by the disintegrating influence of years of civil commotion.

Other influences than Bacon's large-scale plan contributed to the foundation of the Royal Society. Evelyn was one of its founders, and his letter to Boyle in 1659 indicating his willingness to endow at his own expense a College the members of which "would resign themselves to live profitably and sweetly together after the manner of the Carthusian Convent in Paris", shows that the example of the monasteries survived their demolition; his College was to do for science what the monasteries had done for religion.

Harvey's Contribution.

Due recognition has not been accorded to Harvey's place in the life-history of the medical society, though it is plain for all to see in the indenture, by which he conveyed to the College of Physicians his patrimonial estate of Burmarsh. Harvey was not the man to weave from his imagination the insubstantial fabric of a dream, as Bacon had done; he sought to build on foundations that lay ready to receive his superstructure in his beloved College of Physicians; in his mind, as in Bacon's, the organisation of the medical society had not emerged from the collegiate stage. In this indenture, after providing for an annual feast within the College, he ends with an exhortation "to search and study out the secrets of Nature by way of experiment; and also for the honour of the profession to continue in mutual love and affection among themselves, ever remembering that *Concordiâ res parvæ crescunt, discordiâ magnæ dilabuntur*." In these words Harvey lays down the very lines on which medical societies have subsequently developed, their educational purpose being supplemented by a bond of good fellowship and conviviality. Harvey had only too good reason to appreciate the value of mutual friendliness to the advancement of medical knowledge. The acerbity and antagonism with which many of his professional brethren had greeted his proof of the circulation of the blood had sered the inmost recesses of his soul, and he is recorded as saying that the stoniest soil of all was in the minds of men over 40 years of age. He too had reason to stress the importance of the social bond. All his life he had been a solitary worker, tireless, as John Hunter after him, in the practical study of comparative anatomy. Only once do we catch a glimpse of him in active collaboration with a fellow-worker, comparing notes of his embryological studies with George Bathurst of Trinity College, Oxford, who kept a sitting hen in his rooms to incubate eggs which he examined day by day to observe the stages of development of the embryonic chick. That Nathaniel Highmore was also independently at work at the same inquiry in the same College need not lead us to assume that the College eggs were peculiar in suggesting compellingly the study of embryology, but rather, as John Hunter has naively said of the development of birds in eggs, "It would almost appear that this mode of propagation was intended for investigation."

One more feature of many medical societies is forestalled in Harvey's will, devising a sum of money for a librarian and for the upkeep of the library he had already presented to the College, so that medical men might have ready access to the contributions that others had already made to the sum of medical knowledge; and for the diffusion of knowledge were there not in existence endowed lectures, in which he himself had already achieved immortality by first setting forth in his Lumleian lectures his proofs of the circulation of the blood? Viewed then as a whole there is little in the constitution of the medical societies of to-day on which Harvey has not long since pronounced substantial benediction. Perhaps then our three societies have done well to adopt his patronymic, for the circulation of medical knowledge is as vital to the higher professional life as is the circulation of the blood to higher animal life.

The contrast of Bacon and Harvey is well expressed in some lines of Browning in the Grammarian's Funeral:—

> The low man seeks a little thing to do
> Sees it and does it;
> This high man, with a great thing to pursue,
> Dies ere he knows it.
> That low man goes on adding one to one,
> His hundred's soon hit:
> This high man aiming at a million
> Misses an unit.

The Royal Society.

Time does not permit me to retell the familiar story of the growth of the Royal Society out of the union of those two groups of gifted amateurs known as the Invisible College of Boyle and the Philosophical Society of Oxford, nor to insist on their indebtedness to the pioneer effort of Sir Thomas Gresham in the foundation of his College in 1575. The transition from a group to a society is something more than the passage from a coterie without a name to a coterie with a name; it is the first step towards the transference of an exclusive possession of the few to the participation of the many. The history of British medicine is punctuated with informal groupings of fellow workers, such as those of William Gilbert, Glisson, and Erasmus Darwin, for the tendency to cohere is an instinct of the human herd; such groupings become a society in name, when they adopt a formal constitution, but they do not become a society in spirit until the evangelist spirit animates and inspires them to propagate knowledge beyond the narrow confines of their own community or to enlarge the confines by an extension of membership. This evangelist spirit was dominant in the early years of the Royal Society, side by side with its primary purpose of stimulating the creation of new discoveries. At first the work of the meetings consisted mainly in the exhibition of experiments by members and the reproduction of experiments already made by other scientific workers, together with the reading of papers. Besides discussion of experiments shown, a feature was the devising of fresh experiments to be carried out elsewhere. Great pains were bestowed on keeping in touch with work in other countries by an organised system of correspondence with foreign scientific workers, whose letters were duly communicated to the society. Abstracts of important articles in foreign journals were made and read, so that the purview of the society was international. Further, the society took care by the publication of Transactions to communicate its own work to other countries, as the French *Journal des Savans* had begun to do for Colbert's scientific coterie three months previously; and in taking upon itself the publication of treatises the society was willing to assume the paternity of Newton's *Principia*. Medicine, or rather the embryo sciences out of which medical science was to arise, received generous treatment at the hands of the society, for two of its eight constituent committees, the anatomical and the chemical, were entirely in the hands of physicians who enjoyed there facilities not to be found in the College of Physicians.

So the Royal Society led the way in Great Britain in promoting the mutual exchange of views among its members by means of discussion and in the publication of transactions, which, both in what they received and what they gave, looked beyond the narrow confines of their own country, and both these features have figures in many of their descendant medical societies.

The First Purely Medical Societies.

So far as corporate action for the progress of medicine went, until 1731 the Royal Society and the Royal College of Physicians held the field. In that year there came into existence in Edinburgh the first exclusively medical society in the modern sense. The preface to the first volume of its Transactions leaves no doubt as to the reasons for its foundation, for these are explicitly stated to have been that the constitution of the Royal Society did not allow it to insert in its Transactions several things that a plan calculated for the improvement of physic would easily admit, and further, the belief is expressed that a collection of observations wholly relative to medicine would be the most effectual way to improve physic. It was not that medicine had proved to be a bad stable companion, but only that she could go better in single harness. The change was momentous, for it involved not only the segregation of medicine from the general body of science, but the handing over of its future to those who were not primarily concerned with scientific research, and the consequence of this was inevitable, that the diffusion of knowledge and not its creation became the prime purpose of medical societies. That Scotland should have led the way in the development of the modern medical society is due to the fact that Scotland was the first, inspired by the example of the Dutch, to organise in 1725 a medical school of practical clinical teaching, and the founders of this society were those teachers of the school who desired that their voices should be heard beyond the four walls of the Edinburgh school of medicine. The sole purpose of this society was the publication of medical papers, and there was no provision for reading or discussing them before the society.

In 1752 London followed suit in constituting its first medical society, and here again we must admit direct Scotch influence, for Fothergill, its founder, though a Yorkshireman, had received his academic training in medicine in Edinburgh, and had been a member of its second medical society. The London society limited itself to the publication of papers, and like its Scotch prototype rested on a narrow basis of membership of a few hospital physicians and surgeons. Each society was short-lived in its original form, for the Scotch society, by reversing the process of evolution, became first the Philosophical Society of Edinburgh by the inclusion of philosophy and literature, and later, in 1783, the Royal Society of Edinburgh. In this very same year the English society died a natural death, that not even the quickening influence of an annual banquet could stave off, for it had not been granted the faculty of making the dry bones of medicine live, without the vivifying guidance of Fothergill and William Hunter, who had been its mainstays. Maybe too that their proclaimed purpose of excluding "whatever has rather a tendency to display the parts and erudition of the writer than to advance medical knowledge," led to a dearth of papers. This society, by its example, stimulated a group of Fellows of the College of Physicians, in 1767, under the leadership of Heberden to meet and read papers, which they issued in the form of "Medical Transactions"; but this effort to project the College along the lines laid down for it by Harvey flickered out with the publication of the last volume in 1820. One admirable suggestion in the preface to the first volume may still be practised with advantage: "It is to be wished," says the author, "that writers would not confine themselves to relate only their successful practice. A physician of great experience might write a very useful paper if he would have the courage to give an account of such methods of cure only as he had found to be ineffectual or hurtful." This hushing-up of mistakes and failures unhappily extends beyond writers and is an almost universal feature of hospital teaching to the very great impediment of the growth of clinical knowledge.

In tracing the expansion of the functions of medical societies, we must again look north to Edinburgh, where in 1734 a few students had banded themselves together for mutual assistance in their studies; Fothergill joined them in 1735. By 1737 they had formally organised themselves into a society, which growing from strength to strength built itself a hall, and in 1778 became the Royal Medical Society of Edinburgh. This society marked a definite advance on its predecessor, for it had formal meetings at which papers were read and discussed, but it maintained at first the tradition of exclusive membership. Being at the outset a students' medical society it gives Scotland the claim to have anticipated by many years the formation of the first students' society in London, the Physical Society of Guy's, that was not born till 1771.

Rise of Societies in London and Provinces.

For the first far-reaching democratisation of medical societies we must look to the foundation of the Medical Society of London by Lettsom in 1773. To Lettsom is due the credit of giving actuality to an idea, but beyond all question the society was the natural product of the professional circumstances of the time. Both Fothergill and Lettsom were Licentiates of the Royal College of Physicians, and each had winced under the stigma of exclusion from the Fellowship, which was the virtual monopoly of Oxford and Cambridge graduates, who were members of the Church of England. Fothergill had taken an active part in the struggle that was fought out between the College and its Licentiates, not only in the law courts, but with a show of violence on the floor of the College itself. Now Lettsom sought to sap the very foundations of the citadel of exclusiveness by setting up beside it a rival institution, as like as he could make it in constitution, and as little like in its spirit of professional exclusiveness. One cannot fail to see in its president, treasurer, registrar, librarian, council, library and museum; in the language and ceremonial mode of admission of Fellows; in the annual oration and much else where Lettsom looked for his model. From the first this society possessed a meeting-house furnished with a library, which Lettsom enriched greatly at his death. But there the resemblance ended, for Lettsom saw to it from the first that his society was broad-based on the enfranchisement of general practitioners on the same footing as physicians and surgeons. Lettsom's foundation seems to have served his purpose, for in 1782 a scheme was mooted for the foundation of a rival College of Physicians, to which the Royal College responded two years later by relaxing so far as to admit two rebel licentiates to its Fellowship.

With this democratic society in the field, it may be a matter of surprise that the Medical and Chirurgical Society should have come into existence in 1805. It is commonly alleged that this society was founded in dissatisfaction with the protracted presidency of one James Sims over the Medical Society. I find it hard to believe that our robust ancestors of 130 years ago were unequal to the task of unseating a senile president, and I find a far more satisfying explanation in the professional circumstances of the time. The fact was that a young cuckoo had been hatched and had already become too large for the parent nest, and that young cuckoo was modern scientific surgery, brought to birth by John Hunter. The very change of name from Medical to Medical and Chirurgical tells its own tale, and the chief figure of the surgery of the day, Sir Astley Cooper, figures prominently among the seceders. A ripple had already appeared on the surface of the water, in 1783, when John Hunter had established "A Society for the Improvement of Medical and Chirurgical Knowledge," the membership of which never exceeded 12. So exclusive a body was bound to go under in competition with its new democratic rival, and it died of inanition in 1818. Nor must we forget that the Royal College of Surgeons had come into being five years previously, in 1800.

So, if the birth of the first medical society in 1731 marks the severance of medicine from natural philosophy, and the birth of the Medical Society in 1773 marks the full democratisation of medical societies, we may recognise in the birth of the Medico-Chirurgical Society in 1805 the emancipation of surgery from the mortmain of medicine.

Meantime another notable advance had been taking place in the spread of societies from their metropolitan homes to the provinces. Warrington had a medical society as early as 1770, but no provincial society of that century was so famous as the Gloucestershire Society founded by Edward Jenner in 1788. The minute books of the Gloucestershire Society, in the handwriting of Jenner, are a treasured possession of the Royal College of Physicians, bequeathed to them by Sir William Osler, than whom no one in the whole history of medical societies did more to cement the social bond, by the charm of his personality, the catholicity of his friendship, and the inspiration of his enthusiasm as a crusader. In these manuscript pages you may find a living picture of a rural medical society of the day, but time forbids me to do more than reveal one gem from this treasure house. Rule XIII. reads: "That as a principal part of the view of the Society is the mutual communication of knowledge, without fear, reserve, or any other authority than that of Truth, no new member shall be admitted for these seven years to come whose age exceeds 40 years."

Specialist Groups.

I could have wished for time in which to unravel the tangled skein of fission and fusion, by which the Medico-Chirurgical Society has become transformed into the Royal Society of Medicine, for therein lies a typical record of the evolution of medical societies in the nineteenth century, but I must needs restrict myself to a few outstanding features. The first quarter of the century, indeed almost the first half, was a period of static equilibrium, for surgery had now come into its own and was intent more on its own internal development than on its external relations; the process of decentralisation within the metropolis, which gave birth to the Harveian Society of London, showed however that animation was only in suspense. In the second half of the century we find the growth of medicine and surgery asserting itself in an orgy of fission, out of which arose a succession of specialised societies, each engaged in the pursuit of its own limited ideal; the Medico-Psychological Association seems to have struck the first note in England in 1841. But though fission was the dominant note, fusion never passed entirely out of sight. Time and again we find overtures for reunion of the Medical with the Royal Medico-Chirurgical Society, and efforts of young seceders to re-establish relations with the parent body; it remained, however, for the twentieth century to reconcile these antagonistic tendencies by a comprehensive scheme of federation. Of these specialist secessions two are of special interest. In 1846 the Pathological Society gave expression by its foundation to the feeling that existing societies paid inadequate attention to pathological subjects. It was indeed the case that until its foundation, in a period when the intensive study of morbid anatomy had become a central feature of medicine, provision for the exhibition of morbid specimens existed only in name; and in 1850, when the Pathological Society was seeking shelter beneath the roof it had recently deserted, the reply of the Council of the parent society was that the exhibition of many recent specimens would probably create a nuisance.

So again in 1867 the Clinical Society came into being as a result of the belief that the parent society cultivated too little the practical aspects of medicine and surgery but expected its members to extract nutriment from a dry diet of papers. Yet this young society for a decade of years was content to talk about cases instead of exhibiting them, and it was not till 1879 that it formulated regulations for the exhibition of living cases, and these seem to have borne no fruit until 1882. A lesson might have been learnt from the Medical Society, which was showing cases at its meetings as early as 1861.

Communications and Companionship.

In the contribution of medical societies to the advancement of medical knowledge we must look for no harvest of great discoveries; their function is rather to afford a meeting-place for the mutual exchange of everyday ideas. They do afford the opportunity to advance or to receive new ideas, to submit them to criticism and correction, and to purge thereby the dross from the ore, and in this intercourse of fertile minds new conceptions will certainly be engendered. They do provide facilities for intercommunication to every type of practitioner, and one lesson of Jenner's life seems to be that even in the isolation of a country practice, amid the hourly demands of a toilsome calling, it is possible with the aid of societies and interchange of ideas with those more fortunately situated, as John Hunter was, to keep the mind alive to every new source of information and even to carry out original investigations in many branches of medicine, biology, and natural history. The modern development of libraries, too, has brought wide facilities at a trifling cost to every practitioner's door, and along with the medical journals has rendered easy communion with the great minds of the present as well as of the past, both in this country and beyond the sea. Societies, too, have been important agents in promoting among medical men that feeling of good fellowship that is essential for fruitful coöperation; men's minds are massaged by rubbing against each other, and they rub off their angles by mutual attrition. In this conviviality has played its part, however humiliating it may be to reflect that the tiger in man needs ever to be appeased by the prospect or retrospect of a meal. La Rochefoucauld has said that nothing is so bad as we imagine it to be, and he might well have added "nobody." Few of us but are aware of some personal prejudice, founded on no better grounds than gossip or misunderstanding, melting like snow in the warmth of personal intercourse.

Anyone who studies the domestic history of medical societies cannot fail to be struck with one circumstance. Time and again a new need has arisen, but the dead hand of inertia has prevailed, and no step is taken to meet the new need; then fission takes place, and a fresh society emerges—often out of the very vitals of the parent society and to its detriment. Why is it that societies tend to lose responsiveness to their environment? Is it that their official administration has in the past been far too much in the hands of the older members? Were Harvey and Jenner and Osler right in believing that 40 years is apt to be quite as critical an age in the lives of men, as it is alleged to be in women's valuation of their own lives? If so, would it not be well that every society should have a regulation that at least one-half of its governing body should be under 40 years of age? That is a question to which I leave each one of you to make his own answer.

MATERNAL DISABLEMENT.*

By W. Blair Bell, B.S., M.D. Lond., F.R.C.S. Eng.,
F.C.O.G., Hon. F.A.C.S.,

OBSTETRICAL AND GYNÆCOLOGICAL SURGEON, ROYAL INFIRMARY, LIVERPOOL; AND PROFESSOR OF OBSTETRICS AND GYNÆCOLOGY IN THE UNIVERSITY OF LIVERPOOL.

LECTURE II.

It was shown in the preceding lecture that there is a vast amount of maternal disablement following pregnancy, parturition and the puerperium, directly or indirectly caused; and that whereas the maternal death-rate is about 0·5 per cent. of all live-birth deliveries† the disablement rate would seem to be no less than 10 per cent. of all pregnancies. Such a state of affairs alone calls for serious national consideration. It seems almost incredible that every year one woman in every ten of those who bear children is to be more or less disabled or has to endure an operation to cure her injuries. Yet, in the absence of exact figures this seems a conservative estimate. Besides, probably many more bear in silence minor lesions which may prove fatal later. It is not unreasonable to hope that with an organised maternity service, exact statistics will be forthcoming a few years hence.

To every student of the subject of maternity in these islands it must be clear that while the mortality should be reduced, and can be reduced, possibly by about one-quarter or one-third, there are few, I think, who knowing all the circumstances would be prepared to go so far as the Minister of Health[1] did when he stated that "not less than one-half—it might be more—of these maternal deaths were preventible." Until the state of affairs which I envisage has existed for two generations such an improvement is but an armchair dream. There must be a large irreducible minimum so long as the present high percentage of pre-adolescent crippling obtains among girls. Still, it may be possible by organised effort to save one life, now lost, in every 1000 labours—a saving to the country of about 1000 women a year. But it follows, too, from what has been said that women in danger who are saved are generally women seriously injured; consequently, putting aside the question of producing sound mothers, a properly organised scheme should include the prevention and treatment of obstetrically crippled mothers, as well as the saving of their lives. If 1000 lives were conserved, it seems not improbable that, employing the same ratio (one-third), 20,000 women might annually be saved suffering and disability in the immediate future. I need say nothing of the gain, economic and domestic, that would accrue to success along these lines.

---

* The Ingleby lectures delivered in the University of Birmingham on May 21st and June 4th, 1931. Lecture I. appeared in THE LANCET of May 30th.

† In this country the maternal death-rate is estimated in reference to every 1000 live children born. This is surely an incorrect method. It would be higher—probably 0·6—if all cases of stillbirth were included as they are in the Scandinavian countries.

I think that this lecture can, therefore, be best employed in the presentation of some ideas on the more important administrative aspects of a national maternity service. I want to make it quite clear, however, that they are my own views only, although I know they are strongly supported by some of the leading obstetricians in Great Britain.

My remarks are not intended to reflect adversely on anyone or anything. Medical practice and medical facilities pass through many stages of evolution, and so does the human mind. The suggestions advanced are merely for another great step forward, and I realise there will be many more in the future. It is, I think, generally admitted that large changes from the present somewhat disconnected and haphazard methods are overdue, and that criticism without construction does nothing more than hamper progress.

A Central Administrative Council.

All practising obstetricians are, I think, agreed that a fundamental requirement is that there should be an *ad hoc* central, independent, administrative body of small size—say 14 in number—and as far as possible autonomous in character. This council should consist of representatives of the Ministry of Health, public health authorities, the British Medical Association (representing general practitioners), the British College of Obstetricians and Gynæcologists (representing consulting obstetricians), and of pædiatricians, with an independent chairman. It will be noted that representation, at any rate at first, of the nursing service has been omitted, and this is because in my opinion the nursing personnel needs great alteration, and the introduction of conflicting interests at the start would be most undesirable.

Recommendations and reports of the central administrative council, like those of a Royal Commission, should be submitted directly to the Government—that is, in fact, to the Minister of Health. The Government would, of course, have the power to reject any proposal, but would be answerable to Parliament, and so to the country, for its actions and policy in this direction. Information and instructions should be distributed by the Ministry of Health, whi should be responsible for conformity on the part county councils and municipalities.

It is said that the establishment of this *ad hoc* bo would cut diametrically across the existing legislati procedures and authority. Parliament has co ferred the responsibility of preserving the health the nation on the Minister of Health who ac presumably, on the advice of his department; and l further legislation—as in the recent local governme Act—powers are devolved on county councils a municipalities. In all this there is no effecti arrangement made to ensure that those who kno most about the subject shall be consulted directl and the whole business is disintegrated, rather tha coördinated, among the numerous and heterogeneo bodies in which authority is vested. It is absolute essential that there should be some central authorit to amalgamate public and voluntary effort.

Since feeling is being stirred by all political partie because there are 3000 immediate maternal death yearly, what will be said when I assert the annu mortality is in reality 8000–10,000—for remote a well as immediate mortality should be considered— and that about 60,000 mothers are crippled annually Surely all political parties will be prepared to vote fo any Act of Parliament which would confer powe to deal with the question on a *competent* and *efficien executive body*, such as that suggested. At any rate it is by this course alone that an immediate and appreciable change will be effected in this appalling maternal holocaust. We scrapped procedure and legislation to save life in the late war. Let us do so again in this matter of maternal life and disablement.

General Organisation.

One of the great difficulties of organised maternity work at the present time is the scattered distributio of maternity practice. While in the large cities, especially those with teaching-hospitals, a considerable degree of coördination and coöperation is possible, if not actually in being, in the smaller urban and rural districts, adequate facilities are non-existent or imperfectly realised, and unified control is difficult to establish, and will become impossible unless some central council such as that I have indicated is brought into being.

What is needed first of all is a system of linking-up, much on the lines of military medical services in war-time. The whole country should be divided into areas in each of which one or more large bases, preferably with teaching-hospitals, are situated. Such a base could function for a district with a radius of 50 miles. County town hospitals in this area should act as field hospitals and the smaller outlying hospitals as casualty clearing stations and emergency centres.

The "competition" between voluntary and municipal effort must cease, and all resources must be pooled. At the present time, urged by the Ministry of Health to speed up facilities, certain municipalities are erecting large maternity hospitals and are conducting maternity homes, under the ægis of the medical officer of health without reference to the leading consulting and practising obstetricians in the places concerned, with the result that the beds are not available for teaching purposes, and are not always in the charge of expert obstetricians even in large cities.

It may be said in regard to such a position that, whereas the financial resources are at the disposal of the public authorities, expert knowledge and skill are almost entirely the monopoly of the voluntary organisations. Surely such inequalities of distribution of the fighting forces is contrary to the interests of the public; coördination and coöperation under unified control are essential. So it is that I press urgently for a concrete national service to secure the linking-up and the pooling of all resources—intellectual, material, and financial—in order that coöperation, coördination, and therefore general efficiency, which is often lacking to-day both in hospital arrangements and the medical, nursing, and administrative services, may be obtained.

I shall now turn to some of the details of a complete scheme, but first let me enumerate the desiderata for such an organisation, in order that I may afterwards enlarge on some of them.

Desiderata.

ACCOMMODATION FOR TRAINING AND PRACTICE.

1. *Base Hospitals.*—(*a*) For teaching and training of students and nurses. (*b*) With university laboratory facilities. (*c*) With maternity (minimum 40 beds) and gynæcological wards (minimum 30 beds). (*d*) With consultative antenatal, postnatal, and infant welfare clinics—internal and external. (*e*) With specialist facilities.

2. *Field Hospitals.*—(*a*) The larger general hospitals. (*b*) With clinical laboratory facilities. (*c*) With maternity wards (minimum 25 beds). (*d*) With specialist facilities. (*e*) Antenatal, postnatal, and infant welfare clinics—internal and external.

3. *Emergency Hospitals.*—(*a*) Cottage and small country town hospitals. (*b*) With one-quarter of the total number of beds for maternity cases—not less than 3 in all. (*c*) Antenatal and postnatal clinics—internal.

4. *Hostels for Nurses.*—(Domiciliary practice).

5. *Domiciliary Arrangements.*

PERSONNEL.

1. *Medical.*—(*a*) Consultants: obstetrician, physician, surgeon, radiologist, ophthalmologist, rhinolaryngologist, dentist, biochemist, pathologist, and pædiatrician. (*b*) General practitioner and anæsthetist.

2. *Nursing.*—Maternity sister superintendents, maternity sisters, maternity staff nurses, and maternity nurses. All to be fully certificated nurses with a certificate in obstetrics.

3. *Administrative.*—Central administrative council; Ministry of Health; local executive in each area.

Accommodation.

Accommodation is related to in-patients and out-patients—antenatal, natal, postnatal, and child welfare—to laboratory facilities, to undergraduate and post-graduate students, to medical and nursing indoor staff, and most importantly to the housing of the "district" nursing staff. The last I shall consider separately. With the "linked-up" system advocated the needs in different parts of each unit would obviously vary, but economy would be served by the facilities at the base being available for the rest of the unit.

BASE HOSPITALS.

The base hospital accommodation should be in one, but often necessarily in more than one, large general teaching-hospital in the city forming the centre of the unit. General hospitals are preferable in every way to special maternity hospitals for the following among other reasons:—

(1) *Finance.*—The cost of building a maternity and gynæcological department in, or attached to, a general hospital is much less than the cost of building a special maternity hospital, for one administrative block and other building arrangements in the former serve the whole. Moreover, no special maternity hospital, so far as I know, contains a gynæcological department; and it is absolutely essential that there should be gynæcological wards in association with every maternity department. The cost of upkeep, too, is more spread-out, and therefore less per maternity bed in a general than in a special hospital.

(2) *Special Consultative Facilities.*—Clinical, radiological, and laboratory (often university) coöperation is more readily available in a general than in a special hospital. Moreover, a sense of proportion is maintained, especially in antenatal work, for the student sees the consultative side of it when he is doing his medical clerkship since he accompanies his chief when he visits the maternity wards to examine cases of heart disease and pregnancy and other medical conditions, and to give advice concerning their management. Such excellent teaching facilities do not obtain in special hospitals. It is most desirable, as we have seen, that obstetrics should not be divorced from medicine and general surgery, any more than it should be separated from gynæcology.

(3) *Nursing Staff.*—In general hospitals the responsible staff all become fully certificated (S.R.N.), and the maternity wards are staffed by the same nurses as those in charge of the rest of the associated clinics—antenatal, postnatal, infant welfare, and gynæcological, as well as the medical and surgical.

The fully certificated nurse acquires a conscience for asepsis, working as she does in a surgical atmosphere, and, owing to her medical and gynæcological experience, she is competent to attend to all the antenatal and postnatal difficulties that may arise as well as the natal in which she should receive full obstetrical training. Enough was said in the first lecture to make it clear that there is a very considerable amount of constitutional as well as gynæcological disablement—matters quite outside the province of the ordinary midwife, yet requiring skilled nursing. In many special maternity hospitals the sisters—and even the matron—have the certificate of the C.M.B. only, and are not scientifically qualified, therefore, even to train the ordinary midwives in the modern requirements of maternity work.

It will be gathered that one of the essential features of a national maternity service should, in my opinion, be the employment of fully certificated nurses (S.R.N.) with a further obstetrical certificate. The present midwife type should be gradually eliminated. I shall deal with the matter more fully directly, for the present clear-cut difference of opinion on this question must be examined in all its aspects.

The famous, long-established maternity teaching hospitals, would, of course, function in base centres in association with general teaching hospitals, and we need not consider their facilities further, for during recent years the disadvantages attaching to them have been recognised and remedied, so far as this is possible. It must, however, be urged that no new maternity hospitals should be erected, as is now being done in many municipal areas. There is no justification for such expensive and far-from-ideal institutions. Better much that with coöperation between voluntary and should be reduced, and can be reduced, possibly by about one-quarter or one-third, there are few, I think, who knowing all the circumstances would be prepared to go so far as the Minister of Health[1] did when he stated that "not less than one-half—it might be more—of these maternal deaths were preventible." Until the state of affairs which I envisage has existed for two generations such an improvement is but an armchair dream. There must be a large irreducible minimum so long as the present high percentage of pre-adolescent crippling obtains among girls. Still, it may be possible by organised effort to save one life, now lost, in every 1000 labours—a saving to the country of about 1000 women a year. But it follows, too, from what has been said that women in danger who are saved are generally women seriously injured; consequently, putting aside the question of producing sound mothers, a properly organised scheme should include the prevention and treatment of obstetrically crippled mothers, as well as the saving of their lives. If 1000 lives were conserved, it seems not improbable that, employing the same ratio (one-third), 20,000 women might annually be saved suffering and disability in the immediate future. I need say nothing of the gain, economic and domestic, that would accrue to success along these lines.

I think that this lecture can, therefore, be best employed in the presentation of some ideas on the more important administrative aspects of a national
maternity service. I want to make it quite cl
however, that they are my own views only, wards.
I know they are strongly supported by s maternal
leading obstetricians in Great Britain. infection—
My remarks are not intended to r eated by expert
anyone or anything. Medical d for this reason

and so does the huma uber of beds should be
advanced are merely
and I realise the IELD HOSPITALS.
It is, I think s would consist of the better-equipped
from the p als in the smaller towns. They should
hazard or their immediate district. In each there
without e a maternity department served by an
progr al clinic and in association with antenatal
s in the neighbourhood. The more serious
d difficult cases should be referred to the base
centre. Since at present in most cases maternity beds in these institutions are provisional, it would be advisable to build blocks affording proper accommodation and isolation facilities. Indeed, these would be the same as those obtaining at base hospitals but on a smaller scale. A standard plan, such as that illustrated, should be utilised, but adapted to local exigencies.

EMERGENCY HOSPITALS.

Emergency accommodation should be provided in the ordinary rural cottage hospitals, in which a few maternity beds should be maintained for the immediate district in which they are situated. Cases from them or the antenatal clinics close by could be referred to the base hospital, or in specially urgent cases assistance obtained therefrom.

ISOLATION IN OUTLYING AREAS.

In outlying urban and rural areas it would probably be found desirable to have one conveniently situated isolation hospital, or block, to meet the needs of a large district. This might be situated in the same town as that in which there is a considerable popula-

should be distributed by the Ministry of Health, which should be responsible for conformity on the part of county councils and municipalities.

It is said that the establishment of this *ad hoc* body would cut diametrically across the existing legislative procedures and authority. Parliament has conferred the responsibility of preserving the health of the nation on the Minister of Health who acts, presumably, on the advice of his department; and by further legislation—as in the recent local government Act—powers are devolved on county councils and municipalities. In all this there is no effective arrangement made to ensure that those who know most about the subject shall be consulted directly and the whole business is disintegrated, rather tha coördinated, among the numerous and heterogeneou bodies in which authority is vested. It is absolutel essential that there should be some central authorit to amalgamate public and voluntary effort.

Since feeling is being stirred by all political partie
because there are 3000 *immediate* maternal deat
yearly, what will be said when I assert the ann
mortality is in reality 8000–10,000—for remote
well as immediate mortality should be considered—
and that about 60,000 mothers are crippled annually
Surely all political parties will be prepared to vote f
any Act of Parliament which would e used for the
to deal with the question on es and for the work of
executive body.
it is antenatal, postnatal, and infant welfare
clinics scattered further away throughout the area
would be connected immediately with the field or emergency hospital, but difficult or doubtful cases would be referred to the base hospital directly. These clinics could all best be held in the same place, a pædiatrician or general practitioner, according to the locality, undertaking the infant welfare clinic.

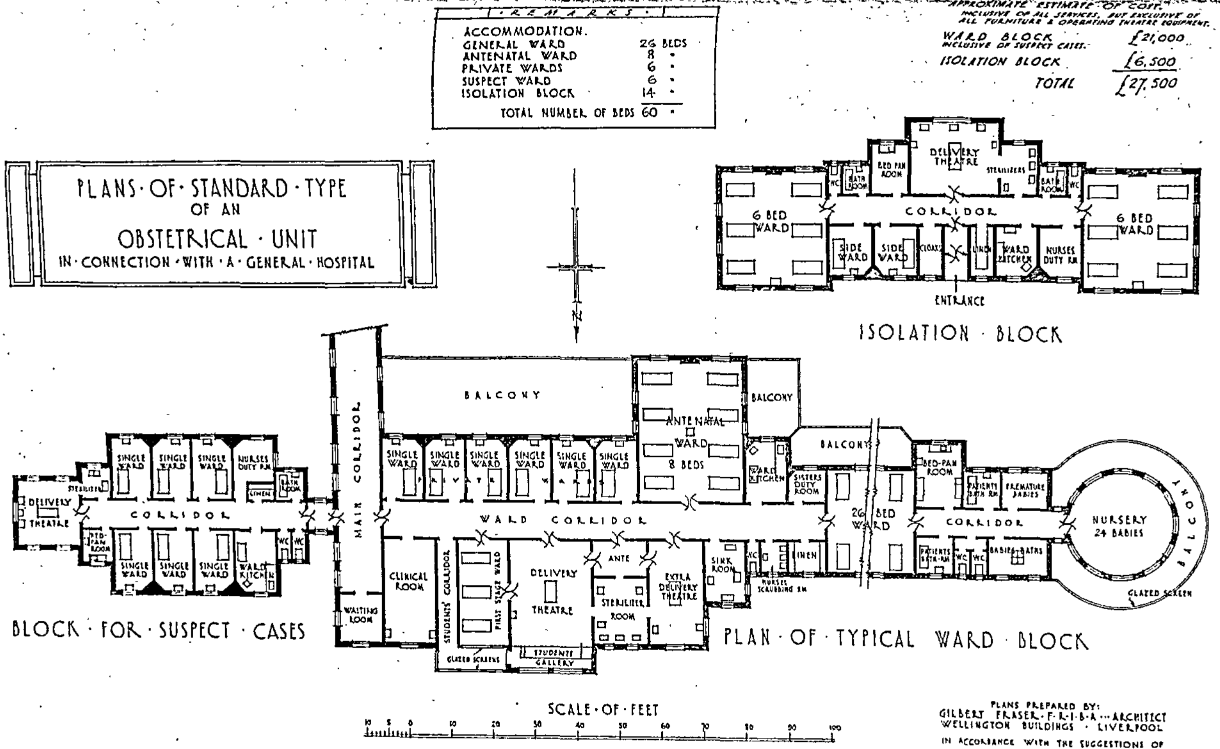
Special Services.

An efficient *anæsthetic service* should be maintained not only in the large base hospital centres but in the outlying districts, and this should be available in all areas for domiciliary practice. This is a matter that requires very careful consideration, in view of the inherent difficulties of anæsthesia, and the methods thereof in certain cases. A readily available *motor service* should be at the disposal of every doctor who wishes to transfer a patient to hospital. *Home-helps*, in those cities where a proper organisation for supplying them has been in existence, have proved of great value in domiciliary practice, and should be incorporated in the national maternity service.

Personnel.

MEDICAL.

Base Hospitals.—The control of base centres should be in the charge of a consultant obstetrician and gynæcologist, preferably of professorial rank, for this would give him direction of the laboratory for investigation and research, and bring university facilities and prestige into the national maternity service. He should, of course, work in full coöperation with his consultant colleagues in the various base hospitals, if there were more than one in the centre, and with the public health and nursing authorities. He should also be responsible for all the teaching arrangements. Numerous junior consultants should be in charge of the clinics and a pædiatrician should undertake the infant welfare work. The many other specialists already mentioned should be definitely coöpted to the service at the base. The



Plan of a standard three-division maternity department attached to a general teaching-hospital. The admission room, which should be near to the hospital entrance, is not shown. The main ward is "broken" in the plan. It will be noted that the three divisions are self-contained, and that in the suspect blocks beds are in single rooms only, in order that the cases may be removed after investigation to the isolation block or to the clean ward according to the findings. There is accommodation for a few private cases. Sunny open-air balconies should be provided in the "clean" division and in the isolation block; these are not shown in the plan of the isolation block. Attention may be called to the bed-pan-sterilising and storage room, the room for premature babies, the round nursery with *a big balcony and vita-glass roof, and to the arrangements* for students to observe labours in progress.

assistant staff should be available for consultative and operative work within the area of influence of the base centre.

In the field hospitals general practitioners would no doubt be in charge with juniors assisting in the department of obstetrics and the associated antenatal clinics.

It seems probable that in the future, with the improved undergraduate and post-graduate teaching that is now foreshadowed, and with the conferment of diplomas in obstetrics a very competent general level of knowledge and practice will be reached; but this should not lead to each rural centre becoming a base, for it must be remembered that the teaching will be conducted at the real base centres, and that the men who devote their lives to the subject will be stationed there specially equipped by experience, long training, and facilities for the more difficult part of the work. Moreover, it is here that physicians, pædiatricians, radiologists, and other specialists will be attached to the service. If, however, the scheme adopted be a really national one with the maintenance of a complete system of records, not only of maternal mortality but also of disablement, a check can be kept on the practice throughout the country; and this will become especially useful provided the chief obstetrical officer in each district has direct and confidential access to the central administrative council. In all the circumstances I have envisaged—namely, better undergraduate and post-graduate training, increased local facilities and friendly consultative coöperation—there need be little fear that the medical service throughout will be highly efficient and loyal to the interests of all concerned.

NURSING.

I now return to a part of the national maternity service which requires further consideration, and the more so in that opinion on the subject is divided, in order that once and for all I may examine the arguments that have been advanced for perpetuating a system which I hold to be wholly inadequate to the requirements of modern scientific obstetrics.

Many agree with the view that the advent of the fully certificated nurse-midwife is inevitable, but only in the sense that this natural evolution must, as they think, come to pass. At the same time advocates of the present type of midwife affirm that she is satisfactory, although a longer period of training would be an advantage.

This is a point of view I find it difficult to understand. Either the present midwife is all that can be desired, or she is not. If the latter be the case, and it is, as I shall show, impossible for many reasons to educate her further—say for two years—why should we not at once adopt the principle of the S.R. nurse-midwife?

I, myself, am of the opinion that a nurse should be State-registered before she is allowed to take an obstetrical certificate, and that as soon as practicable none other should be allowed to undertake maternity work. It is interesting to note that the idea of the S.R. nurse-midwife is accepted in the interim report of the Departmental Committee on Maternal Mortality (1930).

The chief arguments used by those who advocate the retention of the partly trained midwife are as follows.

(1) Since it is admitted that the present training is inadequate, the midwife, it is said, should have two years' training, and this should include some teaching in general medicine and surgery.

(2) The present midwife is best suited to the conditions of maternity practice of a domiciliary character: (*a*) she is unlikely to attempt to interfere with labour; (*b*) she has borne successfully and well the brunt of maternity practice for many years; (*c*) the high mortality-rate is not the fault of the midwife; (*d*) a maternity service could not be established without her—that is, the fully trained nurse would not undertake the ordinary domiciliary practice.

(3) In the Scandinavian countries, where midwives with two years' training are employed, the maternal mortality is less than half of that in this country.

The United States are quoted as having a high maternal mortality-rate, and by an advocate of our present midwifery system[2] it has been said that this is because "they have no midwives," and that "there is the peak of maternal mortality."

My *main thesis is, of course, maternal disablement*, but this is directly related to efficient practice, and indirectly to the number of maternal deaths, and further all of the nursing in connexion with maternal disablement is beyond the knowledge and training of the ordinary midwife.

Before developing my scheme for the employment of the State-registered nurse with an obstetrical qualification, I shall deal with the arguments submitted above by those who would retain the present type with further training.

(1) In respect of further training it is the opinion of many of us that a very large number of the women who present themselves for the present training, and are almost automatically accepted, are uneducable, especially in a scientific subject. It might be possible to get over this difficulty by a preliminary examination, or by taking only one in every ten applicants as obtains in Denmark; but in either case there would be few midwives in the north of England. Supposing, again, that the present class were accepted and a further period of one year's training in respect of medicine and surgery ordained. Where is this to be given? Certainly not in the big teaching-schools. It is doubtful whether any hospital giving a full training to nurses would admit them. It would mean a revolution of the nursing system, for many of those intending to take the full course would be excluded. Further, the present class of midwife could not afford two years' training. It must be noted that in Sweden the midwives are not taught anything at all about medicine and surgery during their two years' training, so Prof. Essen-Möller informs me. Moreover, in this part of the world the women are of a higher class than obtains in this country.

(2) (*a*) It is true that in this country the midwife does not interfere. In Scandinavia the midwives are taught to apply forceps. The real point is whether the former know enough to seek assistance *in proper time.* Some experienced midwives undoubtedly do; many do not; all should.

(*b*) The midwife has certainly done good work; but her predecessor was not hard to follow. The question, however, is this: can she give the same skilled attention as the fully trained nurse? She knows nothing of constitutional antenatal conditions, and nothing about postnatal. A nurse who has been trained in medical and gynæcological wards is familiar with both. Moreover, as I have already said, a nurse who had seen much of general surgery acquires a sense of surgical cleanliness and *technique* unobtainable in any other way.

(*c*) The low mortality attributed to midwives I hold to be a fallacy, for they call for medical assistance in about 25 per cent. of all cases *attended* by them.

(*d*) The impression of many that the domiciliary maternity service could not be conducted without the present type of midwife is, I think, erroneous. The question resolves itself into the following:—

(1) Are there enough fully certificated nurses holding an obstetrical qualification? There are. In Scotland, for example, in 1925–26, 496 women entered for the C.M.B. examination, of whom 351 were already fully certificated and 145 not certificated; in 1928–29, 403 women entered of whom only 40 were not fully certificated. Again, in England, in 1928, 2811 persons entered for the C.M.B. certificate, of whom as many as 1730 were already fully certificated (S.R.N.). It is truly said that only about 25 per cent. of the State-registered nurses with the C.M.B. certificate practise midwifery. But more are doing so every year. The "Jubilee" nurse-midwives are all fully certificated, and they do domiciliary practice. At any rate, there are enough fully certificated (S.R.N.) with obstetrical qualifications for the whole country if they would engage in domiciliary practice. This brings us to the second point.

(2) Can the inducements be made attractive enough to ensure that a sufficient number of fully trained nurses will engage in practice? I think they can, and I shall deal with this matter directly.

(3) Last, in support of the suggestion that midwives—that is, women with the C.M.B. certificate only—should be retained, with perhaps a longer period of training, it has been asserted by those who clearly have not studied the question fully on the spot that in the Scandinavian countries the maternal mortality is considerably less than our own[‡] and that this is due to the two years' training given to midwives. No statement could be more misleading and less true. So far as the midwives themselves are concerned, they are undoubtedly superior in general education and position in life to those in England and Wales—especially in the north of England. In Denmark about 30 in all are qualified annually, and of all those who apply for training only 1 in every 10 is accepted; some are of the position of teachers, doctors' daughters, and so on, and I am informed by Prof. Essen-Möller, to whom I am much indebted for information, that attempts are being made in Sweden to secure an even higher class, for among the fully trained nurses in that country are members of the aristocracy.

Two years' training of such a selected body of women is certainly an advance on what is done here. In Sweden, however, no training is given in general medical and surgical nursing; consequently the midwives must be handicapped in antenatal work, but this branch of maternity practice seems to be less necessary in Sweden than in Great Britain. The people of that country live in hygienic surroundings; they are very healthy and well-fed, and in this connexion it is interesting to note that the average quantity of milk consumed by each member of the community is six times greater in Sweden than in this country. Pelvic contraction is almost unknown. Prof. Essen-Möller writes: "Pelvic contractions are very rare . . . . we have no figures of the frequency of contracted pelvis in Sweden, which may prove that contracted pelvis in Sweden, which may prove that those cases are met with very seldom." Hence the low mortality from sepsis, which so often follows difficult and assisted labour.

Again, it is important to emphasise the fact that in Stockholm 94 per cent. of all confinements take place in the wonderfully equipped hospitals; in St. Malmo and Gothenburg about 85 to 90 per cent., and about 30 per cent. for the whole country. In England and Wales, so far as I can calculate, not more than 6 to 8 per cent. of all confinements take place in hospital. In Sweden, taking the country as a whole, about one-third of all cases are confined in hospital. In this country only about one-tenth of all cases are accommodated in hospital—a very notable difference. Moreover, it must not be forgotten that in the Scandinavian countries generally the mortality-rate is much higher—namely, 4·8 per 1000 labours in 1925—than in Sweden in 1922.

It is necessary to examine on its merits the demand made by some that the midwifery service of this country should be modelled on that obtaining in Scandinavia, and this I have tried to do. While there is no doubt that the Scandinavian midwives are superior to ours in that they are selected and have longer training, and being few in number can be carefully watched, the enormous fundamental differences, just indicated, in respect of the patient herself, account for the lower mortality-rate; this is not due to the midwife, as is so often suggested. It may, therefore, be confidently stated, then, that in Sweden the maternal mortality and disablement is low not only because of the good health of the people and hygienic conditions in which they live but also because pelvic contraction is almost unknown, and therefore sepsis is uncommon, and because a large proportion of all cases is confined in hospital under expert obstetricians. The midwives have little or nothing to do with the question.

Since in England and Wales sepsis is responsible for 40 per cent. of all deaths, and this phenomenon is almost always the culmination of a series of contributory factors among which pelvic contraction with "disproportion" takes a high place in the British Isles, it is clear that in this country also maternal disablement following trauma and sepsis will be much more frequent.

The statements made concerning America that "there is the peak of maternal mortality" "because they have no midwives" are, as I have said, inaccurate. In spite of the almost insuperable difficulties of securing uniformity of practice and registration in the different States, the figures are very carefully surveyed in the U.S. Government reports. According to the latest in my possession (1925) the following statistics of deaths from puerperal causes per 1000 live births are given among many others by way of national comparison.

	Ireland.	*England, Scotland, and Wales.*	*United States.*	*Denmark, Norway, and Sweden.*
All puerperal causes	8·2	5·7	6·2	4·8
Puerperal septicæmia	3·1	2·3	2·3	1·7
Other causes	5·1	3·4	3·9	3·1

The United States of America are not at the peak, even for civilised nations. Moreover, we find in the U.S. Government Report the following interesting statement:—

> "Comparing the rates of 1925 with those of 1915, *for* puerperal septicæmia, the United States (with registration area of 1915) had *the same rate* for both years, England and Wales an increase of 6·7 per cent. in its rate. For other puerperal causes the United States showed an increase of 2·7, England and Wales a decrease of 7·4."

I am very grateful to Prof. F. S. Newell, of Harvard University, for much valuable information on the subject.

If any conclusion can be drawn from the above statements it is that America practises what Dr. John Fairbairn calls "meretricious aids" more cleanly than we do, and that our antenatal system is more general than hers. Anyway, there is no justification for such misleading statements as those made.

[‡] This is true of Sweden only, in which country the figures for 1922 show the mortality is almost exactly one-half (2·5 per 1000 labours) of that obtaining in England and Wales. Yet it is probably even less, comparatively, for in Sweden *all labours* are taken into account, but abortions and ectopics are excluded; whereas we include the latter and only count maternal deaths in women who give birth to live children—a quite ridiculous standpoint, for many serious cases end in death both of mother and child. In addition, as I have shown, the maternal disablement in Sweden is negligible.

I have directed special attention to the question of the nursing personnel, not because I wish in any way to assert that our present mortality and disablement rates are due entirely to the present type of midwife *per se*, but because I think it advisable to expose the nature of the evidence which is put forward in support of the claim that she should be retained, and because I do not believe it to be possible to have an efficient maternity service without fully certificated nurses. I may be asked what I mean by this. Let me try to explain.

First, the present type of midwife is anomalous; she is a makeshift between the completely untrained and the fully trained nurse. She cannot, therefore, be regarded by medical practitioners as a colleague in the sense that the fully certificated nurse is. We all know, too, how a surgically competent nurse prevents any laxity on the part of the surgeon or practitioner. She is an influence for good wherever she works, whether it be in a surgical theatre or the home of the patient.

Secondly, no training that can be given to the present midwife—even supposing it were possible for her to afford the expense and that teaching-hospitals were willing to take her—will make much difference to her efficiency. Nor will additional training evoke in her that spirit of comradeship and discipline and willingness to coöperate which are such prominent traits in fully trained nurses, and which are essential to a linked-up scheme in which S.R. nurses will be working within the sphere of influence of their training schools, if what I propose comes to pass.

CONDITIONS AND ENVIRONMENT OF WORK OF THE S.R. NURSE-MIDWIFE.

It is believed that of the State-registered nurses who take the C.M.B. certificate at the present time in England only about 25 per cent. take up obstetrical practice subsequently. We know, however, that in Scotland relatively few women without a full training now take the C.M.B. certificate, and that all the "Jubilee" midwives, with their excellent record, which I have not time to present or discuss, are State-registered, and I have shown that there is no lack of State-registered nurses who take the C.M.B. certificate in England and Wales. What, then, are the causes that lead to their taking certificates but not practising?

First, it is certain that most of the S.R.N. who take the C.M.B. certificate do so because it is necessary or an advantage to possess this qualification if they wish to occupy the higher posts in their profession. Second, medical officers of health appear to make it a *sine qua non* that S.R.N. applying for posts of health visitors shall have the C.M.B. certificate also. In discussing this matter not long ago with the medical officer of health of Liverpool, I suggested that it would be far better not only to insist on this, but also to accept no nurse until she has been for three years in obstetrical practice under a national maternity scheme. Third, the conditions of domiciliary practice are not such as to render the work attractive to educated women; and it is with the last matter I shall now deal.

The conditions essential to the service envisaged, and attractive to the S.R.N., comprise satisfactory arrangements in respect of: (1) housing and feeding; (2) responsibility, and hospital atmosphere and discipline; (3) post-graduate facilities; (4) regular work and holidays; (5) adequate payment and pension; (6) promotion. The last four requirements are relatively simple problems; the first two comprise the crux of the situation.

Hostels should be established throughout each area. These should be occupied by a sister and three to five nurses; and attendant service should be provided. Here the nurses would live in companionship, relieving each other after definite periods on duty, and the atmosphere and discipline of hospital would be maintained. The freshly qualified nurse would work for a time in a hostel in close association with her teaching school to which she would go for regular post-graduate teaching. Later she would be moved further afield. Extended experience and promotion would follow.

Conditions of work.—The nurse should be taught to realise that she is a link in the system whereby the maternity service would be carried on, and that she is as it were an outpost in her area, with an experienced sister behind her and responsible medical assistance always available. She should have periods off duty and regular holidays, and in country districts small cars should be at the disposal of the hostels, that the nurse may not be physically tired. Her material comforts would be catered for and she would be cared for when ill, another being on hand to take her place. Each hostel would supply the nurses required at the antenatal and other clinics—these, indeed, might be held in a specially built room attached to the hostel. Moreover, arrangements could be made for the district nursing to be conducted by the hostel nurses in turn, for periods of, say, three months at a stretch. This experience would be prized, and would maintain their interest in general medicine and surgery.

I believe a really efficient service could be constructed on these lines, and as I have said the expense would not be great—possibly less than the amount expended to-day.

Summary.

In conclusion, it seems to me, then, that there must be a central administrative council as far as possible autonomous, and that in the ideal maternity scheme we must aim at coöperation and coördination of the best type. This can only be secured by amalgamating all the resources of the country, and by ensuring that the service shall be fully linked up in limited areas, and that the personnel shall be as efficient and mutually compatible as it is possible to make it. Now is the time, when the occasion urgently demands and the opportunity presents, for a great step forwards, not only to save the maternal lives but also to ensure that by skilled attention, rightly utilised, crippled mothers shall be fewer than they are to-day.

ST. BARTHOLOMEW'S HOSPITAL APPEAL.—The governors last week decided that until economic conditions improve it would be advisable to reduce to a minimum the activities and expenditure in connexion with the appeal for a million pounds for reconstruction. It was also decided to appoint a committee of not more than five persons with special financial experience to advise upon financial questions as occasion may arise.

ESTIMATION OF THE BASAL METABOLIC RATE

FROM FORMULÆ BASED ON PULSE-RATE AND PULSE PRESSURE.

BY ANNABELLA M. GALE,* M.D., B.SC. GLASG.,
AND
C. H. GALE, M.INST.C.E., A.R.I.B.A.

IN 1922 J. Marion Read [1] of San Francisco suggested that a simple clinical means of estimating basal metabolic rate might be obtained by making use of the correlation between basal metabolic rate, pulse-rate, and pulse pressure. He suggested the following formula :—

$$\text{B.M.R.} = 0{\cdot}683\,(\text{P.R.} + 0{\cdot}9\,\text{P.P.}) - 71{\cdot}5,$$

but subsequently [2] altered the formula to :—

$$\text{B.M.R.} = 0{\cdot}75\,(\text{P.R.} + 0{\cdot}74\,\text{P.P.}) - 72.$$

In 1926 Cameron, Kitchen, and McRae, of Canada, tested Read's formula during an investigation into the basal metabolic rate of young adults, and concluded "that the results do not justify the use of the formula clinically." [3]

The determination of the basal metabolic rate is of the utmost importance clinically, but it is so involved that it can only be estimated in hospitals provided with a large scientific staff and the necessary apparatus, and it is out of the question for the general practitioner. It was thought that if a formula based on pulse-rate and pulse pressure could be evolved and could be shown to give reliable results, it would bring into the hands of the general practitioner a new method of studying disease at the bedside. With this end in view a letter was sent to Dr. Read which met with a most gratifying response. He forwarded all his original figures and permission to make full use of them. This most kind and generous action made the following inquiry possible. Prof. Cameron, of Manitoba University, was also kind enough to supply the unpublished figures of his test of Read's formula. The Russell Sage Institute of Pathology, New York, very kindly supplied a full set of their papers dating back to 1915. The basal metabolic-rate determinations taken in the Russell Sage Institute are conducted in the most scientific and accurate manner, and it is most unfortunate that their results could not be used, as observations of the pulse pressures are not included.

In Prof. Cameron's 134 cases no less than 55·6 per cent. are included in the zone + 10 per cent. to −9·9 per cent. basal metabolic rate and, taking into account that Prof. Cameron's results were fully 10 per cent. or 15 per cent. higher than Dr. Read's, we decided to deal with Dr. Read's cases only. To facilitate the search for a formula showing the relationship between the basal metabolic rate, pulse-rate, and pulse pressure, Table I. has been compiled from 1006 observations by Dr. Read; this differs slightly from the table given in his pamphlet.[4] From the values given in Table I. the various tables and charts in this paper have been constructed.

In Fig. 1, the mean basal metabolic rate for cases in the zone + 10 per cent. to + 0·1 per cent. is taken as + 5 per cent. and in the zone + 20 per cent. to + 10·1 per cent. as + 15 per cent. and so on. In zones in which only single cases occur the observed basal metabolic rate is taken. Now if the basal metabolic rate values are taken as ordinates, and the results of a formula as abscissæ, and in a straight line formula, these will increase simultaneously by equal amounts if suitable scales be chosen—it follows that the ideal straight line formula will coincide with the dotted line A.A drawn at an angle of 45° (Fig. 1). The results of Dr. Read's formula have been plotted on the chart (Fig. 1) and it is seen that it is too flat; the results in the upper zones are too low, and in the lower zones not low enough. On the same chart are shown the curves for pulse-rate and pulse pressures and also for the sum of pulse-rate and pulse pressure. If a dotted line B.B is drawn through the curve P.R. + P.P. parallel to the dotted line A.A the close approximation is at once seen. This dotted line B.B is 111 on the scale to the left of the chart above the dotted line A.A. The formula P.R. + P.P. − 111 = basal metabolic rate is thus indicated, and further investigation proves it satisfactory. The formula is plotted on the chart and may be compared with that of Dr. Read. The formula and results are also shown in Table II.

TABLE I.

	5 %	10 %	15 %	20 %
	%	%	%	%
1. Gale's formula. $\text{P.R.} + \text{P.P.} - 111 = \text{B.M.R.}$	27·5	45·6	57·4	73·7
2. $1{\cdot}06\,(\text{P.R.} + 0{\cdot}74\,\text{P.P.}) - 105 = \text{B.M.R.}$	21·8	45·1	66·2	73·1
3. $\frac{\text{Log}\,(\text{P.R.} + 0{\cdot}74\,\text{P.P.} + 200) - \text{Log}\,301}{0{\cdot}00113} = \text{B.M.R.}$	26·8	44·6	63·4	70·6
4. $\frac{\text{Log}\,(\text{P.R.} \times \text{P.P.} + 6000) - \text{Log}\,8900}{0{\cdot}00257} = \text{B.M.R.}$	24	44·1	55·1	62·6
5. *Read's formula.* $0{\cdot}75\,(\text{P.R.} + 0{\cdot}74\,\text{P.P.}) - 72 = \text{B.M.R.}$	15·3	25·9	36·1	43·6
6. $0{\cdot}5\,(\text{P.R.} + 0{\cdot}74\,\text{P.P.}) - 38 = \text{B.M.R.}$	7·1	15·9	23·1	30

The formulæ should not be judged by the number of cases falling within a given percentage of error, but by the percentage of cases falling within a given percentage of error over the whole of the zones. By the first method the results would be dependent on the number of cases occurring in the different [illegible] zones; by the latter method the result is independent of the number of cases in the different zones.

---

* Mrs. Gale died in November, 1930.

The next question to be considered is the relative influence of pulse-rate and pulse pressure on the metabolic rate. The error in determining pulse-rate is likely to be less than in determining pulse pressure. There is a very marked tendency for these to vary in opposite directions and the variation of pulse-pressure is slightly greater than that of pulse-rate, but the use of a fractional part of the pulse pressure seems scarcely justified until a greater number and more accurate determinations of basal metabolic rates are available. Dr. Read has pointed out[4] "the idea that the pulse pressure varies directly with the stroke volume is not new. Erlanger and Hooker in 1904, after extensive studies, suggested that the velocity of blood flow could be represented by the product of pulse-rate and pulse pressure." The results of the formula

$$\frac{\text{Log}\,(\text{P.R.} \times \text{P.P.} + 6000) - \text{Log}\ 8000}{0{\cdot}00257} = \text{B.M.R.}$$

are shown in Table II, in which formulæ 1, 2, 5, and 6 are straight line formulæ and formulæ 3 and 4 are curves. It shows the various formulæ compared on a percentage basis calculated from the whole of the 1006 individual cases. The formulæ are placed in their order of merit.

It must be remembered that for the purposes of this investigation the accuracy of the observed basal metabolic rate has been taken for granted, but it appears that the personal equation should be taken into account as, although the observations of Dr. Read and Prof. Cameron were made by a similar method, the portable respiration calorimeter yet, as already pointed out, Cameron's results are fully 10 per cent. or 15 per cent. higher than Dr. Read's. It is much to be regretted that observations suitable for this research are not available from the Russell Sage Institute of Pathology, New York, since admittedly their apparatus gives the most accurate result.

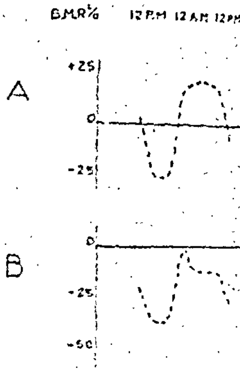
FIG. 2.



The diurnal wave.

SUMMARY.

1. Six formulæ have been calculated and tested on the data of 1006 cases collected by Dr. Read and his staff during the estimation of the basal metabolic rate by the portable respiration calorimeter.

2. Gale's formula P.R. + P.P. − 111 = B.M.R. has been found to give on the whole the most satisfactory results, as seen in Table II., where the total mean percentage of the percentages of all the zones of cases within 5 per cent. error of the observed basal metabolic rate is 27·5 per cent., and of cases within 20 per cent. error, 73·7 per cent. Allowing for the many possibilities of error in the observations of clinical data, this appears to be an excellent result.

3. This method of calculating the basal metabolic rate by the addition of the pulse-rate and the pulse pressure and subtracting 111 make it admirably adapted for use at the bedside by the general practitioner.

THE TWENTY-FOUR HOUR CURVE.

Fig. 2 shows the typical curves of observations made of two subjects at frequent intervals during three years. The curves were fairly constant from day to day. The peak in curve B at about 12 A.M. (noon) was very persistent, but seldom rose above normal. In all cases examined there was a rise from the minimum, at about 4 A.M. to 5 A.M., to the maximum, at about 12 A.M. to 1 P.M., and a tendency to remain steady between 2 P.M. and 8 P.M. For this reason the afternoon appears to be the best time for taking the basal metabolic rate. The curves were obtained by observations taken every two hours by Gale's formula, in some cases without waking the subject. It is doubtful if the curves could be obtained by any other method.

THE PATHOLOGY AND ÆTIOLOGY OF BRAIN ABSCESS.*

By William Evans, M.D., M.R.C.P.Lond.,
MEDICAL FIRST ASSISTANT, LONDON HOSPITAL.

(*Concluded from p. 1235.*)

(B) Hæmatogenous Spread.

In this section are included cases in which brain abscess had followed the transmission by the blood stream of infected material originating in a distant focus of suppuration. This distant source of infection must be regarded as a frequent and important factor in the ætiology of brain abscess, as it provided the cause in 46, or 23·7 per cent., of the 194 cases. In 22 instances the abscess had formed as a complication of intrathoracic suppuration, and in 24 cases brain abscess had followed extrathoracic suppuration. As the abscess occurring in the latter group of cases differs in many respects from that found in the former, each will be described separately.

METASTATIC BRAIN ABSCESS RESULTING FROM INTRATHORACIC SUPPURATION.

Cerebral abscess established as a complication of chronic intrathoracic suppuration is of considerable interest in that it is usually the sole manifestation of pyæmia. Of the chest conditions which are liable to be complicated by brain abscess bronchiectasis is by far the most important. Empyema may produce a similar result, but much less frequently. The peculiar tendency of this group to form a chronic type of brain abscess, generally solitary and almost invariably the only lesion indicative of a pyæmia, warrants its consideration in a separate subdivision. The abscess is embolic in character. Presumably, micro-organisms or fragments of infected thrombus in a tributary of the pulmonary vein are transported in the blood stream and become lodged in a terminal radicle of the cerebral arteries. Acute localised encephalitis results, and a brain abscess is formed.

(*a*) *Brain abscess complicating chronic bronchiectasis.* Brain abscess is a fairly common complication of chronic bronchiectasis. An examination was made of 321 cases in which *chronic* bronchiectasis had been found at necropsy, and brain abscess was discovered in 11, or 3·4 per cent. No brain abscess could be demonstrated at necropsy in 494 cases of *acute* purulent bronchiectasis. It will be seen, therefore, that it is the chronic form of bronchiectasis which possesses the peculiar tendency to give rise to this complication. In the present series there were 17 cases, so that 8·7 per cent. of all abscesses were due to chronic bronchiectasis. This percentage would be considerably raised if the 24 cases of cerebral abscess occurring in general systemic pyæmia were ignored as being clinically unimportant; bronchiectasis would then be found to be the cause of brain abscess with a frequency next in order to that of middle-ear and mastoid infection. Further analysis of the figures shows that when brain abscess complicated intrathoracic suppuration it was secondary to chronic bronchiectasis in 77·3 per cent. of the cases.

The abscesses occurred in 13 males and 4 females. They tended to be more frequent in adult life; six subjects were over 40 years of age, whilst all were between 19 and 51 years. Amongst the 17 cases the abscess was single in 11, or 64·7 per cent., and two or more in number in the remaining 6. They were generally of a large size when solitary, but when multiple they tended to be smaller, varying in size in individual cases from a pinhead to a cherry. The seat of the abscess was usually in the cerebrum, and only very rarely did it form in the cerebellum. The incidence was as follows: centrum semi-ovale 76·2 per cent., temporo-sphenoidal lobe 9·5 per cent., cerebellum 9·5 per cent., pons 4·8 per cent. Thus the centrum semi-ovale, or the white matter in the cerebral hemisphere, proved to be a prevalent and favourite site for this type of abscess. Centrum semi-ovale, *per se*, is not, however, a sufficiently accurate term to define the position of the abscess; the abscess may in this area be frontal, occipital, or parietal; these three sites are given in order of frequency. The abscess did not form with greater frequency on either side; it was on the right in seven, on the *left* in seven, and on both sides in three.

In 16 cases the brain abscess proved at necropsy to be the only evidence of a pyæmia, but in one case an embolic abscess in the right kidney and a large septic infarct in the upper pole of the spleen were also present.

The bronchiectasis in two cases had followed infection of the lung by a foreign body in the air passages; in one case it followed pneumonia; in one it followed direct spread of the infection from a subdiaphragmatic abscess; in two it was tuberculous in origin; in 11 the cause was not definitely ascertained. No satisfactory explanation can be advanced to show why a brain abscess so rarely complicates pulmonary tuberculosis with cavity formation and extensive destruction of lung tissue, in comparison with its relatively frequent occurrence as a complication of chronic bronchiectasis resulting from any other cause. But the fact that two cases fall in this series should emphasise that brain abscess is not an extremely rare complication of bronchiectasis following pulmonary tuberculosis.

The formation of a brain abscess was not determined by the extent of the bronchiectasis in the lungs. The tendency appeared to be only slightly greater in extensive lesions where large and prominent fusiform and saccular bronchiectatic cavities were present than in the less pronounced examples of bronchiolectasis, where the condition was none too obvious when viewed with the naked eye, but was conclusively proved to be present by microscopical examination. This has been conspicuous in the present investigation which disclosed the lesion in the lung to be slight in 7 of the 17 cases; in 4 cases bronchiolectasis had provided the cause, and it cannot be too greatly emphasised that, where a brain abscess has been found at necropsy and no apparent primary cause is immediately discovered, a diligent search should be made in the lungs for possible focal or diffuse areas of chronic bronchiolectasis.

It is significant that with only two exceptions the bronchiectasis in all cases involved the lower parts of the lungs, was invariably confined to the lower lobes, and was usually unilateral. In the two exceptions the bronchiectasis was confined to the apex of the lung, and in both the bronchiectasis was tuberculous.

No advantageous conclusion can be drawn from a study of the relationship between the bacteriology of bronchiectasis and the resulting brain abscess. More than one variety of organism was generally present, and a culture of the abscess content invariably grew similar colonies to those cultivated from the bronchiectatic cavity which provided the initial zones; by the latter method the result is independent of the number of cases in the different zones.

abscess in all cases placed in this group
d in a generalised or systemic pyæmia,
ough the latter accounts for 24, or 12·3 per
of all cases of brain abscess, clinically it is
ed as the least important of all causes, because
prevailing pyæmia invariably proves fatal, the
al areas of suppuration in the brain and other
gans forming as a terminal event.

Brain abscess is not a common lesion in systemic pyæmia; investigation of 576 consecutive examples at necropsy of such pyæmia, complicating osteomyelitis in 113, otitis media in 46, puerperal sepsis in 49, and other lesions in 368, demonstrated brain abscess in only 15, or 2·7 per cent. Septic infarcts in the spleen and kidneys, and pyæmic abscesses in the lungs and small and large intestines were far more constant features.

This type of brain abscess may be single or multiple. In 13 cases more than one abscess was present. In 11 cases the abscess was single. The abscess in two cases had reached large dimensions. In five cases the actual size of the abscess was not recorded. In 17 cases the abscess was small, varying in size from a pinhead to a pea; in many of these cases a diligent search was made at necropsy in order to disclose their presence. The position of the abscess varied greatly; most commonly it was in the centrum semi-ovale or in the cerebral cortex; less commonly it occurred in the cerebellum, pons, the basal ganglia, or in the external and internal capsules. The causes of the pyæmia, the size and site of the brain abscess, and the sites of abscesses forming in other tissues are given in Table V. Reference to this Table will show that osteomyelitis supplied the most common

this investigation the accuracy of the observed basal metabolic rate has been taken for granted, but it appears that the personal equation should be taken into account as, although the observations of Dr. Read and Prof. Cameron were made by a similar method, the portable respiration calorimeter yet, as already pointed out, Cameron's results are fully 10 per cent. or 15 per cent. higher than Dr. Read's. It is much to be regretted that observations suitable for this research are not available from the Russell Sage Institute of Pathology, N
York, since adr ve cases.

B.A. = number of brain abscesses; c.s.o. = Centrum semi-ovale; M. = multiple; Cereb. = cerebellum; L. and S.I. = large and small intestine.

Secondary infection of a neoplasm.—Such a source in the ætiology of brain abscess must be exceedingly rare. The reports of 115 necropsies in which neoplasm of the brain was present demonstrated that in no instance had suppuration occurred in the brain and ed an abscess. Of these neoplasms 82 were nata, 15 secondary carcinomata, 10 secondary mata, and eight angeiomata. In one case a hæmorrhagic and necrotic deposit of carcinoma centrum semi-ovale of the brain was secondary growth in the suprarenal body. On micro- l examination the growth in the brain was to be infiltrated with leucocytes but abscess on had not resulted.

dary infection of a tuberculoma.—It appears e present investigation that suppuration in a tuberculoma is rare. No such example l *in the series of 14,534 necropsies examined.* osed frequency appears to depend upon f microscopic examination. Thus the of caseous material in a tuberculoma may naked eye an appearance closely simulating suppuration. Further it may be found at that a focus of suppuration in the cere- where a tuberculoma is most commonly *is* associated with generally or partially eminated tuberculosis. Where middle-ear and mastoid disease is excluded it is not unreasonable to conclude from the naked eye examination alone that the suppuration has occurred in a pre-existing tuberculoma. The second source of fallacy is illustrated by one case in this series.

During life a male, aged 32 years, had suffered from pulmonary tuberculosis; necropsy showed cavitation in the apex of the left lung with slight purulent bronchiectasis and nodules of broncho-pneumonic consolidation. Miliary granulomatous tubercles were scattered over the under surface of the diaphragm and throughout the spleen and kidneys. A solitary abscess was discovered in the left lobe of the cerebellum, and the middle ears and mastoid antra were found to be clean and free from infection. A somewhat natural deduction was made at necropsy that the abscess had formed as the result of suppuration occurring in a tuberculoma. Histological examination of its wall, however, proved conclusively that it was a simple abscess, and it showed no evidence of tuberculosis. It had evidently occurred as a complication of the bronchiectasis.

(C) Method of Spread Doubtful.

In two cases, although the source of the infection was evident, the path to the brain remained obscure. In one case a large abscess had formed in the left frontal lobe in a child aged 6 years. A small subperiosteal abscess was also present in the left coronal suture, but appeared to be unconnected with small abscesses situated under the adjacent dura. Muco-pus in the left antrum of Highmore seemed to have provided the source of infection, but its path to the brain was not evident. In the other case an abscess (5·5 cm. diam.) was found in the right frontal centrum semi-ovale in a man aged 47 years. Pus was found in both antra of Highmore, and in the frontal and sphenoidal sinuses. There was no thrombosis of the cranial venous sinuses. Examination of cultures prepared from the brain abscess and from the antrum disclosed a pure growth of streptococci of remarkable length and arranged in chains. This finding would appear to establish the accessory nasal sinuses as the source of infection, but in this case also the method by which the infection spread to the brain was not obvious.

(D) Source, and therefore Method of Spread, Doubtful or Unknown.

In three cases a source was not found at necropsy, but the history suggests that the abscesses were pyæmic. In one case, a young adult aged 17, an abscess was found in the left side of the pons. There was a history of pneumococcal arthritis of both hips following an attack of pneumonia two years before death. Necropsy showed a healed arthritis of the left hip-joint and deep scars about the hip. A man, *aged* 32 years, with a streptococcal abscess in the left parietal centrum semi-ovale had suffered from severe quinsy five months before. In a man, aged 46 years, with an abscess in the left frontal centrum semi-ovale there was a history of carbuncles 14 months before.

In two cases there was a history suggesting infection of the ear, but the middle ears and mastoid antra were found to be healthy at necropsy. In a boy, aged 14 years, there was an abscess in the left lobe of the cerebellum, and a doubtful *history of* discharge from the ear was obtained. In another boy, aged 19 years, there was an abscess in the left temporo-sphenoidal lobe; there had been earache four months before death, and wax had been removed from the left ear. In neither of these cases was the nose and its accessory sinuses examined at necropsy. In the second case the necropsy was confined to the head.

In ten cases no source of infection was found at necropsy and there was no history of a possible source. In one case, where an abscess was found in the right frontal lobe, the necropsy was confined to the head and the nasal accessory sinuses were not examined. In nine there was a full necropsy, but in two, examination of the accessory nasal sinuses had been omitted. The sites of the abscesses have been indicated in Table VI.

PYOCEPHALUS COMPLICATING BRAIN ABSCESS.

Pyocephalus was found associated with brain abscess at necropsy in 40 per cent. of the cases; *it* is to be regarded, therefore, as a frequent complication. It appeared to have been established in one of two ways:—

(1) The abscess had extended and ultimately had ruptured into one of the ventricles of the brain, invariably into the lateral ventricle on the corresponding side. This extension of the infection, as

already mentioned, was marked in its early stages by the presence of a finger-like area of encephalitis projecting from the abscess towards the ventricle; in the later stages this area became a diverticulum of the main abscess; eventually this reached the ependyma of the ventricle, and ruptured into the ventricle. The rupture was marked clinically by the sudden introduction of grave symptoms.

(2) The other method by which the infection had spread into the ventricles setting up gross pyocephalus occurred with equal frequency, being found in 50 per cent. of the cases which demonstrated this complication at necropsy. Here the initial step in the process appeared to be the occurrence of leptomeningitis; the infection presumably had reached the ventricles from the subarachnoid space via the foramina in the roof of the fourth ventricle. Clinically this was not identified with the occurrence of catastrophic symptoms as was the case in the previous mode of spread, the process being a gradual one.

THE ASSOCIATION OF MENINGITIS WITH BRAIN ABSCESS.

The association of leptomeningitis with brain abscess was found to be a common one. In its distribution it was either generalised, or localised to a small area over the site of the abscess. In one form or another it was found to be present in 67 per cent. of the cases of brain abscess discussed in this paper. In 70 per cent. of these the purulent leptomeningitis was general; in the remainder it was localised to the surface of the abscess.

OTHER CONDITIONS ASSOCIATED WITH BRAIN ABSCESS.

The relationship between thrombosis of the cerebral sinuses and brain abscess has already been considered. Septicæmia as indicated by hyperplasia of the pulp of the spleen with or without engorgement was present in 30 per cent. of all cases where a full necropsy was conducted. Parenchymatous degeneration of the liver, kidneys, and myocardium was also present in varying degree of severity. Internal and external hydrocephalus with flattening of the cerebral convolutions were commonly observed, and post-operative hernia cerebri was sometimes present.

I am greatly indebted to Prof. Hubert M. Turnbull for his permission to use the records of the Bernhard Baron Institute of Pathology, and for his valuable criticism and help.

ETHER AS A CAUSE OF DEATH AFTER PROSTATE OPERATIONS.

By R. J. Minnitt, M.D. Liverp.,

HONORARY ANÆSTHETIST, THE ROYAL INFIRMARY, AND THE DAVID LEWIS NORTHERN HOSPITAL, LIVERPOOL.

I HAVE long felt that the mortality-rate in prostate operations is far too high. For many years I have noticed that patients for whom the prognosis seemed favourable have died from uræmic conditions some five or six days after operation, although the pre-operative blood-urea has been within what are called normal limits.

Statistical evidence is ample to demonstrate these facts. In a hospital report for two separate years the death-rate is shown to be over 50 per cent. in two-stage prostatectomies, and almost 50 per cent. in the one-stage. In all operations undertaken for bladder conditions connected with the prostate, the death-rate is over 50 per cent.

It is well known that the effect of an ether anæsthetic on renal function is considerable. As far back as 1899 and 1900 R. C. Kemp and W. H. Thompson in America and B. W. Buxton and A. G. Levy, in this country, were putting forward theories to account for the albuminuria after ether anæsthesia. In 1927 Haines and Milliken[1] examined between 60 and 70 cases, and showed that when ether was administered albumin was present in the post-operative urine. It appears, therefore, that ether produces transient renal damage, probably slight cloudy swelling. Florence Stephen[2] has similarly reported albuminuria in all of a series of cases examined after ether anæsthesia, and has suggested that the anæsthetic causes changes in the renal cells.

In the accompanying Table I give urea estimations before and after anæsthesia, and 24 hours and 48 hours later. It should be noted that no change takes place in the urea during the time of anæsthesia, but the Table suggests two things: (1) the higher the urea content of the patient, the greater the rise in the day or two following the operation; (2) there was no change in the blood-urea on the days following administration of gas and oxygen (one case).

Comparison of Urea Estimation in Relation to Anæsthesia.

Operation.	Method.	Amount of ether used.	Time of anæsthesia.	Urea mg. per 100 c.cm.		
				Before and after.	24 hours after.	48 hours after.
		oz.	mins.			
Gastro-ent.	Open ether.	20	60	38–38	N.	44
"	"	16	45	N.–41	45	61
Gastro-ent.*	Gas/oxy/ether endotracheal.	3½	60	49–49	78	72
Appendicec. and cæcopexy	Open ether.	7	35	33–N.	35	28
Goitre removal.	Gas/oxy/ether endotracheal.	2	55	20–20	N.	23
Appendicec.	Gas/oxy/ether face mask.	1	20	N.–26	33	30
"	"	4	45	18–20	21	24
"	Gas and oxy.	Nil.	25	33–35	35	35
Radium insertion.	"	"	20	N.–20	35	30
Appendicec.	Gas/oxy/ether face mask.	2	25	25–25	34	38

* This case was found to have hyaline casts in the urine, and a blood-urea of 62 mg. per 100 c.cm. ten days after operation. Probably a patient with some pre-operative renal damage.

N.= No estimation. Gastro-ent. = gastro-enterostomy. Appendicec. = appendicectomy.

As an illustration of what happens in prostate cases I mention a patient who had a one-stage prostatectomy under gas and oxygen anæsthesia, with the addition of 3 oz. of ether, the time taken being three-quarters of an hour. The blood-urea before operation was 38 mg. per 100 c.cm., and it was estimated daily for four days, and then two days later. The following are the figures:—

41 mg. per 100 c.cm.	first	day after operation.
96 mg.	" "	second	"	"
138 mg.	" "	third	"	"
127 mg.	" "	fourth	"	"
96 mg. per 100 c.cm.	sixth	"	"

It is quite true that this patient did not suffer clinically from untoward symptoms. He was a strong, healthy man, aged 65 years, but it is manifest that the condition of the blood-urea following the operation was important, and under less favourable conditions might have been disastrous. It will be noticed, however, that the blood-urea before operation was within what are looked upon as normal limits.

---

[1] Haines, W. H., and Milliken, L.: Jour. Urol., 1927, xvii., 147.

[2] Stephen, F.: Brit. Jour. Anæsth., 1929, vi., 109.

The conclusions I draw from the foregoing biochemical investigation are as follows: 1. The higher limits of what is called normal blood-urea are abnormal. Cases where it is high will develop a far higher blood-urea after anæsthesia. This applies to all operations. 2. The cause of the increase is the effect of ether on the renal cells. 3. In any case of enlarged prostate, with a blood-urea approaching 40 mg., the operation should be performed in two stages. 4. When there is an abnormal blood-urea and any renal damage, gas and oxygen anæsthesia only should be used.

PROTECTIVE ACTION OF GRANULATION TISSUE AGAINST THE ABSORPTION OF TOXINS.

EXPERIMENTS WITH TETANUS TOXIN AND COBRA VENOM.

By Matthew White, M.B., F.R.F.P.S. Glasg., F.R.C.S. Edin.,

VISITING SURGEON, ROYAL HOSPITAL FOR SICK CHILDREN, AND TO THE ELDER HOSPITAL, GLASGOW.

(From the Pathology Department of the University and Western Infirmary, Glasgow.)

It has long been known that granulation tissue exerts a protective action against the penetration of pyogenic organisms from its surface into the deeper tissues. Thus Billroth (1865, 1871) demonstrated that in dogs the repeated application to a granulating wound of dressings soaked in putrid pus was without ill-effect either locally or on the animals' general condition; whereas when similar material was injected into the subcutaneous tissue inflammation, fever, or even pyæmia resulted. Later, Afanassieff (1896) came to the conclusion, from his experiments on susceptible animals, that various virulent pathogenic organisms such as *Bacillus anthracis* and *Vibrio metchnikovi* were unable to cause infection when placed on granulating surfaces. Noetzel (1898) confirmed these results with anthrax bacilli in guinea-pigs, rabbits, and sheep; the critical period at which the surface was protected was found to be the fifth or sixth day after the production of the wound. Noetzel failed to find that, as stated by Afanassieff, immunity resulted from such implantation of organisms on granulation tissue. Thus, in the case of a sheep which had repeatedly tolerated the application of anthrax bacilli to a granulating surface, Noetzel excised the wound two days after the last inoculation, and death from anthrax occurred 48 hours after the operation; the freshly exposed tissues had evidently become infected from persisting bacilli or their spores. This protective action of granulation tissue against infection with pathogenic organisms contrasts with the ready absorption of crystalline substances, such as potassium iodide (Demarquay, 1869) or pilocarpine (Hack, 1880), when applied as solutions to surfaces covered with granulation tissue.

TETANUS TOXIN.

In the case of tetanus toxin, however, Noetzel (1898) showed that granulation tissue was apparently an effective barrier, since the usual symptoms failed to develop when toxic fluid cultures were introduced into five- to eight-day wounds in sheep, and the animals remained well. In view of the great importance of this observation the work has been repeated.* Tetanus toxin was used and rats were selected, since, owing to their high susceptibility to this poison, a ready indication could be obtained as to whether or not absorption had occurred. Under ether anæsthesia an incised wound about half an inch long was made in the skin of the gluteal region after the hair had been clipped and the patch cleansed. The muscle-fibres were then separated by inserting the blades of sharp-pointed scissors until a small cavity was made in the muscle; into this cavity a small plug of cotton-wool was inserted, and the skin wound was sealed with collodion. After a varying period in different animals the wound was reopened and the cotton-wool plug removed, the greatest care being taken to avoid causing any bleeding. A platinum loopful of the dry powdered toxin was then placed in the wound cavity, a fresh plug of cotton-wool inserted, and the wound sealed as before with collodion. It was found that, by making the platinum loop sufficiently small, the quantity of powder lifted was fairly constant, and by actual weighing represented about 20 times the minimum lethal dose for the size of rat used. While the usual aseptic precautions were observed, the attainment of complete asepsis in the wounds was not attempted.

TABLE I.

Days (a).—Interval in days between infliction of wound and introduction of toxin.

No. of animal.	Days (*a*).	Result.	No. of animal.	Days (*a*).	Result.
1	0	General tetanus.*	14	5	Delayed local spasms: died on 16th day.

13	6	Delayed local spasms: died on 8th day.	26	9	"

* Indicates killed with an overdose of chloroform.

† Wound reopened five days after inoculation, with abrasion of granulations and bleeding: local spasms.*

Note.—All those animals recorded as "well" were observed over a period of several weeks, with the exception of rat No. 20.

The table shows in detail the results obtained, and these may be summarised as follows:—

(*a*) Seven rats were inoculated with the toxin immediately *after the infliction* of the wound, and all developed acute general tetanus within 36 to 48 hours, and were killed with chloroform.

(*b*) Five rats were inoculated with the toxin four days after the infliction of the wound, and of these two remained completely well and three developed local spasms in the wounded leg and were killed.

(*c*) Eight rats were inoculated with the toxin five days after the infliction of the wound, and of these six remained well and two developed local spasms in the wounded leg five and six days *after inoculation, and died on the eighth* and sixteenth days after inoculation respectively.

(*d*) Six rats were inoculated with the toxin six to nine days after infliction of the wound, and all remained well.

Briefly, of 12 rats inoculated *before the fifth day only* two failed to develop tetanus; while of 14 rats inoculated on or after the fifth day 12 remained well, and the remaining two developed local tetanus only.

From a study of these results it appears that when the interval between the infliction of the wound and the insertion of the toxin exceeded five days the animals were protected from the action of the toxin. When the interval was four or five days a proportion of the animals (8 out of 13) remained well, while the remainder (5 out of 13) developed spasms localised to the wounded leg, and seemed otherwise healthy.

---

* I am indebted to Dr. R. A. O'Brien, of the Wellcome Physiological Research Laboratories, for a supply of tetanus toxin in solid form, obtained by precipitating the fluid toxin with ammonium sulphate.

The appearance of spasms localised to the neighbourhood of a wound has been interpreted clinically as evidence of either a relatively slight infection or the presence of a certain degree of immunity, as in cases treated with antitetanic serum. It seems reasonable to conclude that in a healing wound some process has taken place which, after the fifth day, affords protection from the action of the toxin. On or about the fifth day the process is apparently incomplete in that a partial protection only is afforded. As regards the nature of the protection, Pettersson (1911) has shown that, of the cells commonly present in young granulation tissue, the leucocytes, macrophages, and lymphocytes of guinea-pigs, rabbits, and fowls possess little or no power of fixing tetanus toxin. In this connexion the result of a further experiment on rat No. 20 is important. This rat was inoculated with the toxin on the fifth day without apparent ill-effect, but five days after the inoculation the wound was reopened and a fresh plug of wool inserted. In the process some bleeding occurred from the granulations, and within 48 hours the animal developed local spasms in the wounded leg. Obviously sufficient toxin was still present in the wound cavity to cause symptoms of tetanus when the conditions were suitable for its absorption. The evidence, therefore, does not appear to support the view that there is any marked degree of fixation or destruction of the toxin locally by the granulation tissue; it would rather appear that the toxin persists in situ without undergoing absorption. Since various crystalloids are readily absorbed from granulating surfaces, the tetanus toxin may fail to be absorbed into the deeper tissues and the circulation on account of its physical characters as a colloid which is quite inert locally. The protective action would seem to be accounted for by this non-absorption, together with the failure of access by the toxin to lymphatics or nerve-fibres, which are absent from granulation tissue.

COBRA VENOM.

A similar series of experiments was also carried out with cobra venom which, like tetanus toxin, produces poisonous effects chiefly in virtue of containing a neurotoxin. The venom was in the form of fine particles, and the administration of a constant dose was not feasible. The average quantity employed, however, was much in excess of the minimum lethal dose. Twenty-five rats in all were employed, and 20 died within 24 hours of inoculation, the interval between the infliction of the wound and the inoculation varying from five to ten days. Five rats remained well, the interval in their case being six or seven days. The wounds of those rats that died showed no characteristic changes compared with the wounds of those that survived. In the case of the cobra venom, therefore, the protective action of granulation tissue has not been established.

CLINICAL AND LABORATORY NOTES

ALARMING RECTAL HÆMORRHAGE IN UNSUSPECTED TYPHOID.

By Hamilton Bailey, F.R.C.S. Eng.,

SURGEON TO THE ROYAL NORTHERN HOSPITAL, LONDON.

A PATIENT is seized with abdominal pain accompanied by considerable if not alarming bright red rectal hæmorrhage—thrice in my experience this syndrome has proved the only manifestation of typhoid. It is to these cases and to diagnostic problems arising therefrom that I wish to draw attention.

CASE 1.—A previously healthy woman of 38 complained of sudden abdominal pain and nausea 48 hours before admission. Early in this attack she passed a motion containing much bright red blood. Dull pain continued up to the time she entered hospital, when another stool consisting entirely of blood, mostly bright red but containing some clot, was evacuated. I was asked to see her regarding the possibility of the symptoms being due to an intussusception. On examination she appeared pale, the temperature was normal, and the pulse-rate 98. The only physical sign on abdominal examination was deep tenderness in the right iliac fossa. On passing a finger into the rectum I noticed that it felt hot. Remembering occasions on which this sign had proved of value in the diagnosis of obscure cases of typhoid, a specimen of blood was sent for Widal's reaction. It was returned "strongly positive." With appropriate medical treatment the patient recovered.

CASE 2.—Late one night I was summoned urgently to see a boy of 14 who was stated to be bleeding per rectum "like a tap." His history was that he had had abdominal pain for ten days. For the past 24 hours the stools had been frequent, and latterly had consisted entirely of bright red blood. The pulse-rate was 100 and the temperature normal, and he complained of pain in the region of the descending colon. The abdomen was somewhat distended, but on palpation there were no other physical signs. The rectum was full of red blood, and a considerable number of dark clots were passed after the rectal examination. No rash could be seen and the tourniquet test for purpura was negative. The notes state: "? typhoid, ? intussusception." Widal's reaction was requested. On the following morning I learned that he had had a good night and was somewhat better. The Widal reaction was returned as "negative T.A.B." At 3 P.M. I was again called. The pulse-rate had now risen to 120 and rectal hæmorrhage had recommenced. The nurse stated he had passed nearly 1½ pints of pure blood during the past four hours. He was blanched and obviously in imminent danger from loss of blood. As soon as possible I transfused the patient with a pint of blood from his father, whose blood was compatible. Improvement was striking and immediate. He passed a good night, but early the following morning complained of considerable spasmodic lower abdominal pain. Some blood-clot was passed per rectum, but apparently there was no fresh hæmorrhage. As the abdomen was still distended I felt that laparotomy should no longer be delayed. Under spinal anæsthesia lower laparotomy was performed. No pathological condition was found, but the large intestine appeared heavy and dark with blood. The abdomen was closed and he was returned to bed. For five days he continued to improve. No fresh bleeding had occurred since the transfusion, and on the sixth day he passed a normal stool. On the eighth day his temperature, which had previously been normal or subnormal, began to rise, and he looked toxic. On the tenth day diarrhœa began and the temperature rose to 101°. The Widal reaction was repeated, and was returned: "typhosus 1—640, positive +++; para 'A'—negative; para 'B'—positive 1—20." He passed into a delirious state and d on the thirteenth day from the time of the first ervation.

ASE 3.—A clerk, aged 30, was sent to hospital as a case intestinal obstruction. He stated that five days pre- usly he had been seized with acute abdominal pain and n afterwards had passed half a pint of bright red blood. the following day he had vomited twice and again ssed blood. The pain and the bleeding had continued d the stools had been largely composed of blood. The tient did not look ill. His temperature was 99·6° and pulse-rate 98. On examining the abdomen it was at ce evident that there was considerable distension. The tum was empty and the examining finger showed a little od. An enema was given and was returned blood- ined without any fæces. I passed a sigmoidoscope and w some blood and blood-clot in the sigmoid, but other- se the examination was negative. He was returned to d and instructions were given to measure the girth of e abdomen every three hours, and also to report imme- ately any untoward symptoms. By the following morning e tape measure showed that the abdomen had enlarged ore than one inch, and he complained of severe spasmodic ntral abdominal pain. An enema produced the same sult as before. A diagnosis of intussusception probably e to an inverted Meckel's diverticulum was made. On ening the abdomen, by a curious coincidence, the first ing which presented was a Meckel's diverticulum over o feet in length. From its apex there was a cord running the umbilicus. The cord and the diverticulum were cised, but as they were obviously not causing obstruction rther examination was made. The cæcum and colon ere systematically examined. On coming to the splenic exure a change was seen and the whole of the large gut om this point onwards was thickened, blood-red, and hot. he abdomen was closed, and blood taken for a Widal. he report was "Widal's reaction strongly positive." As he patient had never received any typhoid inoculations here was now no doubt that the symptoms were due to phoid. Recovery followed.

DIAGNOSTIC PROBLEMS.

In a case of more or less sudden abdominal pain ccompanied by considerable rectal hæmorrhage he following possibilities are to be considered. It s assumed that a rectal growth will be eliminated by he clinical examination.

1. *Typhoid fever.*

2. *Intussusception.*—The amount of blood passed n cases of intussusception in adult life may be onsiderable, and differential diagnosis becomes really difficult. If the stool is closely examined, mucus will surely be discovered. In five out of six examples of proved intussusception occurring in adolescent or adult life[1] which I have treated, a lump has been easily felt in the abdomen at the clinical examination. In the sixth case a lump could not be felt, but sigmoidoscopy was rewarded by a unique view of the apex of an intussusception with a carcinoma upon it.

3. *Purpura with abdominal symptoms.*—The presence of purpuric spots may be noted. In doubtful cases the tourniquet test should be applied. I have discussed elsewhere the problem of purpura as an acute abdominal emergency.[2]

4. *A bleeding duodenal ulcer.*—It is possible for hæmorrhage to be the first intimation of duodenal ulceration. In this instance blood passed per rectum is unquestionably dark—so dark, in fact, that it is usually described as "tarry." On this account a bleeding duodenal ulcer hardly ever enters the clinical picture, but in the problem before us it is necessary to exclude it.

I have presented this subject as I have seen it. No doubt workers in other fields are confronted with abdominal pain associated with violent rectal hæmorrhage from other causes. For instance, it seems probable that bilharzia might produce this syndrome.

AVERTIN NARCOSIS IN UNUSUAL CIRCUMSTANCES.

By Douglas Belfrage, M.B. Camb.,

ANÆSTHETIST TO ST. GEORGE'S HOSPITAL AND ST. MARK'S HOSPITAL.

The following case is of interest from two points of view: (1) it illustrates circumstances in which avertin narcosis may be the only practical means of making the performance of an emergency operation possible; (2) it suggests that avertin may be a useful method of treatment in one of the conditions which was present—namely, delirium tremens.

A man, aged 59, had been suffering for some time from an inoperable carcinoma of the larynx. Tracheotomy had been advised, but had been refused by the patient's wife until it should become necessary. On April 4th respiratory obstruction came on rapidly, and by the evening the need for tracheotomy was urgent. Unfortunately, on this very day the patient developed delirium tremens.

I first saw the patient at 9 P.M.; he was cyanosed, and the cyanosis was increasing. The respiration was markedly stertorous, and all the accessory muscles of respiration were strongly in action. The patient was not violent, but extremely restless, having to be held in bed, and quite inaccessible to reason or argument; this was in spite of morphia gr. 1 which had been given in the preceding six hours.

A dose of avertin equal to 0·1 g. per kg. of body-weight was rapidly run into the rectum, and most of it was retained. In 15 minutes the patient became quiet and lost consciousness, and was transferred to the theatre. When the first incision in the neck was made he was breathing rather more quietly than before, but with less effort; cyanosis was still increasing, and was by now severe. There was no movement when the incision was made, and no anæsthetic was given. Before the tracheotomy was completed, however, respiration ceased, and, in spite of administration of CO_2 and oxygen through the opening in the trachea, did not begin again, and the patient died.

Death was due to suffocation, which the avertin may or may not have accelerated, but at the same time there can be little doubt that a few hours earlier the operation would have been successful. Circumstances, however, made this impossible, and small regret could be felt since the result was euthanasia for a patient whose immediate future would otherwise have been far from comfortable.

The only alternative to avertin in this case would, so far as I can see, have been an attempt to perform the operation under local anæsthesia while holding the patient still by violence. Any kind of inhalation anæsthetic was impracticable, and the intravenous administration of nembutal or one of the barbitones would probably have been impossible.

The prompt and efficient action of avertin upon a patient with delirium tremens, in which most narcotics and hypnotics are so notoriously ineffective, and who had already had morphia gr. 1 without any considerable quietening effect, suggests that where the administration is possible avertin might be the drug of choice to give in troublesome cases of this condition. The effect would presumably last for some hours, and the dose could be repeated without any danger so far as present experience goes.

I am indebted to the kindness of Mr. Eric Steeler for permission to publish this case.

Fewer Road Accidents.—At the annual meeting of the Victoria Hospital, Lewes, it was stated that during the last few months the average number of road accidents treated had fallen from 28 or 30 a month to six or seven. The diminution is attributed to the working of the new Road Act.

MEDICAL SOCIETIES

EDINBURGH OBSTETRICAL SOCIETY.

AT a meeting of this society on May 13th Dr. H. S. DAVIDSON, the President, took the chair, and a paper on

Uterine Prolapse

was read by Miss GERTRUDE HERZFELD and Miss MARGARET TOD, embracing an investigation into 227 cases of prolapse operated on between 1922 and 1929. Of the 227 cases, 132 were traced for periods varying from one to seven years. As regards symptoms, the complaint of "something coming down" was not universal; a woman with cystocele, rectocele, and cervix at the vaginal orifice might have little local discomfort, but reported for discharge or backache. Frequency of micturition was one of the most constant symptoms in all varieties of prolapse and was present before operation in 70 per cent. of the 227 cases, while every case of total prolapse had incontinence. Vaginal discharge was complained of in every case where a lacerated cervix was found, and 30 out of 34 such cases also complained of backache. On the other hand, only 10 out of 39 complete prolapses made this complaint. Complications after operation were associated with sepsis and consisted either of secondary hæmorrhage which occasionally occurred after amputation of the cervix, or, still more rarely, of sloughing of the wound.

Table Analysis of Results of Operation.

Condition found at operation.	Totals.	Cured, no symptoms.	Uterus, &c., in good position, but urinary symptoms present.	Prolapse recurred.	No symptoms. Slight cystocele found on examination.	Post-operative pregnancies.	
						Norm.	Instru.
Cystocele only ..	11	7	3	1	0	0	0
Rectocele only ..	6	4	2	0	0	1	2

Cystocele with hypertrophy of cervix.. ..	7	5	2	0	0	1	1
Cystocele and rectocele with hyper. of cervix	13	12	1	0	0	1	0
Cystocele and rectocele with lac. cervix ..	19	17	2	0	0	2	0
Complete prolapse	20	17	0	1	2	0	0
Total ..	132	109	18	2	3	8	3

The technique of operation evolved by Donald and Fothergill of Manchester was almost always followed in all cases. The accompanying Table shows that 127 out of 132 patients (96 per cent.) were completely cured, though 18 patients had a slight complaint of frequency of micturition. In all these the urine was acid, and in the majority a slight *Bacillus coli* infection was noted. Two cases, done early in the series, showed partial failure with recurrence.

The conclusions reached were as follows: (1) Surgical treatment of uterine prolapse is a safe and satisfactory method of treatment. (2) Abdominal surgery is never required in this condition. (3) The operation results in a feeling of well-being often not experienced by the patients for many year previously. (4) Pessary treatment, while palliativ as regards symptoms, should be used only in case where operation is out of the question, or in ver young women.

Heart Disease and Pregnancy.

DR. A. RAE GILCHRIST read a paper in which he sai that four years' experience of cardiac cases in th antenatal department and wards of the Royal Maternit Hospital, Edinburgh, had led to the conclusion tha no more accurate method of assessing the ability o these cardiac women to go successfully to term wa to be obtained than by grading them accordin to the functional efficiency of the heart. The type o valvular disease and the ætiology and degree o the cardiac hypertrophy were in themselves of almost no help in prognosis. The actual structural change in the heart mattered little. The all-important factor was the functional efficiency of the heart muscle. This could readily be assessed by noting the response of the patient to her everyday activities. The classification of cardiac disease outlined by the New York Heart Association had proved of great assistance. At the time of the first examination an attempt ought to be made to classify the patient according to one of the following groups:—

Group 1.—Those, who though suffering from organic heart disease, were able to perform their habitual physical activities without any unusual distress, fatigue, or dyspnœa.

Group 2A.—Those who were able to perform their usual activities, but had some slight discomfort in so doing. They had a slight limitation of physical activity, which showed itself by shortness of breath on climbing stairs, on walking uphill, or after performing household duties.

Group 2B.—Those who had a definite limitation of physical activity. They were unable to perform their usual duties without resting at intervals. Several halts were necessary in climbing a flight of stairs. They had given up attempting the more strenuous household duties and at night the ankles might be a little swollen.

Group 3.—Those few whose cardiac reserve was minimal. They were unable to carry on any physical activity without discomfort. They could at the most only walk a few yards and that with difficulty. They had a greater or less degree of congestive heart failure even at rest in bed.

Those in Group 1 gave rise to little or no difficulty. In Group 2A also pregnancy and labour caused but little anxiety, though if the second stage was prolonged the timely use of forceps was indicated. Many patients who came into Group 2B before the sixth month would require Cæsarean section at or about term. Others who developed such a grade of failure in the later months and who responded satisfactorily to treatment would be able to deliver themselves spontaneously and without risk. Women in Group 3 were almost as certain to die if they went into labour spontaneously, or if any obstetrical interference was attempted before circulatory conditions were adequately treated. Heart failure of this degree in the first few months of pregnancy was probably unrelated to the demands of the fœtus. Hysterotomy should be performed as soon as the woman was judged fit enough. In the later months this degree of heart failure could be avoided by adequate antenatal care directed to improving circulatory efficiency. If a case was seen with this degree of failure with labour imminent energetic medical measures must be instituted at once. It was an axiom that no women should be exposed to the additional strain of active obstetrical interference before every endeavour had been made to improve the circulation. Left alone they might deliver themselves successfully and often prematurely; interfered with, they were almost certain to die, if not at the time of intervention then in the early days of the puerperium. Happily such cases were not very common.

In 95 cardiac cases carefully followed through pregnancy, labour, and the puerperium, 92 per cent. of the patients survived pregnancy. The percentage of women who delivered themselves successfully at or about term was roughly as follows: Group 1, 85 per cent.; Group 2A, 77 per cent.; Group 2B, 56 per cent.; and Group 3, 18 per cent. There were no Cæsarean operations in Group 1. In Group 2A these amounted to nearly 8 per cent., but in the light of present experience had probably been unnecessary. In Group 2B the Cæsarean sections were 38 per cent. and in Group 3, 55 per cent. Many of the cases were done under spinal anæsthesia with admirable results, but chloroform combined with oxygen seemed safe in skilled hands. Ether was doubly irritating to lungs a trifle congested, and gas, if it caused any cyanosis, embarrassed the heart by anoxæmia. The anæsthetist was more important than the anæsthetic.

ROYAL SOCIETY OF MEDICINE.

SECTION OF LARYNGOLOGY.

At the summer meeting of this section on June 5th Mr. **Frank Rose**, the President, took the chair, and Dr. A. **Brown Kelly** (Glasgow) read a paper by himself and Dr. Leonard Findlay on

Congenital Shortening of the Œsophagus and the Thoracic Stomach resulting therefrom.

In œsophagoscopy of nine cases having congenital stenosis of the œsophagus, no hindrance was encountered at the entrance to the œsophagus, but sometimes the lumen contained a good deal of cloudy fluid, and in almost every case it was much dilated. At a depth which varied in different patients the lumen quickly diminished to a small opening, which was found to be the upper end of the stenosis. In most of the cases examined this region showed rhythmical movements—i.e., it opened with inspiration and closed with expiration. The endoscope could easily be passed through the stenosed part, whose length varied between 0·5 and 2 cm. On emerging from the stenosis, gastric mucosa was encountered. These conditions found at the stenosis were just those present in the diaphragmatic part of a normal œsophagus. The so-called congenital stenosis was really the cardiac canal situated opposite the seventh instead of the ninth or tenth thoracic vertebra. One could apply the terms epicardia and cardia respectively to the regions at the upper and lower end of the stenosis. In several cases, to decide where the œsophageal joined the gastric mucous membrane, a small piece of the lining membrane below the apparent junction was removed, and was found to consist entirely of gastric mucosa. When trying to locate the upper end of the stomach, the œsophagoscope was introduced until it reached the gastric mucosa, a fragment was removed if necessary, and a radiogram was taken with the tube in situ. Having located the cardia and marked it on a tracing of the radiogram the distance was measured to the hiatus, and the result gave the displacement of the cardia, and, presumably, the amount of shortening of the œsophagus. Calculations so made gave results in seven cases which varied from 2 to 6 cm. A few autopsies had shown that a congenitally short œsophagus was occasionally met with.

Dr. **Leonard Findlay**, speaking on the clinical aspect, said that in all the nine cases vomiting started early, not of spasmodic character, but persisting throughout the meal. When such a symptom was reported, a soft stomach-tube was passed and an obstruction met with. At first he thought the condition might either be ballooning of the lower part of the gullet or dilatation of the œsophagus itself. Radiography was not sufficient to demonstrate it; examination must be made during the act of swallowing, and the patient must be on an inclined plane to encourage delay of the food along the gullet. In the child the position of the junction of the stomach and œsophageal mucous membrane varied considerably—namely, from 4 mm. above the hiatus to 10 mm. below it. It was wrong to think of the œsophagus as a comparatively narrow tube opening into the large sac of the stomach; the two were a continuous whole, and during swallowing the œsophagus widened out and conformed more with the stomach to allow of the passage of food.

Mr. **Harold Barwell** said it was as yet early to realise the various implications in this new conception. If the intrathoracic cardia was a common condition, he wondered in what way it was connected with congenital stenosis.

Dr. **Brown Kelly** said that three years was not a long enough period to enable one to know what happened to these patients at a later period of life. Possibly as the children became older some change took place which enabled the cardia to descend; there was no pathological evidence that the condition was permanent.

Autodilatation of the Œsophagus.

Prof. **Georges Portmann** (Bordeaux) read a paper on the Treatment of Cicatricial Stenosis of Œsophagus by Autodilatation. The principle underlying this treatment was that the patient carried out the dilatation without knowing it, the instrument progressing by peristaltic movements of the walls of the œsophagus. Confronted with a case of cicatricial stenosis, Prof. Portmann first did a gastrostomy under local anæsthesia. When the wound had healed, a filiform bougie was pushed in from the top to the bottom of the stricture and, controlled by the œsophagoscope, as far as the stomach. The extremity of the bougie was taken out through the opening of the gastrostomy after the patient had fasted 12 hours. At the mouth of the gastrostomy he introduced a No. 22 Nelaton probe, whose eyes enabled the stomach to be washed out. After 400 c.cm. of boiled water had been put in the stomach the cystoscope was introduced and the postero-internal wall of the stomach was explored from various angles. A thick silk thread was then tied to the end of the bougie and it was withdrawn. To this "endless" thread, passing from the mouth to the gastrostomy opening, dilating olives could be attached, the smallest being devised to enter the stricture first. At first he used bone olives, but found that they became gradually digested by the patient, therefore he was now using ones made of a silver alloy. When the olives had passed the stricture they fell into the stomach, the patient feeling well all the time. When the olives were in the stomach they were withdrawn through the gastrostomy opening. Three to six days were required for the passage of the olives through

MEDICAL SOCIETIES

EDINBURGH OBSTETRICAL SOCIETY.

At a meeting of this society on May 13th Dr. H. S. Davidson, the President, took the chair, and a paper on

Uterine Prolapse

was read by Miss **Gertrude Herzfeld** and Miss **Margaret Tod**, embracing an investigation into 227 cases of prolapse operated on between 1922 and 1929. Of the 227 cases, 132 were traced for periods varying from one to seven years. As regards symptoms, the complaint of "something coming down" was not universal; a woman with cystocele, rectocele, and cervix at the vaginal orifice might have little local discomfort, but reported for discharge or backache. Frequency of micturition was one of the most constant symptoms in all varieties of prolapse and was present before operation in 70 per cent. of the 227 cases, while every case of total

prolapse had incontinence. Vaginal discharge was ..moval
complained of in every case where a lacerated cer- cleaning.
was found, and 30 out of 34 such cases also comp- ..e voice was
of backache. On the other hand, only 1- -rmal; all the
39 complete prolapses made this comp- ..lves heard. One
plications after operation were ..ube for 70 years and
sepsis and consisted either of se- ..ion catarrh did occur he
which occasionally occurred common mistake was to divide

wound. ..e cannula into the narrower and

Table Analy- ..glottic larynx.

..s **Dundas-Grant** had a good word for
..ler tube; it was easy to insert and it was
..cable, but it also came out too easily. He
..ued it with a quarter-circle tube; it improved
.. Parker to put a sliding collar on it. In many
Conditic..ays the Durham tube was ideal, but it should be
at or bent at more than a right angle.

Mr. **Herbert Tilley** described Sir StClair's communication as one of the most valuable ever presented to the section. Those with long experience recognised the pathos of cases where tracheotomy for diphtheria in children was done too high, perhaps even through the cricoid cartilage. The resultant permanent stenosis was difficult to cure.

Mr. **Ritchie Rodger** spoke of a patient of his who 11 years ago came because he had stenosis from tuberculous laryngitis and perichondritis, and whose condition he regarded as unsatisfactory so long as he continued to wear his tube. The patient saw Sir StClair Thomson and was assured that no ill-effects need follow the permanent wearing of the tube.

Mr. **Walter Howarth** had been struck by the contentment shown by the patients brought forward. Indeed he wondered whether surgical attempts to correct stenosis were worth while, seeing how comfortable these patients were. A type of case in which surgery was difficult was that in which stenosis followed the falling-in of the cricoid cartilage when tracheotomy had been done too high.

Prof. **Portmann** said he had found, in many men with stenosis following war wounds, that it was well to do tracheostomy, then clear away the cicatricial tissue, and after the stenotic process had ceased, to do a plastic operation. This was preferable to the patient always wearing a tube.

---

not experienced by the patients for many years previously. (4) Pessary treatment, while palliative as regards symptoms, should be used only in cases where operation is out of the question, or in very young women.

Heart Disease and Pregnancy.

Dr. A. **Rae Gilchrist** read a paper in which he said that four years' experience of cardiac cases in the antenatal department and wards of the Royal Maternity Hospital, Edinburgh, had led to the conclusion that no more accurate method of assessing the ability o-
these cardiac women to go successfully to ter-
to be obtained than by grading them-

BCG Immunisation of Infants.

He pointed out that most people we..
taneously vaccinated against tuberculosis by ..
accidental "paucibacillary" contaminations in
youth. To protect man from tuberculosis ..
of immunity, which sensitised against tuber-
failed to cause progressive lesions, should be ..
artificially. Only living bacilli would i..
effectively, but spontaneously attenuated ..
could not be used, because they tended to ..
their virulence as spontaneously as they had ..
Experience had shown that avian and para-..
bacilli could not be used to vaccinate ma..
Prof. Calmette and Mr. C. Guérin had therefore
working for nearly 30 years at the pro..
creating a strain of hereditarily and fixedly a..
tubercle bacilli, comparable with the anthrax
cines of Pasteur. The strain known as BCG
been obtained by 230 passages on a highly ..
lipoid-containing culture medium prepared with
ox bile. This strain had never produced prog-
tuberculous lesions which could be inoculated
passage. It was absolutely harmless, but ..
injected or ingested it produced resistance ..
severe infection as effectively as did spont..
infections. The results of inoculating 317 chi..
between 1921 and 1924 had been so encouraging ..
the Pasteur Institute had decided to put BCG at ..
disposal of any laboratory or physician desiring ..
study its effects. Since 1924 research on ca..
monkeys, and apes and infant vaccination had ..
undertaken in many countries and a vast amount
experimental research work had proved the per..
innocuousness of the vaccine and its efficacy in prot-
ing against tuberculosis. The infantile death-r..
from tuberculosis—both in tuberculous and in health..
families—sank nearly to zero after vaccination a..
the general mortality markedly diminished. Vacc-
nated children resisted all kinds of infantile dise..
better than the non-vaccinated; this was probabl..
due to non-specific immunity. The Pasteur Institut..
had collected statistics from the whole country a..
had found that the general mortality among vacc-
nated infants was 6 per cent., while among th..
unvaccinated it was from 16 to 25 per cent. William
Park, of New York, had vaccinated 200 infants and
found the mortality among them in the first four years
of life was 0·9 per cent.; among 400 unvaccinated

infants born and brought up under the same conditions the mortality was 3–4 per cent. There were now more than a million vaccinated children in the world, 336,000 in France. The adoption of B C G in all countries was desirable, and it was a cheap method, since the Pasteur Institute gave the cultures free to all sanitary services. A number of workers were concerning themselves with the problem whether these bacilli could regain their virulence after repeated passage; so far no evidence for this possibility had been observed. Petroff had claimed to isolate two types of bacillus from B C G, one of them being occasionally virulent. His cultures, however, had been shown to be contaminated. A proportion of all children born were certain to meet virulent tubercle bacilli sooner or later; they might as well be given the chance of meeting avirulent bacilli, in a perfectly harmless form, before the dangerous contact occurred. England, Austria, and Portugal were the only countries in Europe not yet applying anti-tuberculosis vaccination; Prof. Calmette hoped that it would not be long before they, too, had joined the crusade.

Dr. ROBERT HUTCHISON proposed a vote of thanks. He said that Prof. Calmette had come as a missionary to this country and had set forth a case for the most serious consideration, at least, of B C G vaccination. The best vote of thanks would be the promise to introduce it in this country.

Sir WELDON DALRYMPLE CHAMPNEYS seconded the vote of thanks, saying that in this country several great names were associated with tuberculosis, but in France tuberculosis was Calmette. In France his name sufficed for a method to be accepted.

SECTION OF COMPARATIVE MEDICINE.

AT the meeting of this section on May 27th Prof. G. H. WOOLDRIDGE, the President, took the chair, and a paper on

Gland-grafting in Veterinary Practice

was read by Mr. G. P. MALE. The first recorded attempt to graft a gland was, he said, that made on a fowl by John Hunter in 1767. Some of the most important recent research in this direction had been carried out by Steinach, chiefly on rats and guinea-pigs, and this worker had succeeded in producing many intermediate changes between male and female. The results of the implantation were chiefly manifest in behaviour; a formerly sluggish and indifferent male animal would, after grafting, become vigorous, combative, and much interested in the opposite sex. Aged females, when engrafted, resumed their breeding, and the senile symptoms receded. The principle had been applied in human beings; portions of testicle from young anthropoid apes, if implanted into the human tunica vaginalis, survived for some time. Steinach produced similar results by ligation or resection of the vas deferens on one side, or later, if necessary, on both sides. The damming-back of the semen caused degeneration of the spermatic tissue and hypertrophy of the interstitial cells, with consequent increase in the output of the hormone. Brown-Séquard claimed that by subcutaneous injection of emulsions of testicular extract he was able to produce in a man aged 72 a marked accession of physical and mental powers; but such treatment must, of course, be frequently repeated.

In Mr. Male's investigations all the domestic animals on which he had operated were suitable subjects for grafting, and the gland graft took. The graft need not be implanted on the testis or ovary in order to get results; it would take effectively anywhere where it was protected from injury and where the nourishing fluids were sufficient. Aged male animals after grafting showed returned youth and vitality, and had their powers of reproduction restored. As an economic proposition, gland-grafting should be valuable to breeders. He had not tried the method in order to hasten maturity in young animals.

One case Mr. Male related was that of a Sealyham bitch, 6 years old, which after several litters failed to breed; there was absence of œstrus. Two complete ovaries were implanted, one on each side, from a year-old whippet bitch, and in a month or two there was a marked alteration in the recipient; she was temperamentally more lively, played with other dogs, and took notice of male dogs. She had a normal "heat" soon after the operation, was mated, and had three strong puppies. Another bitch had been barren two years, but after grafting produced three puppies, and had been in season many times since. To date, only one bitch which had been grafted failed to respond. Among the horses, a thorough-bred mare, 9 years old, had been barren for years although served by different sires. In 1928 she was grafted, and in 1929 produced a foal. The operation had been disappointing in cows, and in them it was only done as a last resort. For rams, boars, and bulls, however, grafting was an important economic proposition. In the case of one pedigree ram, 6 years of age, a noted sire, whose progeny were making record prices at shows, the sexual power showed great diminution, and grafting was accordingly done in 1927, the whole testicle from a young ram being grafted into each flank. One graft took well, the other became detached. In 1928 this ram produced 13 lambs, in 1929 10, in 1930 36, and in the following season 48.

In the operation itself the two most important considerations were strict asepsis and speed. In small animals a convenient site of implantation was the flank; in larger animals the centre of the neck was best. General was preferable to local anæsthesia, though the latter did not appear to interfere with the graft. He made a pocket in the subcutaneous tissue, and this obviated suturing the gland into position after the grafting.

DISCUSSION.

The PRESIDENT thought the results reported should encourage further trial. Some feared that when an animal of superior breed was receiving a gland from an inferior one, there would be deterioration as a consequence, but this did not seem to be borne out by Mr. Male's work.

Major J. B. WALKER said he would have liked to learn what was the condition of the female in each case before the grafting was done, as well as after. He gave some instances of rejuvenation in pack-horses during the war as a result of gland-grafting, and said that for this purpose he found thyroid grafts as efficacious as ovary. By careful choice of cases he believed one could promise 100 per cent. of successes.

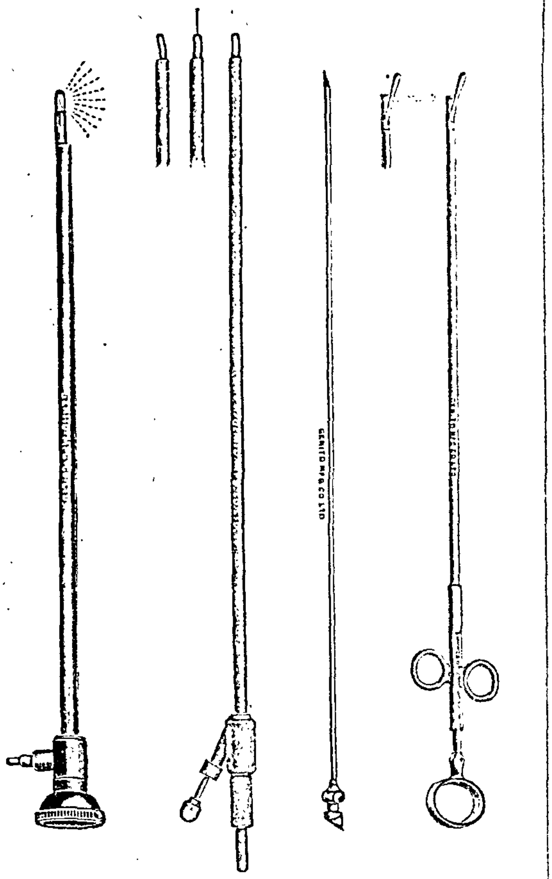
Captain S. R. DOUGLAS pointed out that good results in rejuvenation could be obtained by sterile mincing of gland, and injecting this through a trocar. Results were rapid.

Captain S. R. REYNOLDS considered that mass statistics were needed before definite conclusions were arrived at as to the wisdom of gland-grafting. Mr. Male had not mentioned why the animals referr [illegible] sterile. Careful choice of those to be de with must be made, otherwise the operation could easily get into disrepute. The value of the engrafted gland must be short-lived, necessitating a repetition of the procedure. Every horse so dealt with should be registered and its subsequent performances should be recorded.

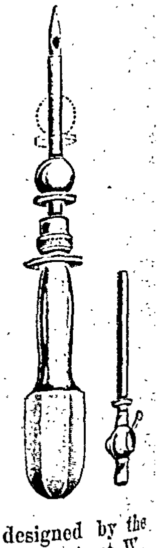
Mr. MALE, in reply, said he did not know a means of estimating the degree of ovarian deficiency in an animal. He had not had experience with thyroid grafting. One veterinarian had grafted 25 bitches, and succeeded in 22. The longest recorded life in the grafted tissue was 18 months, but perhaps the operation revived the activity of the animal's own glands. Animals were always carefully chosen.

NEW INVENTIONS

A SET FOR THORACOSCOPY AND THE DIVISION OF ADHESIONS.



THIS set of instruments for thoracoscopy and the division of adhesions is the result of the experience we have gained whilst using the Jacobæus, Davidson, and Chandler instruments and we believe it to combine the best points of these various appliances. Because of the definite increase of mobility and accuracy of working which the double puncture method gives we have adopted this method; we regard the suggestion that the extra puncture adds to the risk of sepsis as having no basis in reality, especially as more than one puncture is frequently needed by the single method on account of difficulties of approach; and we have found that emphysema is generally less marked by the double method, probably because there is less movement of the instrument and cannula. The set comprises: a boilable telescope with an angle of vision of 30°, two spare lamps and cable, a trocar, faucet, and two cannulæ of identical size, two stainless steel needles 10 in. long-fitting a 5 c.cm. record syringe with a bayonet catch, for anæsthetising the adhesions, and two endodiathermy electrodes made to our suggestion, the one straight and the other angled in order that it may be possible to work at right angles to the adhesion from any angle at which the cannula may have been introduced. These electrodes are constructed on the same principle as that used in the Chandler instrument—namely, that through a large hollow diathermy electrode a thin tungsten wire controlled at the proximal end can be pushed forward for use with the cutting current. A Maurer pattern articulated hook for investigating the dimensions of the adhesion completes the set. The telescope allows an excellent vision of the adhesion both at distance and close up and the cutting can be undertaken at the optimum viewpoint; by means of the two cannulæ of equal size the telescope may be interchanged with the electrode so that viewing or cutting can be done from either aspect, thus rendering the right angle telescope, which can be supplied as an extra, practically unnecessary. The telescope being metal there is no insulation to give way in straining to reach an adhesion. By means of the electrode described above it is possible to coagulate and cut without the complicated change over switch and two foot switches necessary when using Maurer's method. By means of the long needle through the second cannula the base of the adhesion is easily anæsthetised, cutting out the necessity for another expensive piece of apparatus. The set comprises all that is necessary for the dealing with adhesions by the two-puncture method and will be obtainable in polished mahogany case. The electrodes are used in conjunction with the special diathermy apparatus designed by the Genito-Urinary Co., Ltd., 28a, Devonshire-street, W., who are the makers of this apparatus.



A. J. SCOTT PINCHIN, M.D. Lond.
H. V. MORLOCK, M.D. Lond.

SPACE ALLOWANCE IN INFECTIOUS DISEASES HOSPITALS.—Warwickshire county council has called the attention of the Rugby rural district council to the requirement of the Ministry of Health that a space of 144 square feet must be allowed to each patient in infectious diseases hospitals. Dr. H. G. Ward, the medical officer of health, told the council that this meant that at the Rugby Joint Hospital at Harborough Magna, where there is now accommodation for 22 beds and 12 cots, there would be room only for 13 beds, and that accommodation would have to be provided for 20 additional beds. The council decided unanimously to oppose the demand, the chairman remarking that they "must fight this expenditure to the very last ditch."

REVIEWS AND NOTICES OF BOOKS

Quantitative Clinical Chemistry.

Vol. I.: Interpretations. By JOHN P. PETERS, M.D., M.A., Professor of Internal Medicine, Yale University School of Medicine; and DONALD D. VAN SLYKE, Ph.D., Sc.D., Member of the Rockefeller Institute of Medical Research. London: Baillière, Tindall and Cox. 1931. Pp. 1264. 54*s.*

Prof. Peters and Mr. Van Slyke have provided a standard work on the ground common to medicine and biochemistry of which no review can adequately express the value. Six years ago the authors began the task of compiling a handbook on quantitative clinical medicine. The close collaboration of a clinician and biochemist over such a period resulted n a most comprehensive collection of material which had outgrown the scope of a single book. They wisely decided to divide the work into two olumes. Vol. I. deals with "Interpretations," while ol. II. will be devoted to "Methods of Analysis."

The present volume—on interpretation—contains 1 chapters, of which the most informative discuss tal metabolism, non-protein nitrogen and nitrogen etabolism, uric acid, proteins of blood plasma, ine and other body fluids, calcium, chlorides, and hosphorus.

Each chapter contains a very full bibliography nd we have the authors' assurance that "all articles ave been examined personally by one or other with few unattainable exceptions which are specifically entioned; and the references even to these have en verified." This may serve as an indication of e care and diligence with which this volume has en prepared, especially when it is realised that the tal references number nearly 4000. Each chapter almost a monograph on the particular subject der consideration. Neither author is alone responsible for a *complete* chapter because the interests of the clinical chemist and the chemical clinician are so far interlocked that seldom could either leave a paragraph written by the other entirely untouched.

The physiological rôle, distribution, and properties of each substance are first dealt with; then follows a discussion on its significance and variations in various clinical conditions. Much original work is included, and it is worthy of note that treatment is not neglected. In the chapter on total metabolism, the disorders of the thyroid gland are discussed. Little time is spent on classification, but the review of recent work is substantially complete though no mention is made of Holst's work on blood iodine.

Under the heading Carbohydrates, diabetes is fully considered. The authors have wisely refrained from too exhaustive a discussion on practical applications and interpretations. They have preferred to offer their own experiences and this section of the book has great value. They describe the significance of the level of the fasting blood-sugar in diabetes as depending on: (1) severity of the disease; (2) type of the disease; (3) presence or absence of complicating conditions; (4) diet, and treatment which the patient has received during the preceding period; and it is in connexion with (4) that much useful information is given. Renal function tests are compared and discussed, blood-urea and creatinine, phenolsulphonephthalein excretion, and hæmoglobin content being specially considered. Simultaneous blood-urea and urinary urea tests are strongly advocated by the authors as the most reliable indication of kidney function. By means of a simple formula, a "maximum" or "standard" urea clearance is obtained according as the patient excretes more or less than 2 c.cm. of urine per minute respectively. They regard this volume of blood cleared of urea per minute as a measure of renal function. One of them (V. S.) has stated that in hæmorrhagic (or glomerular) and degenerative Bright's disease (nephrosis), decrease in blood-urea clearance is proportional to glomerular destruction, whereas in the arterio-sclerotic kidney it serves as an index of damage to arterioles. The diagrams on the cases of nephritis illustrating the complete biochemical picture is rather difficult to follow. The different types of nephritis are referred to throughout the various chapters according to the subject matter, and this serves to provide a useful classification, based upon the work of Volhard and Fahr, and Addis. In the chapter on calcium the influence of the endocrine glands on calcium metabolism and serum calcium in connexion with the associated clinical conditions is fully discussed.

This work is encyclopædic and when complete will be a classical book of reference on quantitative clinical chemistry.

Surgical Emergencies in Practice.

By W. H. C. ROMANIS, M.B., M.Ch. Cantab., F.R.C.S. Eng., F.R.S. Edin., Surgeon to St. Thomas's Hospital, &c.; and PHILIP H. MITCHINER, M.D., M.S. Lond., F.R.C.S. Eng., Surgeon in Charge of Out-Patients, St. Thomas's Hospital. London: J. and A. Churchill. 1931. Pp. 608. 18*s.*

IN this work the aim of the authors has been to provide the practitioner with a book in which he can find really practical information on surgical conditions with which he may be compelled to deal, and the authors have taken as their definition of emergency those conditions which call for treatment, either operative or non-operative, *within 48 hours.* The pathological aspects of the subject have been omitted and in the main the text is abstracted from the authors' well-known text-book of surgery, the presentation being concise and clear. It is perhaps open to question, however, whether the definition of emergencies has not been unduly stretched, and whether a book of this type may not sometimes be an inducement to imprudent interference on the part of the practitioner. If, however, this danger is kept in mind, and the family doctor is prepared to assess each case with a modest recognition of the bearing his own lack of constant experience may have on its ultimate issue, it can do no harm. Practitioners who wish to have at hand a sound book to which they can refer before undertaking emergency surgery could do no better than to buy this book.

Prevention of Disease in the Community.

By CURTIS M. HILLIARD, Professor of Biology and Health, Simmons College, Boston, Mass. London: McGraw-Hill Book Company. 1931. Pp. 193.

MUCH important and useful health knowledge has been provided in small bulk in this book. It is up to date, interesting, and easily read. A chapter on immunity presents the known facts in a way which can be readily understood. The principles of vaccination and diphtheria immunisation are explained, and the value of such processes as a means of reducing the incidence of disease in a community are emphasised. The old theories as to the importance of bad odours and defective drainage as the causes of certain diseases, and of ptomaines as the cause of food poisoning, are effectively disposed of. A chapter on milk supplies is well compiled; the author emphasises the nutritional value of milk, but at the same time draws attention to the fact that only by scrupulous care in the methods of production and in the handling of milk can a safe supply be assured. The book should be of use to students taking courses in hygiene in secondary schools and colleges, for whom it is primarily intended, and to teachers engaged in lecturing on health to older children. It is also quite suitable for the instruction of lay-workers in public health, such as health visitors and school nurses. The photographic reproductions are not very good.

Technique, Effects, and Uses of Swedish Medical Gymnastics and Massage.

By Dr. J. ARVEDSON. Translated by Dr. MINA L. DOBBIE. London: J. and A. Churchill. 1931. Pp. 200. 12*s.* 6*d.*

IN medical gymnastics at the present time conflicting modifications of technique and outlook are being tried out and assessed. It is useful therefore to have a clear statement of orthodox practice in our hands. We are thus indebted to Dr. Mina Dobbie for her initiative and energy in giving us a translation of the second revised edition of Dr. Arvedson's "Handbook of Massage and Medical Gymnastics," which, with its companion volume—"Medical Gymnastics and Massage in General Practice"—is based on the principles of the Central Institute, Stockholm. The book before us is clear in matter, type, and general arrangement. Dr. Arvedson, unlike Ling, prefers to consider massage as an entity, and not a subdivision of medical gymnastics; so the first section of the book is devoted to an able description of massage technique with explanations of the effect and reactions of each kind of massage. More space is devoted to direct nerve treatment than in many similar handbooks, and clear anatomical guides for accessible treatment points of the peripheral nerves are supplied. This is of value in indicating—as does the Kellgren-Cyriax method—that many nerve injuries or loss of tone can in skilful hands be dealt with outside the electrical department. In each section, whether referring to remedial movements, special scoliosis treatment, or to grouped exercises influencing circulation and respiration, the muscle work, aims of treatment, and effects are clearly outlined. Home exercises are described and the book finishes by applying the knowledge accumulated to general rules for compiling medical gymnastic tables, or one might say, a medical prescription of exercises.

Those teachers who are working on very modern lines may regret that Dr. Arvedson has not incorporated newer tendencies, such as the emphasis on rhythm and mobilisation in re-educative work, but for examination purposes the book supplies a sound structural basis, and is a good handbook for students. The book is freely illustrated and though the photographs date from 1906 and show in some cases a rigidity of posture not now affected, they serve their purpose well.

Archives of Neurology and Psychiatry.

From the Central Pathological Laboratory of the London County Mental Hospitals, Maudsley Hospital, Denmark Hill, London. Edited by FREDERICK L. GOLLA, M.B. Oxf., F.R.C.P., Director of the Laboratory and Pathologist to the London County Mental Hospitals. Vol. X. London: P. S. King and Son, Ltd. 1931. 15*s.*

THIS tenth volume of the Archives consists, like its predecessors, of a series of reprints of papers by the various workers in the pathological department of the London County Mental Hospitals Service. The articles cover a very wide range. There are several on the pathology of general paralysis, and its treatment by induced malaria and tryparsamide. Others deal with the state of the blood in the psychoses; for instance, the sugar and chlorine content, the protein partition of the serum, and the acid-base equilibrium. Dr. Golla himself writes on some recent work on the pathology of schizophrenia, and with Dr. S. Antonovitch on the respiratory rhythm in its relation to the mechanism of thought and on the relation of muscular tonus and the patellar reflex to mental work. Among papers reprinted from THE LANCET is one on the excitability of the respiratory centre of psychotics by Dr. R. G. Marsh; studies in the acid-base equilibrium by Dr. Isabella Robertson; an article on the functions of the liver in induced malaria by Dr. R. G. Williams; and Dr. E. Mapother's impressions of psychiatry in America. Three papers deal with epidemic encephalitis: the patellar reflex, the ocular syndrome, and the oculogyric crises.

The twenty-six contributions gathered here constitute a valuable contribution to psychopathology, and their presentation in one cover will be a convenience to those interested in this branch of medicine.

Gynecological and Obstetrical Pathology.

Including chapters on the Normal Histology and the Physiology of the Female Genital Tract and the Peritoneum. Second edition. By ROBERT TILDEN FRANK, A.M., M.D., F.A.C.S., Gynecologist to Mount Sinai Hospital, New York City. London: D. Appleton and Co. 1931. Pp. 547. 30*s.*

THE first edition of this book appeared eight years ago. The many notable advances in the interval have made it necessary to rewrite certain sections, especially the chapter dealing with the relation of the normal histology of the female genital organs to symptoms and physiological function. A new chapter has been added dealing with the peritoneum, and that on obstetric pathology has been amplified. The title of this book is rather misleading, since the part dealing with obstetric pathology extends to only 45 pages, and this includes ectopic gestation and chorion epithelioma. The author almost disarms criticism by his admission that "to deal adequately with this large subject would require a separate volume." Two outstanding features of the book are the bibliography at the end of each chapter and the 423 illustrations, almost all of which are original. As a work of reference it is valuable.

THE LANCET.

LONDON: SATURDAY, JUNE 13, 1931.

LONDON'S UNIVERSITY CENTRE.

THE housing of the University of London, which has been for years the subject of acrimonious discussion, seems likely to be finally provided for on a site of some ten acres northward of the British Museum. The headquarters of the University have been successively located at Somerset House, Marlborough House, Burlington House, Burlington-gardens, and at South Kensington, and as reported in 1911 by the Royal Commission, of which Lord HALDANE was chairman, "His Majesty's Government has been responsible for the housing of the University throughout its history." The University buildings in Burlington-gardens, familiar to an earlier generation of graduates, were erected by and at the expense of the Government in 1871 for the exclusive use of the University, and the foundation-stone still bears its name, while its adornment with the statues of NEWTON, HARVEY, LOCKE, BENTHAM, and others testifies to the academic purpose of the buildings. It was in 1899 that the Senate was induced, somewhat reluctantly, to transfer the University headquarters to what was described by the Treasury as "an adequate and dignified home for the University in the Imperial Institute buildings" at South Kensington. At that time, under the Act of 1898, the University was undergoing one of its reconstitutions, and the Government vouchsafed, in a Treasury minute of Feb. 16th, 1899, that the new accommodation would *not only* be fully equal to that at Burlington-gardens but that there should also be "such provision as may hereafter be needed for the full extension and development of the University under the statutes and regulations made by commissioners appointed by the Act of 1898."

Within ten years it was evident that the accommodation at South Kensington was quite inadequate for the growing work of the reconstituted University and was also inconvenient in other respects. In 1912 a first attempt, which proved abortive, to remove the University to a site in Bloomsbury attracted public attention. Other sites at Hampstead, at Kensington, at Somerset House were suggested, and the Senate at one time favoured the Foundling Hospital site for its future home. When Mr. H. A. L. FISHER was President of the Board of Education in 1919 he advised the Government to offer to the University "a site and buildings near the British Museum." In 1920, however, this offer was modified to the exclusion of providing the buildings; it was also conditional on the transfer of King's College to the Bloomsbury site and the surrender of the present premises of the University as well as the site and buildings of King's College to the Government. Owing to the refusal of King's College to move, the offer was declined by the Senate. Eventually, however, the site, after resale to the vendor, was purchased in 1927 for £525,000, the Government contributing £212,500, while the Rockefeller foundation generously provided the funds required for completing the acquisition of the land. The Treasury made their contribution on the understanding that it was "intended to be in full satisfaction of any liabilities that might be deemed to lie upon the Treasury under the Treasury minute of 1899 to provide accommodation for the future development of the University."

On Presentation Day last month Earl BEAUCHAMP, the Chancellor, announced that the Court of the University were within sight of securing the money for the buildings to be erected on the site during the next five years, and that the laying of the first stone would take place within the next twelvemonth. Mr. CHARLES HOLDEN, F.R.I.B.A., has now been appointed the architect, and among the first buildings to be erected will be the administrative offices and University hall, the Library, and premises for the institute of historical research, the Courtauld institute of art, and the officers' training corps. The Birkbeck college, the London day training college, the students' union, and possibly residential chambers may also be erected on the site. The cost of the scheme is anticipated to be between £2,000,000 and £3,000,000. The Court may congratulate themselves on having secured Mr. HOLDEN for so important and responsible a task. The new Underground building at St. James's Park, and the King's College for Women at Campden Hill are examples of the beauty and distinction of his conceptions.

◆

A MATERNITY SERVICE.

WHILE much has been written about mortality in childbed, the crippling effect of maternity upon many of the survivors has not received the attention it deserves. Some 3000 women die each year in England and Wales as the direct result of childbirth, but it is almost as disturbing to know that 60,000 mothers, or 10 per cent. of the whole parturient population, are disabled, many of them gravely. If the late results of child-bearing are considered, an additional figure of 5000 may be added to the primary mortality, giving a total annual loss of 8000 women in England and Wales. These facts cited in Prof. BLAIR BELL's first Ingleby lecture, published in our issue of May 30th, constitute a grave indictment of the present-day risks of motherhood and emphasise the urgent need for coördinated national effort to combat them. His second lecture, which appears in this issue, sets out the basic principles which should underlie any comprehensive scheme of remedy. Prof. BELL envisages the formation of a central council, small in number, and consisting of representatives of all interested parties; such an ad-hoc body would presumably act in an advisory capacity to the Minister of Health, and as such its establishment should have the support both of practising obstetricians and of public health authorities. It is refreshing to find someone calling a halt in the present competition between voluntary and municipal effort, and advocating the pooling of existing resources. Year by year under the pressure of public opinion the State is accepting greater responsibility in attempting to solve the problems of maternal mortality and disablement. Stimulated by the Ministry of Health many municipalities are erecting large maternity hospitals and conducting maternity homes. Prof. **Bell** points out that these institutions are coming under the ægis of the local medical officers of health without reference to local obstetricians, with the result that the beds are not available for teaching purposes and, what is more important, are not always in the charge of experts. Chaos results from the curious fact that whilst financial resources are at the disposal of the public authorities, expert knowledge and skill are at present almost entirely at the disposal of the voluntary organisations. Such a distribution of assets must lead to wastage of public funds without corresponding gain in net results. Pooling of available resources—intellectual, material, and financial—is essential in order to ensure efficiency in the medical, nursing, and administrative services.

The scheme outlined by Prof. **Blair Bell** includes and utilises all existing facilities without needless multiplication of small units, isolated in function and personnel. Many of the municipal antenatal clinics and maternity homes are staffed by young medical graduates with a public health diploma and a few months resident experience at a maternity hospital. Applications are being received by teaching authorities from medical officers of health to provide short post-graduate courses to fit junior officers to take up new duties in the maternity service. But expert obstetric knowledge cannot be gained by attendance at such courses, and the possession of a diploma in obstetric medicine should be of more value than a diploma in public health for those who accept the responsibilities of obstetric practice. The problem is really one of organisation and the proper utilisation of existing facilities, rather than of additional units. In many communities, large and small, in Great Britain to-day we have voluntary and municipal hospitals existing side by side, each jealous of the activities of the other and yet both working for the common weal. On the one side is tradition coupled with expert knowledge and skill; on the other are the facilities provided by public funds and administrative capacity. Prof. **Bell** conceives of base, field, and emergency hospitals, coupled up with existing antenatal, postnatal, and infant welfare clinics, the whole supervised and directed by the Ministry of Health through a central advisory council, and bridging the gulf between conflicting interests. General medicine and surgery are no doubt confronted with similar problems, but their need is not so urgent. For a truly national maternity service this country has the personnel, the necessary expert knowledge, skill, and equipment at its disposal if it will but use them.

On the position of nursing in such a service Prof. **Bell** holds views which will meet with criticism. He would have every midwife a fully qualified and State-registered nurse, and he points to the fact that the best results quoted in this country are those of the "Jubilee" nurse-midwives. In Sweden, where mortality from obstetric causes is notably low as compared with such countries as Ireland and the United States, the majority of confinements are attended by midwives who have had two years' training without general medical and surgical experience, and this fact has been used in support of the argument for maintaining the British midwife and improving her training. Conditions in Scandinavian countries are however very different from conditions here. The careful selection of women chosen for training, the good physique of the mother, the large proportion of confinements taking place in hospital, all these favour the Swedish solution. British mothers are often not of good physique; partly from choice and tradition, partly from necessity nine-tenths of them are confined in their own homes; the midwife may be an uneducated woman with a short and special training. Few would dissent from Prof. **Bell** that the fully certificated nurse-midwife, if available, would be a great asset in a maternity service; unhappily no more than 25 per cent. of the nurses who obtain the C.M.B. certificate subsequently practise midwifery. The work is arduous and the rewards poor. But with improved conditions of service, better educated and better trained women would be attracted and in course of time the midwife pure and simple would be superseded. The provision of hostels, regular hours and holidays, adequate payment and a system of promotion are all factors which must enter into the establishment of an efficient service. There is no lack of material if it is mobilised upon sound lines.

On the urgency of the problems set by Prof. **Bell** there can be no difference of opinion and his appeal to the Ministry of Health, the public health services, the voluntary hospitals, and the practitioners generally should not pass unheeded.

◆

OUR PRISON POPULATION.

The annual report [1] of the Prison Commissioners, just issued for the year 1929, contains the usual survey by the Medical Commissioner. It is the last we shall have from Dr. G. B. **Griffiths**, who retired last year after long and honourable service, and was succeeded by Dr. **Norwood East**. Dr. **Griffiths** contrasts present prison methods with those which obtained when he first took up work as medical officer over 35 years ago. There were then no Mental Deficiency Acts. The cases now known as mental defectives were lumped together, with those now considered non-certifiable, under the vague description "weak-minded," and were usually treated under modified prison discipline.

---

[1] H.M. Stationery Office. Cmd. 3868. 1s. 6d.

Until the enactment of Section 1 of the Act of 1913 (afterwards modified in 1927), the medical officer had no standard to work to, except perhaps Maudsley's dictum respecting "absence or deficiency of a greater or less number of the cerebral reflexes"—a standard which, as Dr. GRIFFITHS remarks, could not confidently be mentioned in court because it might conceivably be applied to the deaf, dumb, or blind, and could hardly do general duty in relation to criminal responsibility. Before the 1913 Act the mentally deficient prisoner, on completing his sentence, took his gratuity and was discharged in the ordinary way. Naturally the gratuity was often quickly spent in riotous living, and the discharged prisoner was soon back in prison, having had little to do but commit another offence. With this former looseness of treatment Dr. GRIFFITHS contrasts the modern method—the careful psychological investigation working to the statutory standards, the medical officers alert to recognise and classify mental disease, the certification of the prisoner under the Lunacy or Mental Deficiency Acts, or else his transfer to a special department for mental defectives or a special section set apart for observation, training, and work, and finally, the care for his future if he is still considered uncertifiable on completion of his sentence. Dr. GRIFFITHS estimates that the administration of the 1913 Act has reduced the average daily prison population by at least 200.

We discussed lately[2] the danger and expense which the community suffers through criminal lunatics under a system which has often failed to recognise insanity until crime has been committed. The figures which we then gave are supplemented by those now available in the report under review. In local prisons 102 prisoners were certified insane during 1929; in addition, 278 remand prisoners were found by medical officers to be insane and were dealt with by the courts; 19 persons were found to be insane on arraignment, and 20 were found (in the ridiculous and indefensible phrase which the law has not yet abandoned) "guilty but insane." Another 2268 persons were remanded to prison for observation so that report on their mental condition could be furnished to the court. In a paragraph on the work of aid societies to the discharged prisoner, the report cites other evidence of the mental and physical level of the male convict. Figures supplied last year by the Central Association for the Aid of Discharged Convicts indicate that, out of 1600 men discharged to the care of the association in a period of three years, over 400 were fit for light labour only, 40 were completely unfit to earn a living, and 100 were of low mentality.

Gradually, it seems, our prisons are being emptied. In 1913 the daily average population was 18,155; in 1929 it was 10,861. In this 16-year period the average figure for local prisons has dropped by nearly one-half; it has thus been possible to reduce the number of local prisons from 56 to 31. In the same period the figure for convicts in penal servitude has come down from 2704 to 1461. Sentences, of course, are growing more lenient. In 1913 there were 12 life sentences, in 1929 only one. The size of our prison population is naturally governed not only by length of sentence, but also by the number of committals. There was in 1929 a decline in committals though, as the report explains, this is not due to a positive decrease in crime. Recent criminal statistics show that crime, judged at any rate by the totals of indictable offences known to the police, has not in fact decreased in the past 20 years; but many offences formerly punished by imprisonment are now dealt with by fine or probation. In non-indictable offences such as drunkenness, assault, prostitution, begging, and sleeping-out, there is a striking decline in the number of prisoners; this result can fairly be attributed to improvement in social conditions and social behaviour. Notes by the governors of various prisons suggest that magistrates are still sending youngsters to imprisonment without first exhausting other possibilities. One boy found his way to Birmingham prison for failing to pay a fine for breach of a by-law forbidding throwing stones into the canal, another for riding a bicycle without a light. Kind friends soon paid the money and found employment; could not this have been done without imprisonment? Some instances are undoubtedly difficult. The governor of Winchester prison had 50 lads and young men from Southampton convicted as stowaways. Many were youngsters of excellent character, and the standard sentence of 28 days hard labour looks a little old-fashioned in their case. Women prisoners are dwindling to very small numbers; many of them commit only minor offences. Two women in Hull prison are stated to have nearly 50 convictions for drunkenness; their drink is methylated spirits; they come back to prison month after month for 28 days, and are seldom at liberty for more than a few hours. Frequent return to prison seems also to be a habit of civil process prisoners—such as those who fail or refuse to pay rates, bastardy arrears, or sums due under orders for wife maintenance. If there are people who imagine that imprisonment for civil process is non-existent, they will be surprised to read that there are several thousands of such prisoners. The report has interesting comments on recidivism, prison industries and payment, the Borstal system, and the development of education (and possibly entertainment) by wireless. An appendix contains notes in which voluntary workers describe their experiences. It is tempting to quote such extracts as the aphorism that "few men with hobbies come to gaol." Readers who appreciate the devoted work of the prison visitor should study these notes in full.

EXTENSION OF MERTHYR HOSPITAL.—A memorial to the late Lord Buckland in the form of an extension, which has cost £40,000, of Merthyr Tydfil General Hospital was opened on Friday last, when a bronze statue of him by Sir W. Goscombe John was also unveiled. The enlargement provides greatly increased scope for radiological work, massage, and orthopædic treatment, with specialised departments for eye, ear, and throat cases, together with several extra wards, one of them for children. Sun balconies are attached to the various wards. Lord Buckland was president of the hospital.

---

ANNOTATIONS

DIRECT REPRESENTATION ON THE G.M.C.

At this summer session of the General Medical Council it was held expedient to confer on registered practitioners resident in England and Wales the power of returning an additional member to the Council, and the Privy Council is to be asked to obtain Royal assent, on the understanding that the addition shall not be made until the next election of direct representatives. The last such addition was made in 1909 on the motion of Dr. Langley Browne, who pointed out that representation had been given to the new universities, without additional direct representation to the great body of the profession in the country. His motion was carried by 17 votes to 5, 8 members of the Council abstaining and 3 being absent. Sir Norman Walker, in proposing the addition last week, said that at the first election in England and Wales there had been one representative for 6000 doctors; at the last election the proportion had fallen to one for 8000. In Scotland there was one representative for 5000, and in Ireland one for 3500. It was therefore not unreasonable to suggest that England and Wales should have five instead of four members. He regretted that it was not possible to couple the recommendation with one for redistribution of the constituents. The four present representatives, he said, usually came in and went out in pairs, although occasionally there had been four elections in a year; the addition, he thought, should not be made until the next election. Dr. Letheby Tidy suggested that the proportion of direct representatives to the total size of the Council should be taken into consideration, as otherwise the mere increase in number of practitioners on the Medical Register might be held to justify further representation. Sir Holburt Waring also deprecated taking the size of the constituency as a criterion for representation. One or other of the bodies now represented might demand a second representative on the ground of having 18,000 or more members. The Council, he thought, was already large enough. Sir Robert Bolam, in supporting the motion, said the claim was not based merely on numbers. A very cogent reason was the increasing necessity to have men on the Council in close contact with the daily life of the profession; particularly was this the case in disciplinary work. The complexities of the doctor's new relationship with municipalities and governmental departments were not readily understood by those not engaged in practice. The Council, he thought, should not lay itself open to the reproach of being out of touch with the realities of professional life throughout the country. Money thus spent would be worth spending. Sir Norman Walker's motion was carried by a large majority.

RECURRENT VASCULAR KERATITIS.

Common causes of vascularisation of the corneal surface (as distinguished from interstitial keratitis) are corneal ulcer and phlyctenular disease. A less common cause in this country is trachomatous pannus. It also occurs in connexion with facial acne and mechanical irritation from in-turned lashes. In rare cases it is found without any obvious cause and with recurrences that may continue for years.

Mr. J. H. Doggart[1] has collected twelve of these cases, seven men and five women between the ages of 18 and 62. In four of them the trouble began with a marginal ulcer of the cornea and in five others the corneal invasion followed repeated attacks of conjunctivitis. The cornea is invaded by superficial vessels round its whole circumference. Greyish opacities with indistinct outlines are present in the cornea and with each successive attack the vessels and the opacities approach nearer to the central area when vision is necessarily seriously impaired. Although there is no corneal ulceration in the early stage of these opacities, few cases of long standing escape it. The causation of the disease is obscure, but septic absorption, especially from the teeth, is a possible cause. Apart from cases where a definite septic focus is found the treatment is unsatisfactory. Locally the old-fashioned operation of peritomy can be tried.

STERILISATION AND MENTAL DISEASE.

For many years Dr. Rüdin has been investigating the problems of racial psychiatry in Germany. In a pamphlet issued by the Eugenics Society[1] he summarises some of his more salient findings, as well as his present views on the steps that might be taken to reduce the incidence of hereditary diseases. Among the morbid conditions considered are Huntington's chorea, myoclonus epilepsy, schizophrenia, manic-depressive insanity, idiopathic epilepsy, alcoholism, and mental defect. Rüdin's findings in an extensive statistical investigation of schizophrenia and manic-depressive insanity lead him to think that genetic carriers of these conditions may often be detected through their exhibiting psychological abnormalities of minor grades. "Where one parent is schizophrenic (or where both show a high degree of mental abnormality, as is so often the case in schizophrenic families) 9 to 10 per cent. of the children," he says, "are schizophrenic, with an additional 34 to 42 per cent. of psychopaths of less severe grades, some nearly resembling schizophrenia; this gives a total of 43 to 52 per cent. of offspring affected in one way or another. Where both parents are schizophrenic 53 per cent. of the offspring are schizophrenic and 29 per cent. psychopaths. This gives a total of 82 per cent. of mentally affected individuals and a residual 18 per cent., in whose case, it should be noted, the account is not yet closed, as the attack may occur at later ages." "Manic-depressive insanity," he says, "is more strongly inherited. Where one parent is a manic-depressive 30 to 33 per cent. of the children will show the same disease; there will also be a number of cyclic psychopaths of less severe grade which at its minimum equals the clear-cut cases; thus, the total percentage of mentally afflicted offspring is at least 60 to 66 per cent. Where both parents are manic-depressives, 60 to 65 per cent. of the offspring will inherit the disease, and 35 to 40 per cent. will exhibit minor forms of cyclic abnormality. In fact, practically all the offspring will here be mentally abnormal." It was, moreover, found that the expectation of schizophrenic insanity in Munich and a considerable part of Bavaria reaches 8·5 per 1000 in the average of the population and that of manic-depressive insanity 4·1 per 1000. Rüdin concludes his review of the incidence of these disturbances in the following words: "Any instructed person viewing this situation from a humane standpoint can scarcely escape the conclusion that sterilisation is indicated in these cases." He ends his paper with a plea for more intimate coöperation between geneticists and medical men. Only thus, he holds, can the necessary information be accumulated to enable us adequately to supplement, by genetic methods of prophylaxis, the activities of those who seek to prevent mental illness by applying to the individual the principles of mental hygiene. The application of sterilisation as a preventive eugenic measure is apparently as much hindered in Germany as in England by uncertainties as to the state of the law.

OBSERVATIONS ON POST-VACCINAL ENCEPHALITIS.

THE investigation of cases of post-vaccinal encephalitis has usually led to the opinion that although vaccination is the exciting cause, and a certain stage in the development of the vaccinal infection has determined the time of onset of the nervous symptoms, nevertheless some added factor is needed to set up encephalitis. That this adjuvant is not purely accidental is shown by the irregular distribution of the cases in time and place, especially the preference for certain years or periods and for the smaller communities as opposed to large towns, and by the occasional appearance of groups of cases in small rural areas. There is still a wide divergence of opinion as to whether infection with vaccinia virus itself is the actual cause of the changes in the central nervous system. It has frequently been suggested—notably by the two British committees which reported in 1925 and 1928, and by the Dutch Committee—that post-vaccinal encephalitis may be due to vaccination rousing into activity a latent virus infection. It was thought that widespread latent infections with poliomyelitis in a community might present opportunities for a combined action of the viruses of these two diseases. Such coöperation might be due either to poliomyelitis producing modified lesions in a central nervous system also infected by vaccinia or to some other kind of simultaneous activity of the two agents. That poliomyelitis virus has taken part in the production of post-vaccinal encephalitis has been rendered improbable by comparison of the relative seasonal prevalences of the two diseases and by the definite histological dissimilarity in the great majority of cases. Nevertheless, evidence has been put forward which suggests that a combined action of two viruses might have important results. In 1914 workers at the Rockefeller Institute[1] showed that poliomyelitis virus given intravenously to monkeys did not produce the disease unless damage was also done to the meningeal barriers, and O. Thomsen in 1912 claimed that incubation of mixed poliomyelitis and vaccinia virus into the skin produced typical poliomyelitis. Some experimental evidence of activation of a latent herpes infection by vaccination was advanced by Zurukzoglu in 1927. Dr. E. W. Hurst and Dr. R. W. Fairbrother[2] have lately tested these hypotheses in the laboratory on ten monkeys by combined inoculation into the brain or intravenously, and by inoculation of the skin with vaccinia and the brain with poliomyelitis. They found no reason to suppose that these viruses had any influence on the independent action of each other. The experiments do not give any positive help in the solution of the problem, but make the suggested influence of vaccinia on latent poliomyelitis virus extremely improbable, and give no support to the hypothesis of a combined action of two distinct viruses.

SHORTAGE OF MEDICAL OFFICERS AND NURSES IN THE SERVICES.

THE Prime Minister has appointed a committee to investigate the causes of the shortage of officers and nurses in the medical and dental branches of the three defence services, and to recommend means whereby it may be overcome. Sir Warren Fisher is the chairman and the medical members are Sir Harold Fawcus, director-general, Army Medical Services; Prof. G. E. Gask, director of the surgical unit at St. Bartholomew's Hospital; Sir Arthur Gaskell, medical director-general of the Navy; Dr. A. M. H. Gray, dean of University College Hospital Medical School; and Air-Commodore J. C. McIntyre, director of medical services, Royal Air Force. The secretary is Mr. M. Lindsay Scott, of the Air Ministry.

OSTEOPATH AND ANÆSTHETIST.

PARLIAMENT in 1858 declared the object of the Medical Act to be to enable persons requiring medical aid "to distinguish qualified from unqualified practitioners." For this purpose the Act created a system of registration and instituted the General Medical Council (not necessarily an exclusively medical body) to maintain the Medical Register and to supervise medical education under the control of the Privy Council. If persons requiring medical aid are to be enabled by means of the Register to distinguish the qualified from the unqualified, it follows that any form of partnership or alliance between a qualified and an unqualified practitioner must be ruled out; otherwise the distinction would inevitably be confused. The General Medical Council did no more than faithfully interpret the expressed intention of Parliament when its Warning Notice reminded registered medical practitioners that, if by their presence, countenance, advice, assistance, or coöperation they knowingly enabled an unqualified or unregistered person to engage in medical practice as if such person were duly qualified and registered, they would be liable to have their names erased from the Register. An advertisement by an unregistered osteopath requiring the part-time coöperation of an anæsthetist who must be a registered practitioner was sent to us lately for insertion. It being no part of the policy of THE LANCET to facilitate evasion of the Medical Act, the advertisement was not inserted. Any disadvantage caused by its rejection, however, has since been mitigated by an access of publicity. A daily newspaper, not so angry perhaps with medical journals which have rejected such advertisements as with the General Medical Council for the latent threat of removing the prospective coöperator's name from the Register, has used hard words of this "monstrous tale of medical obscurantism" and "benighted opposition of the medical hierarchy." Thus a generous-minded public is invited again to look upon osteopathy as a profession persecuted by the vindictive tyranny of a medical trade-union which cannot forgive the osteopath his successes.

although the dried unripe fruit is still official in the American book. Accidental poisoning is rare and should be rarer if the biological warnings are heeded, for the whole plant possesses an offensive smell, reminding some of mice and others of the urine of the male cat, while the stem and often the leaves are spotted as no other umbelliferous plant. Moreover, like the greater celandine, the hemlock grows chiefly not in pastures but in hedgerows and waste places within short range of human habitation, both being dependent on a supply of nitrates in the soil. Heavy responsibility attaches to the apothecary who introduced the plant early last century into Chile, where it has since run wild on the nitrated soil. For then the Victorian poet's advice to avoid the weedy bank will not save the cow from chewing the hemlock rank. Apparently when cultivated the plant may lose its unpleasant smell. The dried seeds, although readily distinguishable to the botanist from anise, may be a danger when, as according to Hegi is the case in Italy they are present to the extent of 10 per cent. in commercial samples of this seed.

CENTENARY OF THE HARVEIAN SOCIETY.

THE Harveian Society of London was constituted on Sept. 15th, 1831, as the Western London Medical Society, and less than a fortnight later changed its name to the Harveian Society "in token of the intent strictly to adhere to the course of observation and induction so successfully pursued by the illustrious discoverer of the circulation of the blood." For a hundred years it has adequately fulfilled the purpose of bringing together medical men of every branch of the profession, and its discussions have always been full, free, and intimate. The meetings were formerly held in a room belonging to the Y.M.C.A. in Titchborne-street, just south of Oxford-terrace, Hyde Park, but since the building was demolished by a German bomb, the society has usually met at the Paddington town hall. Its existence for a long period was somewhat uneventful; a little money was accumulated, a lectureship was founded, and the members dined together once a year and occasionally invited their friends to a conversazione where they could smoke, drink, and listen to music. But the election of the late Dr. Charles Buttar as president in 1909 and the advent of Dr. Godfrey de Bec Turtle as treasurer completely reorganised the society. Members whose subscriptions had been years in arrear were no longer tolerated; new honorary and foreign corresponding Fellows were elected, and there was soon a rush of applicants for the ordinary membership. The position was presently strengthened by the generosity of Mr. G. Buckston Browne, who had served on the council and in 1901 had delivered the Harveian lectures. Mr. Buckston Browne well knew the friendly feeling which had always characterised the society and also recognised that research was one of the objects which had been in the minds of the founders but had never been properly carried out for want of funds. He gave, therefore, enough money to perpetuate a love feast and to endow a prize and medal for original work.

The centenary celebrations are going on during the present week under the direction of Sir Thomas Horder, the president, Dr. de Bec Turtle, the treasurer, Mr. C. P. G. Wakeley and Dr. Ronald Cove-Smith, the hon. secretaries. They began on Thursday with a meeting in the Great Hall at St. Bartholomew's Hospital, when Prince Arthur of Connaught was elected an honorary member, and Dr. Raymond Crawfurd delivered the address printed at the front of our present issue. The Buckston Browne dinner takes place in the Grocers' Hall to-day, Friday, with Prince Arthur as the principal guest. In conclusion, Saturday is being devoted to a pilgrimage to Hempstead, in Essex, where William Harvey and many members of his family are buried.

AN ORTHOPÆDIC CENTRE.

THE Wingfield Orthopædic Hospital at Oxford serves the three counties of Oxfordshire, Buckinghamshire, and Berkshire, and the waiting-list is a long one, despite continuous hard work at high pressure. As the years go on there is a slight change in the character of the work. The severe deformities dating from birth or childhood do not now form so large a proportion of cases. This the report before us ascribes to the spread of education and the supervision of child life. It is the industrial cases that are on the increase; the great demand is now for adult male beds for a type of case for which there is no grant from public bodies. A recent gift by Sir William Morris illustrates the recognition by a great employer of labour of the value of the work to the nation and its industry; many of the patients would never again be able to earn their living but for the treatment which they receive, and 15 years ago they would have become a burden on the tax-payer or on the employer. Now those who cannot return to their former occupation are trained in the workshops so that they can at least earn a living. Sir William Morris, hearing that the hospital would have to be rebuilt and that plans for the replacement of four wards were complete, asked to see the plans and gave a sum of £47,000 to defray the cost of rebuilding the hospital, nurses' quarters, and trainees' hostel. The committee were therefore enabled to concentrate on the one problem of erecting an up-to-date hospital. The new wards will be completed during 1931, and arrangements have been made so that the work can be carried out without reducing the number of patients. During 1932 it is hoped to complete an administration block, including operating-theatre, X ray and massage department, gymnasium, plaster-room, and offices. This generous gift does not, however, reduce the need for donations and subscriptions, since the work of the institution could be very largely extended if accommodation were available for all those waiting for help. The fight against tuberculosis goes on without ceasing, and there is very little decrease in the number of cases; although a majority of them now come at an earlier and more hopeful stage than was usual in the past. The work of the numerous out-patient clinics throughout the area served has increased considerably during the year, and an attempt is being made to obtain a complete list of cripples. Good progress has been made at the special school of the hospital, where there are 68 children of school age and 24 workshop trainees. Two new handicrafts were introduced during the year: barbola work for girls, and cane-seating and chair-weaving for boys. There is still a long waiting-list of youths from all parts of the country desiring admission. News of former trainees proves that properly trained cripples can compete successfully with those who have no disability.

ON Tuesday, June 30th, the Duchess of York, as president of St. Mary's Hospital, will lay the foundation-stones of the new medical school and pathological institute. The proceedings will begin at 3 P.M., and Mr. Stanley Baldwin will give a short address.

PANEL AND CONTRACT PRACTICE

INSURANCE PRACTITIONER AND SICKNESS CLAIMS.

The insurance practitioner has not only to treat isease but also, to an extent not required in any other eld of medical practice, to estimate and advise upon e physical and mental fitness of his patients for munerative work. His opinion, expressed in a rtificate given to the insured person, supports each aim for sickness or disablement benefit, and for idence of a member's capacity for work the approved ciety to which he belongs has to look in the first stance to the practitioner from whom the member receiving medical treatment. From the commencement of national health insurance many practitioners re found it difficult to make an estimate of capacity, and a comprehensive memorandum 29/I.G.) issued last week deals with (i) the marked d continuous rise in benefit claims observed in recent ars; (ii) information obtained through recent restigations respecting the causes of the increase claims; (iii) the recent introduction of new regulans[1] for dealing with apparent failure to exercise sonable care in the issue of certificates of incapacity.

SOME ELEMENTARY EXPLANATIONS.

The system, it is recalled, is one of insurance inst the loss of earning power through sickness injury by weekly contributions paid by insured sons and their employers, supplemented in a fixed portion by the taxpayer. These benefit funds st be applied in providing medical, sickness and ablement, and maternity benefit for all insured sons, as occasion may arise, the contributions ing been actuarially calculated to secure the vision of those benefits. Any surplus must equally be used for the provision of additional benefits such as dental or ophthalmic. Protection of the funds against payments to persons not entitled to benefit is afforded in the first instance by the requirement that each claim must be supported by a medical certificate, a second line of protection being afforded by the supervision of claims by approved societies exercised through (i) administrative officers, (ii) sickness visitation, and (iii) reference of doubtful cases to medical referees. Every payment of sickness or disablement benefit to an insured person who is not incapable of work diminishes the funds that would otherwise be available for the benefit of other members of a society. The memorandum notes that the payment to each claimant in a year of a single week's benefit beyond that to which he is properly entitled would have the result of speedily bringing a large proportion of all societies to a state of insolvency. Primarily such illegitimate payments reduce the amounts available for provision of additional benefits. If such payments continue progressively to increase they must ultimately result in a reduction of the statutory benefits or an increase of the contributions requisite to maintain those benefits. Certifying practitioners are asked to realise that they are in a position of responsibility which is abused when they, for any reason, assist any of their patients to obtain, at the expense of their fellow members, benefits to which they are not entitled.

INCREASED SICKNESS PAYMENTS.

There has been in recent years a rise in claims for sickness and disablement benefit of such magnitude as to occasion grave concern among all engaged in the administration of these benefits. Between 1921 and 1927, for instance, the percentage increase in the total number of weeks covered by claims to sickness and disablement benefits was as follows:

—	Sickness benefit.	Disablement benefit.
	Increase per cent.	
Men	41	85
Unmarried women ..	60	98
Married women ..	106	159

and subsequent investigations show that though the claims have fluctuated since 1927, there has been no substantial improvement since that year. In considering possible causes of this increase the most important question is how far it may have been due to an increase in incapacitating sickness and how far to an increase in payments to persons who were not incapable of work. The report of the Government Actuary, published last year (Cmd. 3548), while establishing the continuous rise of claims for both sickness and disablement, brings out the fact that the increase has been in the number of claimants (per cent. of society members) and not in the average duration of claims, which has varied very little. As regards men, the increase in the number of claimants has been mainly in claims of short duration, and among the younger insured persons. The increase has been greater among women than among men, and among married than among single women.

Causes of Increase.

These facts suggest that the increase may have been due not so much, if at all, to an increase in the amount of incapacitating sickness as to economic or other causes not dependent on state of health. If, over so long a period, there had been any corresponding increase of ill-health, there is no apparent reason why it should have manifested itself chiefly in illnesses of short duration, and not to a corresponding extent in cases of serious sickness, causing prolonged incapacity. Secondly, there is no apparent reason why such a change in general health should have affected women to an appreciable degree more than men, married women more than single women, or young people more than old. Thirdly, there is no collateral evidence indicating that the general health of the insured population was appreciably, if any, worse in 1927 than in 1921. On the other hand, reasons readily suggest themselves which (i) might make women more ready to claim than men, married women than single women, and the younger than the older, when in the same state of health, and (ii) might increase the tendency to claim in respect of minor ailments, while not appreciably affecting the tendency to claim in cases of serious illness. But these affect the disposition of insured persons to claim, not the medical justification for issue of certificates of incapacity.

TWO RIDERS.

It has been pointed out by doctors that the observed increase of claims may be partly accounted for by cases of persons who, being genuinely incapable of work, now claim and receive benefit but would not have claimed in the same circumstances ten years ago—the explanation suggested being that it has been due partly to the effects of the present economic depression, as compared with conditions of earlier years, and partly to the greater attention now given by insured persons to considerations of health, through the operation of educational measures of the last ten years, and a change of attitude, for other reasons, towards the claiming of insurance benefits. That there are such cases is common knowledge, but they are not numerous enough to have a substantial effect in producing the observed differences in payments of benefit.

---

[1] See THE LANCET, Jan. 3rd, p. 53.

It has been stated on behalf of insurance practitioners that there has been no lowering since 1921 of their standard of medical certification. The memorandum does not seek to challenge this statement, which is in any case difficult of proof or disproof. Assuming the standard of medical certification to have remained the same, or even to have improved, the material question remains whether it has been found adequate to afford the requisite check against an increased tendency of insured persons to claim when they could not properly be regarded as incapable of work. Patients cannot, it is said, be held responsible for the estimates of their own incapacity, except in the rare cases in which they seek to deceive.

REFERENCES TO THE REGIONAL MEDICAL STAFF.

Analysis of all ordinary references to the regional medical staff in England and Wales in the year 1929 shows that 53 per cent. of those referred ceased to draw benefit after being notified of the reference. Of those referred:

(*a*) Over 14 per cent. received a final certificate from the practitioner in attendance—usually on the day on which the notice of reference was received or the following day.

(*b*) There were 19 per cent. who, not having received a final certificate on one of those days, did not attend for examination when summoned, and ceased to draw benefit.

(*c*) Over 19 per cent., having been examined by an examining officer of the department, were found to be in his opinion not incapable of work.

Reasons which do not lend themselves to summary are given for the view that the proportion of persons referred who cease benefit after the practitioner and insured person have received notice of reference is much greater than could be explained by the two considerations of (i) the lapse of time between the date of the last certificate of incapacity issued prior to reference and the date on which, after reference, the insured person ceases to draw benefit, and (ii) legitimate differences of medical opinion respecting those who are examined by examining officers of the regional medical staff.

Further evidence as to the proportion of persons receiving benefit who are not incapacitated for work is derived from consideration of the facts (*a*) that among the four classes of insured persons—men, single women, married women of 45 and under, and married women of 46 and over—the classes which show the greatest increase of claims from 1921 to 1927 are also the classes in which the highest proportion is now found of persons who cease to draw benefit after reference, and (*b*) that the great increase which has occurred during the years 1922 to 1930 in the number of references by societies to the regional medical staff has not been accompanied by the increase which might have been expected in the proportion of those referred who continued to draw benefit.

Comparative study of the results of references of patients of different practitioners is regarded as confirming this general view, since the differences in these results, in respect of large numbers of insured persons and practitioners, are inconsistent with the supposition that they are explicable by the two factors of lapse of time and differences of medical opinion, already mentioned. The divergences are in fact so wide as to point to the conclusion that a considerable number of certificates of incapacity have been issued which were not justified by the condition of the patient at the time of issue.

EXPLANATIONS BY PRACTITIONERS.

During the latter part of 1930 regional medical officers, it is stated, interviewed a number of practitioners in different parts of the country whose results of reference compared unfavourably with those of their colleagues practising in the same area. Some of the explanations given are regarded as confirming impressions gained otherwise of the attitude of a not inconsiderable number of practitioners towards certification.

(*a*) A substantial proportion of the practitioners interviewed stated that they found themselves unable to certify strictly in accordance with their medical judgment for fear of losing patients.

(*b*) Some said that when their patients complained of illness and inability to work they did not feel justified, even in the absence of any signs of disease, in refusing certificates.

(*c*) Some stated that, although they might believe a patient to have recovered and become able to resume work, they preferred to leave the duty of saying so to the examining officer of the department.

(*d*) Finally, it was not infrequently said that, although a patient might legitimately be considered to be not incapable of work, the doctor knew how difficult it would be for that patient to find work under the prevailing conditions of employment, and he allowed himself to be influenced by compassionate considerations in the direction of continuing to issue certificates.

Such statements, offered in explanation of the high proportion of insured persons on the list of these practitioners who when referred ceased benefit, support the general inference that, in cases sufficiently numerous to have an appreciable effect on the benefit funds, certificates are issued which are not in accordance with the doctor's considered opinion of his patient's capacity for work, but are based either on insufficient evidence of incapacity or on considerations irrelevant to the insured person's title to benefit.

Medical Responsibility.

It is nowhere suggested in the memorandum that insurance practitioners as a whole have been responsible for the increase of claims. The strongest evidence adduced respecting the issue of certificates of incapacity to persons who were not incapacitated is that derived from a comparison of the results of the work of different practitioners. In other words, the standard by which some are judged to have failed to exercise proper care in their issue of certificates is that afforded by comparison of the results of their work with that of their colleagues. It is also clear (the memorandum states) that a considerable proportion of errors in certification are not due solely, mainly or even in some instances at all, to such failings as lead also to errors of treatment, but to failure to appreciate the nature and organisation of national health insurance. Whatever the sources of error however, it is evident that payments of benefit to insured persons when not incapable of work are sufficiently widespread, to call for special efforts by all concerned with a view to the better protection of the benefit funds.

Complaints, it is stated (Circular A.S. 278), are still received by the central departments to the effect

(*Continued at foot of opposite page.*)

SPECIAL ARTICLES

GENERAL MEDICAL COUNCIL.

SUMMER SESSION, JUNE 2ND–5TH, 1931.

Penal Cases Reported by the Dental Board.

The Case of John Forbes McDonald Connar, registered as of 28, Queen-street, Belfast, dentist 1921, who had appeared before the Board on May 13th, 1931. The following facts were then established by the evidence :—

In September, 1930, Mr. George Brannigan, a member of the Royal Liver Friendly Society (National Health Section), wishing dental treatment, called upon one Walter R. Bamford, a dental mechanic, who gave him advice and told him to get a dental letter from his approved society. A week later Mr. Brannigan called again on Mr. Bamford with the dental letter, on which occasion Mr. Connar was also present and both examined Mr. Brannigan's mouth. Shortly afterwards Mr. Connar and Mr. Bamford made two calls on Mr. Brannigan, and on the first call Mr. Connar gave cocaine and Mr. Bamford extracted some teeth, and on the second occasion they did the same thing, except that Mr. Connar also extracted a tooth. Later, Mr. Bamford called twice on Mr. Brannigan and took impressions for the denture, and Mr. Brannigan signed the dental letter which had already been signed by Mr. Connar. Mr. Connar drew the money, £3 6*s.* 3*d.*, from the approved society. Mr. Connar rented a surgery in Mr. Bamford's premises for which he agreed to pay 2*s.* 6*d.* a week, but in fact paid by supplying Mr. Bamford with dental materials to the amount of about £5. Mr. Connar occupied this surgery from July to December, 1930. Mr. Bamford was not a registered dentist and in respect of the facts above mentioned was prosecuted by the Dental Board at Belfast on March 3rd, 1931, pleaded guilty, and was convicted and fined £10 and 20*s.* costs for practising, and 20*s.* and 20*s.* costs for holding out.

The Board found that Mr. Connar had enabled Mr. Bamford to practise as if he were registered, and recommended that his name be erased.

Mr. Connar did not appear before the Council and was not represented. Mr. Harper read a letter from him. After deliberation in camera, the President announced that the Registrar had been directed to remove Mr. Connar's name from the Register.

The Case of Thomas James Willis, registered as of 120, Abbots-road, Cheam, Surrey, dentist 1921. At the inquiry held on May 12th, 1931, the following facts were established by the evidence :—

That Mrs. Goodwin first became acquainted with the said Thomas James Willis in November, 1929, when he was attending her as her dentist. That the said Thomas James Willis committed adultery with Mrs. Goodwin on June 14th, 1930, and June 15th, 1930, and since. They have lived together at Seven Kings, Essex, and at Cheam, Surrey, and are living together now.

The Board recommended that Mr. Willis's name be erased from the Register.

Mr. Willis did not appear and was not represented. The Council directed the Registrar to erase his name from the Dentists' Register.

The Case of Ernest Harold Christopher Bailey, registered (on the Colonial list) as of Harvard House, 11, Collins-street East, Melbourne, C1, Cert. of Qual., 1897 (*cum curriculo*), Sec. 54, Medical Act, 1890 (Victoria).

Mr. Bailey, who is in Australia, did not attend in answer to his notice, nor was he represented at the inquiry held on May 12th, 1931, but his solicitor had written a letter asking for an adjournment. He asked "that this matter be allowed to stand over pending an amendment of the Dental Act which is being brought before Parliament by the Dental Board—i.e., of Victoria—to meet the circumstances of this case." As it was a case of conviction in respect of the receiving of stolen goods, the Board were unable to appreciate how any amendment of the Dental Act could affect the question, and decided to hear the case. The following facts were established by the evidence :—

Mr. Bailey was convicted on Nov. 15th, 1928, at the sittings of the Supreme Court of Victoria held at Melbourne of the following felony—namely, of receiving a number of lathes and an engine, the property of Amalgamated Dental Company, knowing the same to have been stolen, and had been released on entering into a bond for £100 to be of good behaviour for a period of three years, and to come up for sentence when called upon. At the trial Mr. Bailey was defended by Mr. Brennan, K.C., and Mr. Barry. The judge on binding him over said : "In the witness-box the most damning evidence against you was given by yourself. . . . I realise that this is not a case of a man who is known to thieves as a receiver of stolen property. I think that justice will be done if I order that you come up for sentence when called upon."

Mr. Bailey's name had been erased from the Dentists Register of Victoria in consequence of the conviction, and the Board recommended its erasure from the Register of this country.

The President read the section of the Act relevant to cases of dentists convicted of felony in any part of His Majesty's dominions. After deliberation in camera the President announced that Mr. Bailey's name would be erased from the Register.

The Case of James Brown Gibson, registered as of 4, Killermont-street, Glasgow, dentist 1921. At the inquiry held by the Board on May 14th, 1931, the following facts were established by the evidence :—

That on July 14th, 1930, at the Sheriff Court, Glasgow, after a plea of guilty, the said James Brown Gibson was convicted of uttering as genuine a dental letter after forging the signature of the patient (one John M. Henderson) thereto and of attempting to obtain by fraud payment thereon from the Scottish Typographical Association and was sentenced to a fine of £10 or 60 days' imprisonment.

Mr. Gibson was not present and was not represented. Mr. Harper read a letter from his solicitor. After deliberation in camera, the President announced that the Council had directed the Registrar to erase his name from the Register.

Penal Cases Adjourned from Previous Sessions.

The Case of James Gordon Bell, M.C., registered as of Ballochmoyle House, Dunfermline, L.R.C.P.Edin. 1914, L.R.C.S. Edin. 1914, L.R.F.P.S. Glasg. 1914, M.B., Ch.B. 1914, U.Edin., who had been summoned to appear before the Council on charges of having been convicted of negligent driving and drunkenness. At the November session, 1930, the facts had been found proved to the satisfaction of the Council, but judgment had been postponed for six months.

Dr. Bell appeared in answer to his notice. He stated that he had been in a sanatorium, and that his health had greatly improved. He proposed to abstain altogether from alcohol in the future, and had prospects of employment from July next. He produced testi[illegible] character.

(*Continued from previous page.*)

that improper statements made by local agents and visitors, regarding a member's right to sickness or disablement benefit, embarrass medical practitioners in dealing with insured persons. Societies are enjoined to impress on their agents the need for careful use of words in explaining to insured persons their right to benefits, so that it may be clear to them that certificates can only be issued by a doctor if, in his opinion, the insured person is really incapable of work.

The President announced that the Council had postponed judgment for another 12 months, at the end of which time Dr. Bell would be expected to appear again and to produce testimonials to his character and habits.

The Case of James Rutherford Ratcliffe, registered as of 1, Grange-street, Port Talbot, Glam., M.B., C.M. 1897, U.Glasg., who had been summoned to appear before the Council on charges of conviction for drunkenness. The convictions had been found proved at the November session of the Council, but judgment had been postponed for six months.

Mr. Ratcliffe was accompanied by Mr. A. A. Pereira, instructed by Messrs. Le Brasseur and Oakley, representing the London and Counties Medical Protection Society. He produced two strong testimonials to his character and, through his counsel, repeated his expressions of regret and his promise to abstain from alcohol in the future. After deliberation in camera, the President announced that the Council had not seen fit to direct the erasure of Mr. Ratcliffe's name.

The Case of Simeon Moses Cohen, registered as of 1, Ynyswen-road, Treorchy, Glam., M.R.C.S. Eng. 1919, L.R.C.P. Lond. 1919, who had been summoned to appear before the Council on the following charge :—

> "That, being a registered medical practitioner, you on March 15th, 1930, issued the following certificate, viz. :—
>
> 'The Surgery, Treorchy.
> 15.3.1930.
>
> 'I certify that W. King is unable to follow his employment since 15/3/30 owing to illness.
> S. M. COHEN, Surgeon.'
>
> whereas you had not seen or examined the said W. King on March 15th, 1930, which certificate was misleading and improper."

At the November session the charge had been found proved to the satisfaction of the Council, but judgment had been postponed for six months.

Mr. Cohen appeared, and was accompanied by Mr. Oswald Hempson, of Messrs. Hempsons, representing the Medical Defence Union. He produced testimonials to character, and gave assurances as to his future conduct. After deliberation in camera, the President announced that the Council had decided not to erase Mr. Cohen's name from the Register.

The Case of Percy Bateman, registered as of 423, New Cross-road, London, S.E. 14, L.R.C.P. & S. Edin. 1906, L.R.F.P.S. Glasg. 1906, who had been summoned to appear before the Council on the following charge :—

> "That you were on April 2nd, 1930, convicted at the Woolwich Police-court of the following misdemeanour, —namely, of being drunk, and were fined 5*s.* or five days' imprisonment."

The charge had been found proved at the summer session, 1930, but judgment had been postponed for 12 months.

Mr. Bateman appeared and presented testimonials to character. Mrs. Bateman gave evidence that her husband had entirely given up alcohol since entering a home for treatment, and that he was now in practice, doing light work in partnership. He was living in the country, and coming up to town to work daily. Mr. Bateman gave assurances of his intention to abstain from alcohol in future, and explained his present work and habits. After deliberation in camera, the President announced that the Council had decided that Mr. Bateman's name should not be erased from the Register, but that he should be given what the President described as a final chance.

New Penal Cases.

The Case of George Francis Donaldson Perrott, registered as of 46, Belmont-road, Uxbridge, Middlesex, M.R.C.S. Eng. 1928, L.R.C.P. Lond. 1928, who had been summoned to appear before the Council on the following charge :—

> "That you were convicted of the following misdemeanours, viz. : (1). On June 16th, 1930, at the Westminster Police-court, of being drunk while in charge of a motor-car, and were fined £25 and £6 6*s.* costs, eight weeks' imprisonment in default, and your licence endorsed and forfeited for 12 months ; and (2) on March 7th, 1931, at the Bournemouth Police-court, of being under the influence of drink to such an extent as to be incapable of having proper control of a motor-car of which you were the driver, and were fined £30 and £1 16*s.* 6*d.* witness fees, or three months' imprisonment in default, and were disqualified for holding a licence for 12 months."

Mr. Perrott attended and addressed the Council, promising to abstain from alcohol in future. After deliberation in camera, the President announced that judgment would be postponed for 12 months.

THE NEWELL TREATMENT FOR TUBERCULOSIS.

The Case of Herbert Castlemain Hocken, registered as c/o E. Peet, LL.D., 11, Fetter-lane, E.C. 4, L.S.A. Lond. 1901, who had been summoned to appear before the Council on the following charge :—

> "That, being a registered medical practitioner, you have sought to attract to yourself patients and to promote your own professional advantage (1) by being associated with or employed by an individual and/or firm who, to your knowledge, sought to attract patients by advertising and canvassing through the medium of articles appearing in the *Daily Sketch* relating to an alleged cure for tuberculosis known as the 'Newell Treatment'; (2) by accepting persons as patients who to your knowledge had come to you as the direct result of the said articles ; (3) by seeking to induce registered medical practitioners to use in the treatment of their patients and to make themselves responsible for a medicament of whose properties and action such practitioners were not fully informed. And that in relation thereto you have been guilty of infamous conduct in a professional respect."

The complainants were the Medical Defence Union.

Mr. Hocken was accompanied by Mr. Harold Bevir, solicitor, who applied for an adjournment on the ground that an application was being made to the High Court to ascertain whether Mr. Hocken was amenable to the jurisdiction of the Council. This application was not acceded to.

Mr. Hempson, representing the Medical Defence Union, stressed the fact that the charge was *one* of association with a concern that was advertised, and with a medicament of the properties and action of which practitioners were not fully informed. There was no discussion of the value of the treatment. He referred to a series of articles in the *Daily Sketch* in December last and read extracts. The articles extolled the Newell form of treatment for tuberculosis and declared that medical etiquette was preventing public access to it. He recalled the case of Dr. S. Hooker,[1] whose name had been erased for similar conduct, and whose case constituted a clear warning to others. This case was an absolute replica. The articles claimed that the Newell treatment had never been advertised, but they constituted in themselves an advertisement of incalculable value. As evidence that Dr. Hocken was aware of this campaign, and prepared to avail himself of it, Mr. Hempson read a circular letter sent by Dr. Hocken to members of the profession. It set out his attainments in a manner more likely to appeal to the laity than to the profession, and was accompanied by testimonials and terms. The fee of two guineas was payable in advance. The technique-directions were signed by the unqualified Mr. Newell, and not by Dr. Hocken. A second document, signed by O. A. Newell, constituted a reply to letters written in consequence of the *Daily Sketch* appeal. It concluded that patients not under a doctor or those who experienced any difficulty in obtaining the treatment could be arranged for in London. When Mr. Whitwell had written to Dr. Hocken, posing as a patient who had seen the articles in the *Daily Sketch*, he had received a reply making an appointment. At the interview he had been welcomed as a patient coming through the *Daily Sketch*, and had been offered treatment at one guinea an injection, and had been given documents testifying to the efficacy of the treatment. The telephone number was the same as that of Mr. Newell, who was described in the telephone directory as "Dr." O. A. Newell.

---

[1] THE LANCET, 1925, ii., 1192.

Dr. James Neal testified to the communications he had received from members of the Medical Defence Union about the Newell treatment, the *Daily Sketch* articles, and pamphlets about it. He gave it as his opinion that the alleged "full disclosure" of the constituents of the Newell treatment was insufficient to justify a medical man in administering it. In cross-examination by Mr. Bevir, he said that he thought it would be gravely unprofessional of any doctor to use it without further knowledge. He had drawn the attention of the Medical Defence Union to the matter on the third Thursday in February. He had made no personal investigation, and had not sent any warning to Dr. Hocken. He agreed that Dr. Hocken was not mentioned in the *Daily Sketch* articles by name, but said that they implied that some doctor would treat patients. He could not regard the articles as a poor form of advertisement, even if no name, address, photograph, or interview appeared. The effect of the articles was to induce sufferers from tuberculosis to apply to the laboratory for treatment. The medical superintendent of the laboratory was Dr. Hocken, and Dr. Hocken replied to letters addressed there. He could not produce witnesses—other than Mr. Whitwell—who had been to Dr. Hocken as a result of the articles. He was not accusing Dr. Hocken of being concerned in inspiring the articles, but it was obvious to him that the respondent had derived benefit from them. They were all publicity for the Newell alleged treatment for tuberculosis.

Mr. F. D. Whitwell, clerk to Messrs. Hempsons, testified to his correspondence and interview with Dr. Hocken. Dr. Hocken had handed him a circular letter and a pamphlet on which Dr. Hocken was described as medical superintendent. He had been told that a month's supply of treatment would cost two guineas, and that he would need two injections a week for some weeks, according to progress, each injection to cost £1. Dr. Hocken had made no examination of him to see whether or not he was a suitable patient, nor had he inquired the name of witness's doctor.

Cross-examined by Mr. Bevir, he said that Dr. Hocken had read to him the names of three patients whom he had treated. He had not made any note of the names. He paid no fee at that interview, but was told to come again on the next Monday with £3 2s.

In reply to the President, he repeated that Dr. Hocken had made no examination of any kind whatever, but that he had assumed that he would be examined on the Monday, when he returned with the fee.

Mr. Bevir characterised the evidence of the complainants as flimsy and third- or fourth-hand, consisting of a bundle of newspapers. The charge might have been against the *Daily Sketch* or Mr. Newell, but the articles and documents hardly involved Dr. Hocken at all. Stronger evidence was required for a sentence involving professional ruin. The only relevant evidence was that Dr. Hocken's name had appeared as medical superintendent. Desire for gain or payment could not be alleged against him. Mr. Whitwell was a spurious patient, and an agent provocateur; the evidence of such persons was rejected in English courts if any other evidence could be obtained. Even that witness had not succeeded in obtaining evidence that Dr. Hocken was receiving fees, or had ever sought to attract patients. He had advised Dr. Hocken that there was no case for him to answer, and that it was therefore unnecessary for him to go into the box and explain the circumstances of his practice. Dr. Hocken was an apothecary, and an apothecary was entitled by law to sell medicines.

The Council found the first two charges proved and the third not proved, and directed that Mr. Hocken's name be erased from the Register.

PARTNERSHIP WITH A DENTIST.

The Case of Robert Miller, registered as of 77, Constitution-road, Dundee, M.B., C.M., 1889, U.Glasg., summoned to appear before the Council on the following charge:—

(1) That, being a registered medical practitioner, and as such to your knowledge not entitled to receive fees or payment from approved societies for dental treatment to members of such approved societies, you entered into partnership with one R. Whyte, L.D.S., of 9, King-street, Dundee, a registered dentist, for the purpose of using his name and thereby obtaining fees or a proportion of the fees payable by approved societies, in accordance with schemes sanctioned by the Ministry of Health under the National Health Insurance Act, 1924, for dental treatment, to registered dentists only;

(2) That in furtherance of such partnership and purpose you caused the signature of R. Whyte to be affixed to a dental letter by means of a rubber stamp in respect of one Mrs. May A. Lyons, a patient of yours and a member of The Dunkeld Diocesan Catholic Insurance Society, being an approved society, thereby falsely and in breach of the conditions of the scheme for dental benefit representing to such society that the said R. Whyte had personally examined the said Mrs. Lyons and made an estimate for her dental treatment, when in fact, as you well knew, the said R. Whyte had not personally seen or examined the said Mrs. Lyons.

And that in relation to the facts so alleged you have been guilty of infamous conduct in a professional respect.

Dr. Miller appeared, accompanied by Mr. A. A. Pereira, instructed by Messrs. Le Brasseur and Oakley. The complainants, the Dental Benefit Council, were represented by Mr. J. Scott Henderson, instructed by Messrs. Ponsford and Devenish.

Mr. Henderson, in opening the case, explained that Dr. Miller, though as a registered medical practitioner entitled to practise dentistry, had no qualification that would entitle him to have his name on the Dental Register. Dental benefit was an "additional benefit" under the National Health Insurance Act, 1924. The Department of Health for Scotland had sanctioned this additional benefit in the case, among other approved societies, of the Dunkeld Diocesan. One of the conditions was that the treatment must be given by a registered dentist. This fact might, he said, supply a motive for the alleged offence. Under the partnership agreement between Dr. Miller and Mr. Whyte, Dr. Miller received two-thirds of the fees paid to Mr. Whyte. The treatment of Mrs. Lyons was estimated in the "dental letter" to be £6 5s., of which the society were to contribute £3 5s. When a panel patient had come with a dental letter, Dr. Miller had been in the habit of examining the patient himself to see what treatment was required; he had filled up the letter, stamped it with Mr. Whyte's name, and sent it in to the society, and when it came back, had handed it over to Mr. Whyte at 9, King-street, and in due course had sent the patient there for treatment. This estimation and report on behalf of another practitioner was, Mr. Henderson submitted, improper conduct. Mr. Whyte had never seen Mrs. Lyons, and Dr. Miller had claimed 2*s.* 6*d.* from the society as from Mr. Whyte, of 77, Constitution-road, his own address.

Mr. Edmund William Handcock, Secretary in Scotland of the Dental Benefit Council, formally testified to the facts as far as they had come within his knowledge.

Mr. Robert Whyte stated that Dr. Miller had estimated straightforward cases but had sent difficult ones, or patients who had especially desired it, to him. He had found Mrs. Lyons's letter in a drawer. Dr. Miller had said that this patient would probably not return for treatment, so he had signed the form G and given it to Dr. Miller.

Cross-examined, he admitted that he had known that Dr. Miller had used his stamp in cases which he (witness) had not examined. He had asked respondent not to do so, but he had insisted that he was entitled to, and witness had taken no steps because he was dependent on Dr. Miller for everything. Witness admitted that the question of Dr. Miller's procedure had only been raised by small local societies, and not by any large society. He had been licensed in dentistry two or three months before taking up his work with Dr. Miller. The bulk of his patients had been insurance patients coming to him through Dr. Miller. He had never been in Dundee before.

In answer to the Legal Assessor, he said that the cheques from the approved society were made out in his name, endorsed by him, and handed to Dr. Miller for his private account. Witness received one-third of those fees monthly, under their agreement. The patients were Dr. Miller's patients sent to witness for treatment. The forms headed "This should be handed to any registered dentist," were never handed to him by Dr. Miller's patients but went to Dr. Miller.

Mr. H. S. Herbert gave evidence describing the procedure of the Dental Benefit Council.

Dr. Miller, in the witness-box, said that he had practised in Dundee since qualifying in 1889 and had always practised dentistry. He could have qualified under the Dental Act, 1921, if he had been carrying on dentistry as his principal means of livelihood. He had attended insured patients requiring dental treatment until 1926, when his attention had been drawn to the fact that the schemes for dental benefit approved by the Minister stated that treatment must be obtained from a registered dentist. He had then written to various authorities for a ruling and had discontinued dental treatment. When he had entered into partnership with Mr. Whyte he had assumed that it would be in order for him to examine a patient and fill in an estimate, so long as the actual work in the mouth was carried out by his partner. He had a bona fide belief that he was entitled to act as he had done. The partnership had never been concealed. The two names had appeared on the brass plate and on the account forms, and every local agent of the approved societies was aware of it. He had assumed that, having a registered dental partner, he could act for him. The papers would go back, when filled in, to the central society, which would not know that the patient had been examined by him and not by the registered dentist whose name was stamped on them. He had never had a stamp of his own marked "surgeon dentist" because he thought it fairer for the junior partner to be on his own.

In reply to the President he said Mr. Whyte's stamp had been made soon after Mr. Whyte's appointment, he had had it made because Mr. Whyte's name was on the Dental Register, and neither his own name nor that of the partnership would pass on these documents. He would never sign another man's name, but did not regard it as wrong to use his stamp, even to the statement: "I have examined . . ." The stamp belonged to his partner, who—if he did not know at the time—knew afterwards. One object of the partnership had certainly been that he might claim dental benefits to which he was not entitled on his own qualifications.

Mr. Pereira said that Dr. Miller had believed himself entitled to examine the mouths of patients, and had not done any dental work himself. The signature was one of "authority by inference," since Mr. Whyte had known that his stamp was used. Dr. Miller had honestly thought his action correct.

Mr. Henderson maintained that the use of the rubber stamp in this way was likely to deceive the companies.

After deliberation in camera, the President announced that the Council had found the charges proved, but in view of Dr. Miller's age and long experience of dental work before the new Act, and the possibility of bona fide misunderstanding, they had decided not to direct the Registrar to erase his name from the Register.

CHARGES OF IMPROPER CERTIFICATION.

The Case of William Allan, registered as of 9, Margaret-street, Greenock, M.B., Ch.M., 1895, M.D. Glasg., 1898, who had been summoned to attend before the Council on the following charge:—

That being a registered medical practitioner you, on April 9th, 1929, and on various dates subsequent thereto during the period to August 29th, 1930, signed and issued to Duncan McAlpine, an insured person on your list, 42 certificates required for national health insurance purposes, stating that you had examined him on the several dates stated thereon, whereas you had not examined the said insured person on any of such dates or at all during the said period, which certificates were untrue, misleading, or improper.

And that in relation to the facts so alleged you have been guilty of infamous conduct in a professional respect.

The complainants were the Department of Health for Scotland.

Dr. Allan attended and admitted the facts as alleged. Mr. D. Gerrand, representing the Department of Health, laid the facts before the Council and handed in the certificates in question. Dr. Allan explained that he had known the patient for about 20 years; he was being treated for a disfiguring tuberculide which made him extremely sensitive. He was genuinely ill and Dr. Allan had wished to save him the mental anguish of attending the surgery for certificates.

After a long deliberation in camera the President announced that the Council had found the facts proved, and regarded the matter as one deserving grave censure. They were, however, prepared to believe that Dr. Allan had acted from an error of judgment and a mistaken view of duty, and dismissed the case.

The Case of Thomas Joseph McKaigney, registered as of 24, Kelvinside-gardens, Glasgow, L.R.C.P. & S. Edin., 1902, L.R.F.P.S. Glasg., 1902, who had been summoned to attend before the Council on the following charge :—

That being a registered medical practitioner you, by yourself or your deputies, on August 17th, 24th, and 31st, 1929, and Sept. 7th, 14th, 21st, and 28th, 1929, issued to Annie Kelly, an insured person on your list, certificates required for national health insurance purposes certifying that the said insured person had been examined on those dates, whereas the said insured person had not been examined on any of such dates or at all during the said period, which certificates were untrue, misleading, or improper.

And that in relation to the facts so alleged you have been guilty of infamous or disgraceful conduct in a professional respect.

The complainants were the Department of Health for Scotland.

Dr. McKaigney was accompanied by Mr. Oswald Hempson, solicitor, representing the Medical Defence Union. Mr. D. Gerrand, for the Scottish Department of Health, handed in the certificates referred to, and read the findings of the departmental committee.

Mr. Hempson submitted that there was no evidence for the Council to consider. Mr. Gerrand said that his instructions were merely to lay the documents before the Council. Dr. McKaigney had had the opportunity of defending himself before the committee but had not done so.

Mr. Harper, reading from the report of the subcommittee, stated that Annie Kelly had applied for benefit on another occasion and had been told that she was not entitled to it because she had previously drawn it while at work. It had then been discovered that her aunt, Mrs. Griffin, had been drawing her benefit money in her place on certificates obtained from respondent; for this offence she had been imprisoned.

The certificates were exhibited to the Council. They stated the causes of incapacity as chlorosis and anæmia, and a later one as chlorosis and gastritis.

Mr. Hempson objected that the report of this subcommittee, with the statements of witnesses who had not been cross-examined, could not constitute evidence, but the President ruled that the Council could consider it.

Mr. Hempson then called Dr. McKaigney as a witness on his own behalf, and he testified that he could only recollect having seen Annie Kelly the first time, but that his invariable practice was never to give a certificate without examination.

Dr. Bone inquired why the panel cards, which constituted a permanent record, had not been produced by the Department.

Mr. Hempson addressed the Council, again pointing out the inadequacy of the evidence, and submitted evidence of his client's good character.

After deliberation in camera, the President announced that the Council had not found the charges proved to their satisfaction.

The Case of Archibald Carmichael Young, registered as of 9, Eyre-place, Edinburgh, L.R.C.P. and S. Edin., 1925, L.R.F.P.S. Glasg., 1917, who had been summoned to attend before the Council on the following charge :—

(1) That being a registered medical practitioner you, on April 8th, May 8th, and June 7th, 1930, signed and issued to Donald Chisholm, an insured person on your list, certificates required for national health insurance purposes, stating that you had examined him on the several dates stated thereon, whereas you had not examined the said insured person on any of such dates, which certificates were untrue, misleading, or improper.

(2) That being a registered medical practitioner you, on July 8th, August 8th, and Sept. 2nd, 1930, directed or permitted to be issued to the said Donald Chisholm similar certificates by your assistant, J. S. Miller, whereas neither you nor the said J. S. Miller had examined the said insured person on any of such dates, which certificates were untrue, misleading, or improper.

And that in relation to the facts so alleged you have been guilty of infamous conduct in a professional respect.

The complainants were the Department of Health for Scotland.

Dr. Young was accompanied by Mr. S. Henn Collins, instructed by Messrs. McKenna and Co. Mr. Gerrand, representing the Department of Health, produced the certificates in question, the report of the subcommittee, and a letter from the respondent.

Mr. Harper, reading the report of the subcommittee, stated that in this case the certificates had been handed regularly to a messenger who called at the surgery every month. The respondent admitted giving certificates without seeing the patient. He had gone to the patient's house during the material period, but had failed to obtain admission. The patient had been seen on some date in June and again in October and November. Dr. Young's letter to the Department of Health stated that the patient had been incurable, suffering from encephalitis lethargica. The patient had refused to admit respondent to the house although respondent had made repeated and regular efforts to see him, and had tried to obtain admission for the patient into two hospitals, without success.

Mr. Henn Collins admitted, for respondent, that he had signed certificates without actually seeing the patient, but contended that, under the circumstances, they had not been untrue, misleading, or improper, and that their issue did not amount to infamous conduct.

After deliberation in camera the President said that the Council had found the facts in the first charge against the respondent proved; that they regarded the offence as one worthy of grave censure, but that, in view of the circumstances—although these did not constitute an excuse for respondent's laxity—they considered that he had acted from a mistaken view of his functions and an error of judgment due to good nature. They therefore did not find him guilty of infamous conduct, and dismissed the case.

A FORGED DOCUMENT.

The Case of Thomas Benjamin Brandon, registered on the Colonial List as of 605, Stretford-road, Stretford, Manchester, M.C.P. and S. Manitoba, 1915, M.D. U. Manitoba, 1917, who had been summoned to appear before the Council on the following charge :—

That at the Manchester Assizes commencing on Feb. 16th, 1931, you were convicted of unlawfully uttering a forged public document, and were sentenced to three months' imprisonment in the second division.

Dr. Brandon did not appear and was not represented.

Mr. Harper explained the circumstances of the case and read extracts from the newspaper reports of the trial. Respondent had desired to stand for Parliament and had handed in nomination papers bearing forged signatures. His moral character had been severely impugned by credible witnesses.

The Council found the charges proved, and directed that Dr. Brandon's name be erased from the Register.

This concluded the hearing of disciplinary cases, the case against John Roberts Pate, registered as of 37, Beaumont-street, Oxford, M.B., Ch.B. 1915, U. Glasg., having been dismissed as the charge against him was not proved to the satisfaction of the Council.

A DRESSMAKER'S WARD.—The dressmakers in the neighbourhood of the Middlesex Hospital purpose building a ward in that institution. Towards the £25,000, which the ward will cost, £5000 has already been raised.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

MENTAL EFFICIENCY AND DEFICIENCY.

AT a recent Glasgow conference of the Scottish Association for Mental Welfare, Dr. Parlane Kinloch, chief medical officer of the Department of Health for Scotland, pleaded for a return to the Greek ideal of healthy youth. He would like to see a great experiment made in schools with two sets of children coming from the same social circumstances. In one of them the children would receive instruction for an hour at a time, alternating with an hour's physical exercise and outdoor recreation. He would not be surprised if in four or five years these children who had rhythm in their school lives between mental and physical work, would be more efficient mentally than the children who had been confined to the steady six hours of educational work.

Dr. R. D. Clarkson, of Larbert, maintained that injury to the brain at birth is a common cause of mental defect. Many of them could be prevented if antenatal care was recognised as always necessary, and if the standard of education of medical men and midwives was raised. He expressed his well-known doubts about the limits of heredity in mental defect. Dr. R. M. Marshall said that in the ascertainment of imbeciles the test of inability to be taught to manage themselves or their own affairs was not very satisfactory, and that in the higher grades of the condition the crucial test of a trial in the special classes for at least a year was always indicated. In the ascertainment of feeble-minded persons the criterion should be incapacity to receive proper benefit from instruction in the ordinary classes; at school age the question of social adaptability should only be considered when it was raised by the conduct of the individual.

Dr. David Yellowlees said he took it to be one of the objects of the association to create a public conscience in matters of mental diet, especially that offered to children whose selective powers were not yet developed. They could hardly feel complacent if they considered the quality of the cheap reading matter and films provided for children at the present time. Much of that material tended to present to immature minds aspects of life and ideas about life which were terribly false, one-sided, and cheap.

MENTAL DISEASES RESEARCH.

At a meeting of the University Court of the University of Edinburgh, it was reported that Dr. Walter Smith Kay, who died on April 22nd, had bequeathed to the University the sum of £5000 subject to Government duty, the annual income to be applied towards aiding research in mental diseases and psychiatry in such manner as the Court, together with the Professor of Psychiatry, shall think fit.

NURSERY SCHOOLS.

There is, I gather, a good deal of discord between the education committees and the public health committees of the new local authorities about the provision and the superintendence of nursery schools. Under the Notification of Births Acts, health authorities have power to set up such schools, including kindergartens, toddlers' playgrounds, &c., and the Education Act, 1918, empowers the education authorities to provide nursery schools. The powers of the two Acts are leading to some confusion. There is a general wish that the health of children from birth to the end of their school age should be under a united direction; but, obviously, the members of the former education authorities, who have been largely coöpted on to the new education committees, find difficulty in agreeing either with the town council or with the county council members. It will be several years before the counties master their new duties and, meanwhile, as the tendency will be to economise, we may expect a considerable reaction in the work of school health administration. In the south of Scotland, however, there have, as yet, been few indications of such a reaction, and ultimately the unification of the system will bear fruit.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

A SWEEPSTAKE WRANGLE.

A SOMEWHAT sharp debate took place in the Dáil last week over the distribution of the proceeds of future sweepstakes between the voluntary hospitals and the county (rate-supported) hospitals. The Minister had proposed that a quarter of the available funds should be allocated to the county hospitals, and an amendment had been moved to increase the proportion to half. Much of the debate centred about the irrelevant question of the respective merits *of the two classes of institution.* It should be clear to anyone who gives thought to the subject that the county hospitals and the voluntary hospitals should work in coöperation and not in rivalry. A certain improvement in the county hospitals in recent years has, however, led many people to think that these institutions can supply a complete hospital service to the country. The staff of a county hospital consists in most cases of one or two men—a surgeon, or a surgeon and a physician, who also acts as anaesthetist. The surgeon may be provided with an X ray apparatus, but he must be his own expert. He is not provided with any pathological assistance, nor has he the help—except in a few institutions—of any further specialists. It is clear that such a staff cannot deal with more than a limited class of case, and in a small country town an all-round staff is impossible. There will always, therefore, be a considerable number of cases which will require the investigation of a larger staff and the help of a fuller equipment than the county hospitals can provide. Such cases must find their way to the voluntary hospitals. A recognition of this simple fact would have prevented much of the futile discussion in last week's debate. It is not altogether the fault of the deputies that the fact is ignored. The Department of Local Government and Public Health has done nothing to advise local authorities as to the kind of cases that are best treated in the county hospitals, and the kind of cases that should be sent to the voluntary hospitals. The Commission on the poor-law system from which one might have expected guidance as the result of its investigations and deliberations a few years ago, evaded this question altogether. Once the proper function of each class of institution is recognised, much irrelevant but harmful criticism will cease. The proportion of distribution suggested by the Minister was carried on a division.

REFORMS IN LOCAL GOVERNMENT.

In the Senate last week Mr. Mulcahy, Minister for Local Government and Public Health, forecast certain reforms in local government for which he intends shortly to introduce legislation. At present local administration of health affairs is in the hands of county boards of health, bodies nominated by the county councils. This has led to a duplication of activities which is to be got rid of by the abolition of the boards of health. When boards of health were first suggested it was intended that they should contain not only representatives of the rating authority, but also members of the medical and nursing profession and other persons with an expert knowledge of health affairs. As they have existed, however, they have been merely subcommittees of the county councils, and there has been no justification for their separate existence. The other reform promised by the Minister is in the direction of managerial control of local administration. He intends to endow the secretary of the county council, or other similar official, with certain powers as a manager of the affairs of his council.

DUBLIN MEETING OF BRITISH MEDICAL ASSOCIATION.

The Leinster Branch of the B.M.A. has invited Prof. T. G. Moorhead, its present president, to accept nomination as president of the Association on the occasion of its meeting in Dublin in 1933. The nomination has to be confirmed by the Council and by the Representative Meeting.

Dr. Moorhead has had a distinguished career as a physician in Dublin. A graduate of Dublin University, he was appointed visiting physician to the Royal City of Dublin Hospital at an early age. He held for a short time the chair of medicine in the school of the Royal College of Surgeons in Ireland. In 1921 he was elected King's professor of materia medica and pharmacy in the School of Physic, Trinity College, and became a physician to Sir Patrick Dun's Hospital. In 1925 he vacated the chair of materia medica to become Regius professor of physic in the University of Dublin. During the war Dr. Moorhead served in the Royal Army Medical Corps in Egypt and France, holding the rank of lieutenant-colonel. He is at present president of the Royal College of Physicians of Ireland, and president of the Royal Academy of Medicine in Ireland. Prof. Moorhead may count on the loyal support of the profession and public of Dublin in his work as President of the British Medical Association.

ARTIFICIAL PNEUMOTHORAX IN ABSCESS OF THE LUNG.

A RECENT discussion at the Société Médicale des Hôpitaux on the above subject demonstrated once again how, in medicine in general, and therapeutics in particular, black is white and white is black—according to the optical slants of different observers. André Jacquelin, in support of his advocacy of this treatment, referred to eight cases in all of which there was complete recovery and no relapse, although the observation period often ran into several years. He insisted that collapse therapy, instituted early and skilfully, is not only easy and almost painless, but also entails no risk of shock or other danger. Whereat, in the ensuing discussion, no less an authority than Sergent protested that all he had achieved from this treatment was disappointment. He had found its efficacy far from certain, and its freedom from danger a delusion since it may lead to infection of the pleural cavity with resulting pyopneumothorax. So when he did not find an abscess of the lung healing spontaneously in a month or two, he was in favour of operative interference. Rist's contribution to the debate swung the pendulum back to the point where Jacquelin had left it; Rist had seen rapid and complete recovery from abscesses of the lung after the induction of a pneumothorax which, to be effective, should, in his opinion, be induced quite early, before adhesions had had time to form. Certain other speakers followed Rist's lead in support of Jacquelin, while Bezançon raised an interesting collateral point; the patient in whom a pneumothorax has been induced is a comparatively difficult subject for operation should the surgeon have to intervene at a later stage. This consideration should be taken into account when the competing merits of an artificial pneumothorax and a more radical operation are weighed in the balance.

COLLECTION OF POLIOMYELITIS CONVALESCENT SERUM.

Not long ago the Academy of Medicine appointed a commission to study the suggestion that a stock of the serum of convalescents should be provided in anticipation of a return of acute anterior poliomyelitis in epidemic dimensions. A member of this commission, Netter, summarised the situation at a recent meeting of the Academy, presenting the conclusions to which his commission had come. It asks the Academy to endorse the two following recommendations: (1) That in anticipation of the possibility of the reappearance of this disease it would be desirable to put a sufficient supply of the serum of convalescents at the service of the medical profession. (2) That this serum should be obtained under conditions which would guarantee its potency and harmlessness. Although the conditions under which the serum is prepared would eliminate the risks of syphilis and tuberculosis, the commission is in favour of donors undergoing the Wassermann test in every case. It thinks that, with the help of hospitals, doctors, and instrument makers, and publicity in the press, a sufficient number of donors will be found for the proposed pool of serum.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

BIOMETRIC PROGNOSIS.

SOME years ago the Association of Life Insurance Directors, interested by the then recent tables of Prof. Georges Dreyer of Oxford, asked the statistical bureau to investigate the prognostic value of the Dreyer standard and to investigate further the relation of weight to longevity. The material investigated consists of 200,000 males, insured between 1887 and 1908, whose histories have been followed until 1921 or prior to termination of the policy. Dr. Louis Dublin now reports the result of this research. It is found that overweight is dangerous and that the danger increases consistently with the degree of overweight. The relation between age and weight is also important. After age 45 the excess mortality amongst overweights becomes most important. Those who are more than 25 per cent. overweight have a mortality-rate double the normal. In youth it is those who are markedly underweight who run the graver risk. Dr. Dreyer had claimed that well-organised overweights—those with long trunks, large chest girths, and ample vital capacity—are as good risks as those of average weight and build. Dr. Dublin's study showed, on the other hand, that those overweights who are short or medium in height are a better constituted class than those who are tall. Moreover, again in contradiction to Dreyer's teaching, the short overweights have a better chance when the trunk is relatively short. But in the tall overweights the conclusion is different: those with a relatively long trunk had a much lower mortality.

ANALYSIS OF SUICIDES IN NEW YORK STATE.

I have already indicated that the only observable ill-effect of the economic depression upon the death-rate in this country is seen in an increase of the suicide-rate. This conclusion, based on the experience of 1930, is confirmed in that of the first quarter of 1931. The New York State statisticians have in the meantime made an analytical study of their suicide-rate in the year 1930. They find that the increase in New York City is much greater than in the rest of the State (148 to 62), and that the increase has been mainly among men, the number rising from 1563 in 1929 to 1760 in 1930. Among women the corresponding increase was from 574 to 585. It will be observed that three times as many men as women are suicidal. This excess is found especially in the older age-groups. Over 80 years there are seven male suicides, and one female. In the younger age-groups the ratio is only 1·5 to 1.

The method most commonly selected up to 70 years of age was by poisonous gas; above that age hanging. Among men the most prevalent methods were: poisonous gas, 30 per cent.; hanging, 24 per cent.; firearms, 19 per cent. Among women we find: poisonous gas, 39 per cent.; corrosive substances, 17 per cent.; jumping from high places, 15 per cent.

Maj. (temp. Lt.-Col.) M. O. Wilson, Maj. and Bt. Lt.-Col. (temp. Lt.-Col.) T. H. Scott, and Maj. (temp. Lt.-Col.) G. F. Rudkin to be Lt.-Cols.

Maj. A. O. Elliott to be temp. Lt.-Col.

R. C. Langford to be Lt. (on prob.), and is secd. under the provisions of Art. 213, Royal Warrant for Pay and Promotion.

ARMY RESERVE OF OFFICERS.

Capt. E. G. Foley ceases to belong to the Res. of Off. on account of ill-health.

TERRITORIAL ARMY.

Lts. R. Rutherford and O. O. Ryan to be Capts.

R. H. Robinson (late Cadet Serjt., Durham Univ. Contgt., Sen. Div., O.T.C.) to be Lt.

INDIAN MEDICAL SERVICE.

Lt.-Cols. to be Cols.: Bt. Col. R. McCarrison and W. R. J. Scroggie.

Lt.-Col. J. Cunningham retires.

DEATHS IN THE SERVICES.

Col. Sir ROBERT HAMMILL FIRTH, late R.A.M.C., who died on June 6th at the age of 72, received his medical education at University College, London, and qualified in 1879 with the M.R.C.S. Eng. In 1881 he obtained the L.R.C.P. Edin., and in the following year was elected F.R.C.S. A year later he became a surgeon in the Medical Department of the Army, and was with the Hazara Expedition of 1888 and with the Tirah Expedition of 1897–98. He was also employed in the late European War, being three times mentioned in despatches, created C.B. in 1918, and K.B.E in 1919. From 1900 to 1906 he was professor of military hygiene in the Royal Army Medical College, and had held the posts of assistant professor of hygiene at Netley and officer in charge of the School of Army Sanitation at Aldershot. He was the author (with Col. Notter) of the "Theory and Practice of Hygiene"; he was also the author of "Practical Domestic Hygiene" and "Military Hygiene," and contributed many articles to the *Journal of the Royal Army Medical Corps* on scientific subjects and medical history.

Inspector General HENRY CHARLES WOODS died at Alverstoke, in his ninety-first year, on June 3rd. He celebrated his ninetieth birthday on May 20th last, when he received a telegram of congratulation from the King. A graduate of St. Andrews, he entered the Royal Navy as surgeon in 1862, and in 1875 served in the *Serapis* during the tour of King Edward, then Prince of Wales, to India. He was promoted to staff surgeon in 1876, and two years later became medical officer of the Royal yacht. *Osborn*. In 1884 he was promoted to fleet surgeon, in 1895 deputy inspector general, and in 1895 inspector general of hospitals and fleets. He retired in 1901, when he received the C.V.O., and in the following year was made a C.B. Inspector General Woods was an honorary physician to the King.

COLONIAL APPOINTMENTS.

Dr. E. E. Henderson has been appointed Acting Professor of Anatomy in the College of Medicine at Singapore, and Dr. R. N. Brandwood has been made Government Medical Officer in the Gilbert and Ellice Islands, Western Pacific. Dr. G. B. Leicester, Assistant Medical Officer, Mental Hospital, Singapore, has been promoted to Deputy Medical Officer, and Dr. L. C. Wijesinghe, Medical Officer, Grade I, Ceylon, has been promoted to Provincial Surgeon, Ceylon.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED MAY 30TH, 1931.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 107; scarlet fever, 1315; diphtheria, 718; enteric fever, 35; pneumonia, 777; puerperal fever, 55; puerperal pyrexia, 95; cerebro-spinal fever, 48; acute poliomyelitis, 6; encephalitis lethargica, 11; relapsing fever, 1; dysentery, 17; ophthalmia neonatorum, 86. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on June 2nd–3rd was as follows:—Small-pox, 149 under treatment, 7 under observation (last week 160 and 8 respectively); scarlet fever, 1187; diphtheria, 1400; enteric fever, 10; measles, 169; whooping-cough, 410; puerperal fever, 33 (plus 13 babies); encephalitis lethargica, 193; "other diseases," 140. At St. Margaret's Hospital there were 21 babies (plus 9 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox nor enteric fever, 39 (1) from measles, 5 (2) from scarlet fever, 26 (7) from whooping-cough, 22 (4) from diphtheria, 41 (10) from diarrhœa and enteritis under two years, and 46 (6) from influenza. The figures in parentheses are those for London itself.

Only one death from meningococcal meningitis (aged 15–25) occurred in London. Seven deaths from measles were reported from South Shields, 5 each from Liverpool, Leeds, and Sunderland. Liverpool reported 4 deaths from whooping-cough, Newcastle-on-Tyne 3. Diphtheria claimed 5 victims at Liverpool. Manchester reported 6 deaths from influenza, Bristol 5, Rhondda 3.

The number of stillbirths notified during the week was 234 (corresponding to a rate of 40 per 1000 births), including 42 in London.

DEATH CLASSIFIED TO SMALL-POX.

THE death provisionally assigned to Market Bosworth R.D. was that of a man, aged 65, who was taken ill on April 30th and was diagnosed on May 1st as suffering from pneumonia. A rash appeared on May 7th, and he was admitted to the small-pox hospital the following day. Dr. Hart, medical officer at the hospital, reported that "on admission the patient was seriously ill with lobar pneumonia and that the variola rash was well marked. Owing to his age and debilitated condition the prognosis was not good. During the two next days he appeared to be holding his own, but on May 11th the pneumonia spread to the right upper lobe, his condition became worse, and he died early on May 13th." Dr. Hart further states that, in his opinion, while the small-pox lowered the patient's powers of resistance, it was a severe case of pneumonia which would have probably ended fatally without the complication of small-pox.

CORRESPONDENCE

SURGICAL TREATMENT OF DUODENAL ULCER.

To the Editor of THE LANCET.

SIR,—I must express profound disagreement with the conclusions on the surgical treatment of chronic duodenal ulcer set forth by my friend, Prof. C. A. Pannett, in your last issue (p. 1235). Prof. Pannett advocates resection of the ulcer and of a portion of the stomach, a portion that must be of considerable size in order to avoid recurrence of ulceration. I believe this advice to be unsound, dangerous, and misleading. The experience upon which it is based, it is admitted, is really too small; and if I challenge the wisdom of Prof. Pannett's opinion and practice it is because an experience almost twenty times as large as his has led me to conclusions directly in conflict with those he has drawn. Prof. Pannett chiefly discusses the relative merits of two operations only, of gastro-enterostomy and of resection. He omits consideration of gastro-duodenostomy, which, in appropriate cases, and in skilled hands, is the equal of any other method.

The mortality of gastro-enterostomy (8·5 per cent.) in his hands does not, of course, represent the risk of this operation and must be regarded as quite accidental. If patients are adequately prepared for operation by methods I have fully described elsewhere, neither this operation, nor resection for simple disease, should have a mortality higher than, if so high as, 2 per cent. Indeed, the question of mortality no longer demands serious discussion by competent surgeons. The matters which still require most earnest consideration are the indications for operation, the choice of the exact method suitable for each case, the exercise of infinite, daintiest care in every movement during operation, and a watchful interest over all patients for months after recovery from operation. Gastro-enterostomy is perhaps as safe as any abdominal operation can be. I have lost one case in my last thousand, and upon many of these cases cholecystectomy, appendicectomy, or both were simultaneously performed. When adequate care is taken the "perfect results" are over 90 per cent. The chief anxiety centres round recurrence of ulceration. This serious condition has developed in 1·84 per cent. of my cases. This is less than the incidence after resection, so far as I am able to judge. I have given some figures in support of this statement elsewhere. Prof. Pannett found three cases of recurrent ulceration in 83 cases, a higher percentage than many of us have found after the simpler operation, in far larger numbers of cases observed over longer periods. I have myself operated upon 11 cases of recurrent ulceration after resection performed by other surgeons and by myself.

Last year I spent twelve happy days with my old friends the Mayos in Rochester. I was delighted, but not in the least surprised, to find there no sympathy with subversive movements, and to learn that the views I hold as to the surgical treatment of chronic duodenal ulcer are theirs also. It is evident that those most experienced in these matters have refused to be beguiled by continental Lorelei into the pursuit of methods which are more dangerous at the moment of their application, and clearly less satisfactory in the long run.

I am, Sir, yours faithfully,
MOYNIHAN.

Portland-place, W., June 8th, 1931.

To the Editor of THE LANCET.

Mr. Pannett says the object of his paper is to record the results of his own experience, which has led him to conclude that pyloro-duodenal resection is preferable to the older and well-established operation of gastro-jejunostomy.

Let us examine the reasons he gives for this preference. They are: (1) After gastro-jejunostomy he has a mortality-rate of 8·5 per cent., whereas after pyloro-duodenal resection his mortality is 2·3 per cent. (2) The after-results of resection give him 81·5 per cent. cures; after gastro-jejunostomy only 61·5 per cent. On these figures his conclusions seem justified, but I find it as difficult to believe so able a surgeon as Mr. Pannett cannot produce something better than 8·5 per cent. mortality after gastro-enterostomy, as to understand how he can expect to get any reliable evidence regarding after-results founded upon only 51 cases. He himself admits the figures are "absurdly small," so would it not have been better to wait until he had something really impressive before attempting to make heretics of us all?

If figures must be used to prove anything let them be big, for it is only then that they *begin* to be reliable. In the *British Medical Journal* (1929, ii., 1074) Dr. A. P. Luff has reported the results of a statistical investigation on this subject based upon fairly large figures. These are his results so far as they are applicable to the present discussion. There were 995 cases of duodenal ulcer and 454 of pyloric ulcer—these are the same thing, and so we have: (1) 1449 cases of duodenal ulcer on which gastro jejunostomy was performed with a mortality rate of 4·3 per cent. (2) The after-results of gastro-jejunostomy for duodenal ulcer give 91 per cent. cures in 1064 cases followed up. These figures represent the massed achievements of many surgeons at different hospitals. I venture to predict a similarly massed result of resection for duodenal ulcer would make a poor show in comparison, even as Mr. Pannett's does, though he is an expert in this particular operation. Moreover, individual surgeons dealing with fairly large numbers of gastro-enterostomy cases can show a lower mortality-rate than that which apparently pleases Mr. Pannett in the case of his resections.

Mr. Pannett says when the ulcer was a small and soft one he did not feel justified in doing a pyloro-duodenal resection (even though he considers it a better operation than gastro-jejunostomy). I agree that resection is most certainly not necessary in this instance, though I fail to appreciate his argument, but I feel confident that if resection were reserved for the only kind of ulcer which I think might reasonably call for this operation—viz., the posterior type ulcerating into the pancreas—the mortality-rate would be higher than 2·3 per cent., and I got the impression from Mr. Pannett's paper that he does gastro-jejunostomy for ulcers in this place and of this kind.

Just one more criticism. Mr. Pannett says for the stubborn recalcitrant cases of duodenal ulcer there are three accepted surgical operations—gastro-jejunostomy, pyloro-duodenal resection, and pyloro-plasty. Why does he not mention gastro-duodenostomy, which, I think, has a position in surgical procedure more assured than the two he mentions last?

I am, Sir, yours faithfully,
E. R.

Leeds, June 9th, 1931.

THE ST. CYRES LECTURE.

To the Editor of THE LANCET.

SIR,—May I ask you to print in your journal this simple protest against the publication in your issue of May 23rd of a full abstract of my St. Cyres lecture without my knowledge, and without my being afforded any opportunity of correcting the many inaccuracies that your printed account contains. Although it is derived from my lecture I am not prepared to accept responsibility for any part of this publication in your journal.

I am, Sir, yours faithfully,

THOMAS LEWIS.

Department of Clinical Research, University College Hospital, Medical School, University-street, W.C. 1, June 3rd, 1931.

*** By omission of the names of his collaborators our report has made Sir Thomas Lewis appear responsible for certain experiments and conclusions not his alone. We regret that it contains inaccuracies—for example, Potain's name is given as Potter, and Allbutt's theory of anginal pain is attributed to Parry.—ED. L.

ADEQUATE TREATMENT OF SYPHILIS.

To the Editor of THE LANCET.

SIR,—My article has evoked three letters to which I must reply.

In my opinion all that Colonel Harrison has said and quoted with regard to the occurrence of neurosyphilis is not so much to be interpreted as due to the use of a single remedial agent but more essentially to the inadequate amount of it used during a given period—in other words, to the low efficiency index of the course. Similarly with Moore and Kemp's neuro-recurrences, the striking feature of the cases was the utter inadequacy of the treatment—again a low efficiency index. Among their 71 patients who completed the scheduled course—which has an efficiency index of 90—there was no case of neuro-recurrence. So far as the defaulter is concerned, an early and clinical neuro-recurrence—and 90 per cent. of Moore and Kemp's cases occurred within the first six months—is by no means the worst thing that can happen. It is probably the best, for it quickly brings the patient back for further treatment. The defaulter from concurrent therapy may not exhibit a neuro-recurrence, but his uncured syphilis is most certainly causing grave visceral damage, 'though years may elapse before it is clinically recognisable. When his true condition is eventually discovered, not only is the structural and functional damage permanent, but in the interval he almost certainly has conveyed the disease unwittingly to others.

Concerning the elimination of arsenobenzene compound, surely there is experimental evidence (Clausen and Jeans, Kolmer, and others) which goes to show that approximately half of each dose is retained in the tissues and is gradually eliminated over a period of many weeks. Indeed Mr. Lees mentions this in the latter part of his second paragraph. Of course, the fullest therapeutic effect is seen in the first three days after the injection, and this is the reason why, when the patient can attend twice in the first week, we give him during that time two intravenous Conctions of 0·3 g. stabilarsan. I agree that for every hygien neuro-recurrence there must be a number Army S. Col. Nott with cerebro-spinal fluid abnormalities. was also tlies equally to cases treated alternatingly, concurrently, or monotherapeutically. In Report No. 132, p. 48, Colonel Harrison himself says that "a form of treatment which is followed by fewer clinical neuro-recurrences than is another, can be expected also to have considerably fewer cases with pathological changes in the cerebro-spinal fluid." Since, then, there is no difference between our two lines of treatment with regard to clinical neuro-recurrence, may we not assume that the same will obtain in respect of cerebro-spinal fluid? In so far as Bernard's investigation is concerned I would again point out that the value of a line of treatment can only be assessed from patients who have completed the course and not from those who have defaulted.

Mr. Lees seems to suggest that my methods and arguments are supported merely by the 136 cases to which I referred in the *British Journal of Venereal Diseases* (1930, vi., 212). If so, he does me an injustice. These were simply a series of male cases who had completed the scheduled course for early syphilis, had fulfilled the criteria of cure, and who, during an observation period of from three months to nine years, had suffered no relapses, clinical or serological. My thesis is based not upon these only, but upon all the syphilitic patients seen at the Warrington and Salford municipal clinics from 1921 to 1931. However, even upon the number given, I am entitled to give a reasoned opinion. If Mr. Lees really thinks that "most clinicians will be unable to accept an opinion based upon so small a number of cases observed for an inadequate period," then he and most clinicians will likewise be unable to accept the opinions of Colonel Harrison in Report No. 132. There, in respect of sero-negative primary syphilis, there are only 183 cases tabulated (Table G., p. 32), and of these, only 53 completed the course. Of the total, only 25 were under observation for over three years, and 99, or 54 per cent., were only observed for 12 months and under. In 147 sero-positive primary patients, only nine were observed for over three years, and with respect to the 181 early secondary cases, the observation period was over three years in only 11 instances. In this connexion, then, Dr. Allen's remark that I have not observed my cases long enough or adequately enough, applies, of course, with equal force to Colonel Harrison's series. What Dr. Allen's experience may be I do not know, but mine—and apparently also Colonel Harrison's—is that there is only a small percentage of cases that one can keep under observation for more than three years. One must adopt reasonable and practicable standards of cure and observation. Mine are: absence of clinical and serological signs after provocation for at least two, and if possible three, years after the cessation of treatment.

Mr. Lees states that the rest intervals under concurrency are not provided to allow the patient to recover from the toxic effects of the agents, and yet, in the next sentence, he admits just that very thing. He says that the drugs are stored up in the tissues and that the rest intervals are to allow the body to use them up or to eliminate them. If the rest were not given, then surely the accumulation would produce toxic symptoms. That is the clear reason why the rest period is adopted. Mr. Lees finds the incidence of complications very uncommon simply because he introduces so many rest intervals in his course to avoid them. Let him cut out these periods and see what happens. The duration of his course for sero-negative primary syphilis is 103 weeks, during which time there are only 64 weeks of actual therapy, counting the provocative injections as such. Rest intervals occupy 38 per cent. of the time, and treatment 62 per cent. During the 64 weeks of therapy, in only 15 are the drugs given concurrently.

Mr. Lees says that "there is no accepted proof that bismuth when injected into the body produces a toxalbumin." I would refer him to "Le bismuth dans le traitement de la syphilis" by Levaditi (Paris, 1924), p. 262 et seq., and to the references contained therein. My view about mercury is that where there is no contra-indication to Ab.C. or bismuth, to use that agent is a waste of time. I am in full agreement with Colonel Harrison in that we know from past experience of patients "treated conscientiously with mercury for two years, and from observation of later effects, the most that this is likely to do is to keep the serum reactions negative and everybody concerned in a fool's paradise."

Neither Mr. Lees nor Dr. Allen appears to like my method of evaluating therapy. I cannot reply to their criticisms in detail, but perhaps they may find the idea more clearly expressed in the *American Journal of Syphilis* (April, 1931, p. 155). I do not know what to make exactly of Dr. Allen's observations. The first would suggest that he is not very well acquainted with the methods of testing the chemotherapeutic index of a drug. He must surely see how fallacious would be his method. In his third observation he has misinterpreted my meaning. What I do wish to convey is that during the seven-day time-period, whatever the amount of drug given, it should be the optimum for that particular patient at that particular time. One does not give less than is necessary or more than is safe. It is just in this respect that my method does take great account of varying factors such as the condition and age of the patient. The proof of the pudding is the eating thereof. Assessing various schemes of treatment according to the method I suggest, one finds that, for example, in sero-negative primary syphilis, the efficiency index must not fall below 70 in order to get a satisfactory percentage of cures. I have studied the efficiency indexes of some of my relapsed cases, and in none of them has the index been above 70.

I am not seeking to standardise treatment in the way that Mr. Lees suggests. I have merely put forward a method whereby we may have a measuring-rod which will enable us to say that therapy, to be adequate, must not fall below a certain index figure. From practical experience we have found that method useful here, and that is—as Mr. Lees and Dr. Allen will agree—of far more value than their purely theoretical objections. The point is that this method *works*, whereas treatment calculated in terms of quantity of drug given in a certain time is utterly meaningless.

I am, Sir, yours faithfully,
E. TYTLER BURKE.

Municipal Clinic, Salford, June 8th, 1931.

To the Editor of THE LANCET.

SIR,—On June 21st, 1930, you published a very able, and very disturbing, paper by Dr. J. H. Sequeira on the Activation of Syphilis by Treatment, which should be read in connexion with the present discussion. An earlier communication relating to the work of Cesar Boeck and the pathological investigations of Bruusgaard and of Warthin appears in the issue of Jan. 18th, 1930 (p. 159). Together they constitute a severe arraignment of modern methods as failing to prevent serious visceral and neural involvement and proving otherwise doubtfully effective.

And yet it is clear that syphilis seems sometimes to be cured very quickly, and by the simplest means. In hospitals and institutions catering for elderly men one occasionally meets evidence of an early infection, and elicits such a history as the following, quoted as typical. Questioned about the unmistakable scar left by a chancre, the patient, now 70, states that at the age of 19 when on a voyage to the Cape a sore appeared on the penis, and as it was not healing the mate had him swallow regularly some "pills." After about a month the place got well, the pills were stopped, and no further treatment taken. Three or four years later he married; and except for the recent difficulty with his water his health has been excellent, and the married life of himself and his buxom and contented wife quite uneventful. Upon request they bring along several children and grandchildren for inspection; no evidence is found of inherited disease, no history is elicited of miscarriages, and the blood of one of the adults, chosen as representative, is Wassermann-negative. It is therefore reasonable to conclude that the mercury that this man undoubtedly was given proved neither "inefficient" nor a "mere waste of time."

Few will contend that the administration of arsenobenzene preparations constitutes alone an adequate treatment of syphilis. Probably a majority of experienced specialists continue to regard mercury as the necessary complement of arsenic in antiluetic treatment, assigning to bismuth a position somewhere between the other two, as a sort of hybrid possessing something of the properties of each but the therapeutic efficiency of neither.

The arsenobenzene preparations are pre-eminently direct spirochæticides. Sir Jonathan Hutchinson believed that the action of mercury in early syphilis was very similar but that at a later stage it was principally indirect, or in other words, that it was antigenic; and it was his experience that where small doses of grey powder were taken regularly over a sufficient period recurrences were extremely rare. Writing in 1909, he states definitely that no case of paraplegia had ever occurred among his own patients—and he had then been in active practice for 50 years.

Many thoughtful observers believe that the outlook for complete and lasting recovery would be bettered if the treatment of recent syphilis were commenced with a reasonably long course of mercury, given in small doses and chiefly for its assumed antigenic properties, the arsenicals being held in reserve until some immunity or insulation is considered to have been established, when they would be brought forward to reinforce the fully stimulated natural resistance. Although not proved, it is reasonable to suppose that something more than a cell response is evoked by the presence of *Sp. pallida* in the human body. It may well be that the presence of spirochætes in numbers and over a period is also necessary for the acquirement of adequate protection.

I am, Sir, yours faithfully,
H. D. L. SPENCE.

Great Russell-street, W.C. June 9th, 1931.

THE DIFFICULT CHILD.

To the Editor of THE LANCET.

SIR,—In your annotation of May 16th (p. 1097) criticism was made of the extent to which the social worker is allowed to conduct the active operations of child guidance work, and of the inadequate provision for dealing with the more difficult parent of the difficult child. This evoked some comment from my colleague, Dr. Emanuel Miller, and I should like to amplify his remarks. As far as our knowledge goes, we incline to agree that the former criticism may be a just one when applied to the methods of child guidance as practised in American clinics. In our own clinic, which is modified from the American pattern, it is our aim that both diagnosis and treatment shall be kept, at every step, under the close personal care of the physician, believing that this is essential to sound work.

As to the parents who, in our experience as in yours, provide the most frequent and the most difficult problems, our practice is to devote much personal effort to the correction of their psychological difficulties rather than "tacitly to leave them to be handled by the social worker." Detailed investigation of parental habits and of home conditions is, and must be, carried out by the social worker who is specially trained for the work. How many physicians have anything like her experience or skill in this respect? At the same time it becomes increasingly obvious that personal contact between psychiatrist and parent is to be desired in every case. In our last 100 cases, including several children whose attendance has only just begun, one of the parents has been seen by the psychiatrist in 92 instances, both in 32, while other members of the family have been interviewed in 19. Some parents have been sent for periods of so-called convalescence and some have been referred to appropriate clinics for more overt and active psychotherapy.

It is true, as you say, that "the problem of the parent has not been wholly solved by the child guidance scheme," but it has at least been brought more fully into the light, which should be a first step towards solution.

I am, Sir, yours faithfully,

London, S.W., June 5th, 1931. NOEL H. M. BURKE.

SUPERVISION AND DEATH IN CHILDBIRTH.

To the Editor of THE LANCET.

SIR,—While some papers correctly, though briefly, reported an address which I gave before the College of Nursing Post-graduate Course at the London School of Hygiene on May 18th, others did not, and serious mis-statements were included in certain reports. My official position normally precludes me from attempting to correct any perversion of my addresses or papers by communicating with the press. In the present instance, however, I fear that serious misunderstanding may arise from the incorrect attribution to me of a statement that, if I had the supervision of maternity cases, I could guarantee a reduction of three-quarters of the present average mortality. What I did say was that if effective medical and midwife supervision of maternity cases began early enough and was properly maintained up to and after childbirth, ultimately the maternal mortality-rate might well be reduced by as much as three-quarters. This is indicated by the excellent results already secured in existing practice which are recorded on p. 106 of the Interim Report of the Departmental Committee on Maternal Mortality for 1930.

I am, Sir, yours faithfully,

GEORGE NEWMAN.

Ministry of Health, Whitehall, S.W.,
June 9th, 1931.

CHAIRS OF PHYSIOLOGY.

To the Editor of THE LANCET.

SIR,—Surely Prof. J. F. Fulton is wrong when he says (p. 1211) that the Waynflete chair of Physiology at Oxford was created in 1878. Burdon Sanderson was created Waynflete professor of physiology in 1882. Until 1881 the chair was held by my father, George Rolleston, who was Linacre professor of anatomy and physiology. After his death in 1881 the chair was divided into two, Moseley taking comparative anatomy and morphology and Burdon Sanderson physiology. It was not, I think, until some years later that Arthur Thomson was made professor of human anatomy.

I am, Sir, yours faithfully,

June 9th, 1931. CHRISTOPHER ROLLESTON.

*** Our issue of June 17th, 1882, contained the announcement that "advertisements will speedily be issued for the Waynflete professorship of physiology."—ED. L.

MEDICAL NEWS

University of Cambridge.

On June 6th the following degrees were conferred:—

M.D.—R. M. B. MacKenna, C. C. R. Downing, J. P. Marsden, and M. E. Lampard.

M.B.—H. L. Hoffman.

B.Chir.—C. O. Barnes.

Society of Apothecaries of London.

At recent examinations the following candidates were successful: *Master of Midwifery*—A. V. Clemmey, B.M., Archibald Gardiner, M.B., Greta Hartley, M.B., and Eva J. Newton, M.B.

University of London.

At recent examinations the following candidates were successful:—

THIRD EXAMINATION FOR M.B., B.S.

Honours.—H. W. Howell (*a*), and L. H. Howells (*a*), London Hosp.; A. F. Z. Judd (*a*), L.S.M.W.; Muriel H. E. Long (*c*) King's Coll. Hosp.; P. V. Reading (*d*, *e*, University Medal), and T. F. Todd (*e*), Guy's Hosp.; and Marion E. Townsend (*e*) L.S.M.W.

(*a*) Distinguished in Medicine. (*c*) Distinguished in Forensic Medicine. (*d*) Distinguished in Surgery. (*e*) Distinguished in Midwifery.

Pass.—R. M. Alderton, London Hosp.; Gwendolen E. Austin, King's Coll. Hosp.; Frederick Back, St. Thomas's Hosp. and London Hosp.; E. E. Barnett, London Hosp.; A. L. Basham, St. Thomas's Hosp.; J. E. L. Bendor-Samuel, and C. C. Beresford, London Hosp.; Ilma B. S. Bingemann, St. Mary's Hosp.; Helen B. Burt, and Joan Butterworth, L.S.M.W.; A. C. Byles, St. Mary's Hosp.; P. H. Charlton, Middlesex Hosp.; D. O. Clark, St. Thomas's Hosp.; A. R. Clarke, Guy's Hosp.; R. D. Darley, Univ. Coll. Hosp.; H. L. G. Davies, St. Bart.'s Hosp.; S. D. Elliott, Univ. Coll. Hosp.; W. J. Ferguson, Guy's Hosp.; L. P. Friedman, Univ. Coll. Hosp.; R. J. Furlong, St. Thomas's Hosp.; A. P. Gaston, St. Bart.'s Hosp.; J. B. George, St. Thomas's Hosp.; S. J. Golden, London Hosp.; Rebecca Goldstein, Univ. Coll. Hosp.; R. T. S. Goodchild, London Hosp.; P. R. Graves, St. Thomas's Hosp.; S. R. Gunewardene, Univ. Coll. Hosp. and Ceylon Med. Coll.; F. R. Gusterson, St. Thomas's Hosp.; R. L. H. Harris, St. Bart.'s Hosp.; Ruth M. Harris, L.S.M.W.; W. H. Harris, Victoria Univ. of Manchester; William Hogg, St. Bart.'s Hosp.; S. W. Holmes, St. Mary's Hosp.; H. R. Hovsha, King's Coll. Hosp.; D. T. Ishmael, St. Bart.'s Hosp.; Evan Jones, St. Thomas's Hosp.; H. W. Jordan, J. D. Kershaw, and A. T. L. Kingdon, Univ. Coll. Hosp.; Nathan Kramer, St. Bart.'s Hosp.; F. P. L. Lander, Middlesex Hosp.; E. S. Lee, Westminster Hosp.; P. A. T. Lowden, St. Thomas's Hosp.; Mohabeer Luckeenarain, Westminster Hosp.; Univ. Coll. Hosp.; Robert Machray, Westminster Hosp.; Wylie McKissock, St. George's Hosp.; Henrietta M. Macleod, L.S.M.W.; K. M. Masani, and J. H. G. Mason, Middlesex Hosp.; Bertha I. Meyer, L.S.M.W.; T. W. Mimpriss, St. Thomas's Hosp.; Joseph Mindline, Westminster Hosp.; Ian More, Univ. Coll. Hosp.; Kathleen J. Mulvany, Charing Cross Hosp.; Lois M. Munro, L.S.M.W.; W. L. Neustätter, Univ. Coll. Hosp.; G. H. Nowns, King's Coll. Hosp.; J. E. A. O'Connell, and A. P. M. Page, St. Bart.'s Hosp.; D. N. Parfitt, Univ. Coll. Cardiff; F. L. L. Patrick, St. Bart.'s Hosp.; A. L. Pereira, St. George's Hosp.; J. H. Pierre, St. Bart.'s Hosp.; N. S. Plummer, Guy's Hosp.; D. C. Price, St. Bart.'s Hosp.; Helen M. M. Reid, L.S.M.W.; T. S. Rodgers, Westminster Hosp.; K. M. Ross, St. Bart.'s Hosp.; Samuel Scher, Univ. Coll. Hosp.; V. E. P. Senewiratne, Ceylon Med. Coll. and

Univ. Coll. Hosp.; G. C. Sheldon, King's Coll. Hosp.; Helana Sidarous, L.S.M.W.; S. K. Squires, *St. Mary's Hosp.*; *Eileen* M. G. Stevenson, L.S.M.W.; R. G. Thomas, St. Thomas's Hosp.; J. A. White, St. Mary's Hosp.; I. G. *Williams, Middlesex* Hosp.; F. W. Willway, King's Coll. Hosp.; and William Young, St. Mary's Hosp.

The following students have passed in one of the two groups of subjects:—

Group I.—Wolf Aukin, Univ. Coll. Hosp.; H B. Barker, St. Mary's Hosp.; H. W. Benham, Univ. Coll. Hosp.; A I. P. Brown, London Hosp.; Albert Burkhardt, Univ. Coll. Hosp.; E. H. Capel, Middlesex Hosp.; A. F. H. Coke, St. Mary's Hosp.; H. E. B. Curjel, St. Thomas's Hosp.; J. O. F. Davies, Middlesex Hosp.; S. B. Dimson, and P. G. Dowdell, *Univ. Coll. Hosp.*; E. H. Evans, Univ. Coll. Cardiff and Univ. Coll. Hosp.; Phyllis M. Fraser, L.S.M.W.; J. B. Great Rex, St. Bart.'s Hosp.; Hilary S. M. Hadaway, L.S.M.W.; D. W. James, Guy's Hosp.; E. G. M. Jones, Univ. Coll. Hosp.; B. W. Knight, St. Bart.'s Hosp.; G. A. M. *Lintott*, Guy's Hosp.; W. F. McGladdery, St. Bart.'s Hosp.; Dorothy Makepeace, King's Coll. Hosp.; S. F. Marshall, St. Bart.'s Hosp.; *Gwendolen E. M. Meyer, Charing Cross Hosp.*; J. F. Morton, Guy's Hosp.; D. D. Payne, St. Thomas's Hosp.; R. N. C. Smith, and Ben Southwell, Guy's Hosp.; Thomas Standring, King's Coll. Hosp.; F. L. Wheaton, Middlesex Hosp.; S. J. Wheeler, Guy's Hosp.; and E. L. Williams, Univ. Coll. *Hosp.*

Group II.—I. S. Acres, *London Hosp.*; K. C. Buck, St. Mary's Hosp.; Margaret E. Cope, L.S.M.W.; D. F. L. Croft, and J. R. Crumbie, *St. Bart.'s Hosp.*; E. B. *Grogono*, J. M. Harker, and B. T. W. Harvey, London Hosp.; K. L. James, Univ. Coll. Hosp.; Samuel Lefcovitch, Guy's Hosp.; K. S. May, King's Coll. Hosp.; E. R. R. Mellon, Guy's Hosp.; H. S. Morton, London Hosp.; D. K. Mulvany, King's Coll. *Hosp.*; *C. F. Price*, and W. M. Priest, Univ. Coll. Hosp.; J. M. Robertson, Guy's Hosp.; R. W. Scarff, Middlesex Hosp.; M. R. Thomas, and W. J. *Tindall, Univ. Coll. Hosp.*; R. S. Wale, King's Coll. Hosp.; and Gordon Wells, St. Bart.'s Hosp.

L.S.M.W. = London School of Medicine for Women.

International Congress for Light.

The secretary-general of this congress (see THE LANCET, April 4th, *p. 783) asks us to state again* that the meeting is to be held in Copenhagen in 1932 and not this year. A *detailed programme will be* available in the autumn.

Federation of Cremation Authorities.

This association will hold its tenth annual conference in Ipswich from June 19th to 23rd. Among the speakers on the 22nd will be Sir William Willcox, Dr. A. N. M. Pringle, Sir W. Arbuthnot Lane, and Dr. W. E. Dixon, F.R.S.

Reception by R.A.M.C.

The officers of the Royal Army Medical Corps held a reception at their headquarters mess at Millbank, London, on June 4th. A large company of guests was received by Lieut.-General Sir Harold Fawcus (Director-General, Army Medical Services) and Lady Fawcus.

Memorial to Dr. J. Llewellyn-Jones.

On Sunday, June 7th, Princess Victoria visited Gerrard's Cross, Buckinghamshire, to unveil in the parish church a tablet erected to the memory of Dr. John Llewellyn-Jones, who died in February of last year. An address was given by Mr. D. Cotes-Preedy, K.C., Recorder of Smethwick, himself a member of the medical profession and an old friend of Dr. Llewellyn-Jones. A large congregation attended.

Fellowship of Medicine and Post-Graduate Medical Association.

Arrangements for the coming week will be found in our Medical Diary. On June 15th a fortnight's course on diseases of children begins at the children's clinic and various hospitals, and a three weeks' course on tropical medicine at the Hospital for Tropical Diseases. Also starting next week, a course of six demonstrations on fractures, on Tuesdays, Wednesdays, and Fridays for two weeks, will be given at the Royal Albert Dock Hospital at 4.30 P.M. by Mr. Hope Carlton and Mr. Ernest Griffiths. Copies of all syllabuses and tickets may be had from the secretary of the Fellowship at 1, Wimpole-street, London, W. 1.

International Socialist Medical Conference.

At the end of May nearly 200 doctors, representing about ten national socialist medical associations, met in conference at Carlsbad in Czecho-slovakia. Dr. Somerville Hastings, M.P., and Dr. W. Rutherford represented the newly formed British Socialist Medical Association. The chief business of the meeting was the formation of an international association; the central bureau is for the present to be in Berlin with Dr. Ewald Fabian as secretary. At the discussion it was pointed out that in many countries the health of the children, especially those of the unemployed, is being lowered, and that in the younger unemployed men nervous disorder and crime are increasing. A resolution was carried in favour of increased allowances for the unemployed, raising of the school-leaving age to 16, shorter hours of labour, and the building of more houses for the people.

Medical Congress in Carlsbad.

The thirteenth Carlsbad International Medical Educa*tional* Congress (with special reference to balneology) will be held at Carlsbad from Sept. 13th to 19th. Among the participants will be Dr. Philip Manson-Bahr (London) who will give an address on the Dawn of Tropical Medicine. Members of the congress will be *guests of the town during* their visit. Particulars may be had from Dr. Edgar Ganz, Carlsbad, Czecho-slovakia.

Scottish Midwives Conference.

Under the presidency of Dr. Margaret Scott-Dickson, the fourteenth annual meeting of the Scottish Midwives' Association was held at Dundee Royal Infirmary last Saturday. It was felt that the members had a very real grievance in that they were frequently required to give their services without receiving any recompense. Strong criticism was levelled against the handywoman, and members were advised to report cases in which the woman of the house had taken on the duties of the midwife.

Tonsil Surgery in Paris.

Under the auspices of the Association for Post-graduate Teaching of the Hospitals of Paris, a series of discussions and surgical demonstrations on Tonsil Surgery are being given from June 15th to 17th at the Hôpital Necker-Enfants Malades by Dr. J. M. Le Mée, Dr. André Bloch, and Dr. M. Bouchet, with the assistance of Dr. Weill-Hallé and Prof. G. Canuyt. The lectures will be delivered in the afternoon between 4 and 6. The demonstrations will be held in the mornings from 10 to 12. Explanations will be given as required in French, English, German, or Italian. Arrangements are in the hands of Dr. Magdelaine, assistant at the hospital, 149 rue de Sèvres, Paris.

Post-graduate Lectures on Proctology.

The staff of St. Mark's Hospital, City-road, London, E.C., is giving a series of weekly lectures on proctology to medical practitioners. Each lecture will begin at 4.30 P.M., and the following days and subjects have been arranged: Monday, July 6th, Mr. J. P. Lockhart-Mummery: Perineal Excision of the Rectum (with cinematograph demonstration). Thursday, the 16th, Sir Charles Gordon-Watson: Carcinoma of the Colon. Wednesday, the 22nd, Mr. L. E. C. Norbury: Prolapse of the Rectum. Tuesday, the 28th, Mr. W. B. Gabriel: Anal Fissure.

Medical Golfing Society.

The annual summer meeting was held on May 28th at Walton Heath where the 96 competitors were the guests of Lord Riddell. The results were: THE LANCET Cup (scratch), Dr. W. H. Lamplough, all square; Henry Morris Cup (Handicap), Dr. W. H. Lamplough, 2 up. Class 1. First Prize, Dr. J. Wallace; Second Prize, Dr. Gilliatt; best last 9, Mr. George Dawson. Class 2. First Prize, Dr. C. H. Ilott: Second Prize: Dr. C. Branwell; best last 9, Dr. Rolf Creasy. Foursomes: Mr. Rowley Bristow and Dr. W. H. Lamplough after a tie at 3 up with Dr. Galletly and Dr. McGrath. The Knock-out Tournaments and Milsom Rees Cup was won by Sir Kenneth Goadby, the runner up being Dr. Bathurst.

Debt of London Hospital.

At the quarterly meeting of governors last week Lord Knutsford, the chairman, stated that the loan from the bank now stood at £44,000, and that if borrowing continued at the present rate the limit as covered by the general purposes securities would soon be reached. All building extensions are to be postponed until the money is actually in hand.

Testimonial to a Medical Man.

The sum of £501 is to be handed over to the family of Dr. William Muir who died in March at Davidson's Mains, Edinburgh. The sum was the result of a collection raised as a testimonial to Dr. Muir when it seemed probable that he would recover from his illness. For 35 years Dr. Muir carried on practice in the district, with self-sacrificing devotion, and he also interested himself greatly in public affairs, especially in education.

Founders' Day at Alton.

The celebration of Founders' Day at the Lord Mayor Treloar Cripples' Hospital and College at Alton, Hants, last week was marked by the opening by Sir Roger Keyes of the Portsmouth block which contains the Fourth Destroyer Flotilla and Naval Memorial Wards. In the wards are tablets commemorating the names of officers and men who fell in the battle of Jutland. There are 300 children under treatment and 50 boys are being trained in the College. Lord Burnham, the senior trustee, who presided, stated that the old wooden buildings left over from the Boer War are fast disappearing and being replaced by a hospital "that would be a model for the world."

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS.

MEDICAL SERVICES AND THE PETROL DUTY.

On June 8th the House of Commons began consideration of the Finance Bill in Committee. The discussions were limited by the time-table adopted last week, with the result that large numbers of amendments on the Order Paper were not called upon. Clause 1 of the Bill increases the customs duty on hydrocarbon oils from *4d.* to *6d.* a gallon. Lieut.-Colonel Fremantle and other Members had given notice of amendments exempting from the operation of the duty petrol used by medical practitioners and veterinary surgeons in carrying on their medical and veterinary practices and petrol used in hospital ambulance work.

During the debate on the question that Clause 1 should stand part of the Bill,

Lieut.-Colonel Fremantle said that under the Guillotine Resolution the Committee was compelled to pass over a number of amendments to this clause which were of definite importance, and as an illustration he might mention two in which he was particularly interested. They were the amendments which suggested exemption first in the case of ambulances attached to hospitals, and, secondly, in the case of medical and veterinary practitioners. There were precedents for these proposals, and he only spoke of them as illustrating the damage which could be done by imposing a general duty of this sort without giving any time for the consideration of the exemptions. In the Finance Act of 1910, which originally imposed the motor spirit duty, medical men were given a rebate of one-half of the duty in respect of motor-cars owned and worked by them in carrying out the duties of their practice. As regarded ambulances, there was also a definite precedent. At present lifeboats were exempt. Why then should the ambulances of hospitals be taxed? They were required more than ever to-day because of the increasing number of road accidents. The cost of attending to those accidents was not borne by the Government and was not to any large extent borne even by the people who suffered, but was to a large extent borne by the voluntary hospitals, the ambulance services, and the St. John's Ambulance Association.. A very small proportion was paid by the people who had the benefit of those services. He knew that in theory the Government proposed to their Socialist supporters that there should be Socialistic services of this kind, and that all these things should be run by the State; but, on the other hand, they often came to the House of Commons and said: "We have to take things as they are." Then they put even greater burdens upon the people who already had to bear the incubus of these services. They said they were compelled to do so pending the nationalisation of those services. They might one day have the nationalised medical service proposed by Dr. Hastings, but he (Colonel Fremantle) thought that it would be a long time before they had it. It would be the acid test of the theory, because people would then have the opportunity of realising the rights and wrongs, the advantages and the disadvantages, of a mechanical system. This clause would add considerably to the cost of running ambulances and to the expenses of the country doctor. He reckoned that to the ordinary country doctor who covered 20,000 miles in the year, and whose car did 20 miles to the gallon, the extra *2d.* would mean an extra £10 a year. This was a definite case which the Government ought to face. So long as they were dependent to a large extent on voluntary institutions for such essential public services any Government ought to relieve them as far as possible of fresh taxation in so far as it applied to their work in the service of the community.

The clause was agreed to.

Sentence of Death (Expectant Mothers) Bill.

On June 2nd in the House of Commons the Sentence of Death (Expectant Mothers) Bill was read the third time. On June 5th in the House of Lords the same Bill was introduced and read a first time.

HOUSE OF COMMONS.

THURSDAY, JUNE 4TH.

Ice Cream Vendors.

Sir Cooper Rawson asked the Minister of Health if he had, in the interests of public health, considered the desirability of the compulsory registration of itinerant ice-cream vendors with the local authority to ensure control of the conditions of manufacture and the type of premises used in connexion with this commodity.—Mr. Greenwood replied: I could not undertake to introduce legislation on this subject at the present time. I may, however, draw the hon. Member's attention to Section 72 of the Public Health Act, 1925, which requires the maintenance of proper sanitary conditions in places where food is prepared for sale.

Sir G. Penny: Will the right hon. gentleman take samples in order to ascertain whether they are pure?

Mr. Greenwood: I am very willing to discuss with the Ice Cream Merchants' Association, who have been taking up this matter, any possible action that may be taken.

Hospital Sweepstakes.

Mr. Day asked the Home Secretary whether, in view of the public interest taken in the Irish hospitals sweepstakes held on the Derby and other English races, he would now consider the question of setting up a committee to inquire into the conditions that would be necessary and appropriate for the purpose of altering the existing lottery laws.—Mr. Clynes replied: The matter is now under consideration.

Mr. Charles Williams: May we expect a decision on the matter?

Mr. Clynes: You may, but I can say no more at present.

Private Nursing Homes in London.

Mr. West Russell asked the Minister of Health whether he could arrange for an annual report to be issued to show what was being done to improve the standard of private nursing homes in the metropolitan area and to close those which were in unsuitable neighbourhoods and structurally unfitted.—Mr. Greenwood replied: Under the Nursing Homes Registration Act, 1027, the London County Council is the local supervising authority in the metropolitan area outside the City of London, and a report on the administration of the Act is included in the annual report of the council. I understand that a complete statement of the present position will be included in the report for 1930 which is now in preparation.

Mr. A. M. Samuel: Is the right hon. gentleman doing anything to improve the acknowledged bad standard of some of these private nursing homes in the metropolis? Does he do anything to check it?

Mr. Greenwood: That is a matter for my predecessor.

Russian Butter.

Sir N. Grattan-Doyle asked the Minister of Health whether he had any statement to make concerning the report of Mr. Warburton, the official zoologist representing the School of Agriculture at Cambridge, in reference to a foreign body designated as a "parasite" discovered by him in a sample of Russian butter purchased in Cambridgeshire, and whether there was any danger of infection from such foreign body contained in an article of food?

Mr. Greenwood: I have no information on the subject except what has appeared in the press. I am making inquiries and will communicate with the hon. Member.

Sir N. Gratton-Doyle: Does the right hon. gentleman realise the seriousness of what has occurred? Does he realise the possibility of infection being conveyed into this country by Asiatic parasites which are entirely new and are a revelation even to the authorities?

Mr. Greenwood: I have no knowledge myself that one dead parasite could cause much harm to anyone.

Mr. Guinness: Will the right hon. gentleman consult with the Minister of Agriculture as to whether this may not be a case for bringing into force the power of prohibiting an import, just as is done in the case of maggotty cherries, which are far less objectionable or dangerous?

Mr. Greenwood: That is one of the matters into which inquiry is being made.

Lieut.-Commander Kenworthy: *Do these parasites* breed in mare's nests?

Boy's Sight and Vaccination.

Mr. Freeman asked the Minister of Health whether his attention had been drawn to the case of Victor Rands, aged 7 years, of Parsloes Farm, Dagenham, who lost the sight of his right eye as a result of vaccination in October, 1930, by the public vaccinator; whether he was aware that Victor Rands was at the time under treatment for a septic knee; that the child's eye got steadily worse, and the medical officer of health, when he saw the boy at the *minor ailments clinic, recommended him to be taken to the Moorfields Eye Hospital; and whether he would have* a thorough investigation made into this case.—Mr. Greenwood replied: My attention has been drawn to this case, and I have already made inquiry into it. I am informed that the vaccination was performed by a public vaccinator on Oct. 22nd, 1930, with the consent of the parents. The public vaccinator states that he found no physical reason on that date why the boy should not be vaccinated, nor did he observe any evidence of an affection of the eye when he inspected the vaccination on Nov. 4th. It was not until 36 days after the date of vaccination that the boy was taken to the school clinic at Barking on account of his eye trouble. I am advised that the course of events *is not consistent with the suggestions which have* been made that the affection of the eye was the result of vaccination or that vaccine entered the eye at the time of vaccination.

Committee on Food Standards.

Mr. R. J. Russell asked the Minister of Health the terms of reference for the Committee on Food Standards and the personnel appointed.—Mr. Greenwood replied: The terms of reference of the Committee are "to inquire into the working of the law as to the composition and description of articles of food other than milk, and to report what alterations, if any, in the law or its administra*tion appear to be desirable." The Committee is consti*tuted as follows:—Sir Frederick Willis (chairman), Mrs. J. L. Adamson, Mr. W. Barratt, Mrs. E. Beck, Mr. J. N. Beckett, Mr. G. A. Birse, Mr. H. F. Carlill, Mrs. N. E. Cottrell, Mr. A. T. A. Dobson, Mr. H. N. Goodby, Dr. J. M. Hamill, Mrs. Jean Roberts, Mr. R. A. Robinson, Mr. H. Shaw, and Mr. G. Stubbs.

Draft Conventions on Sickness Insurance.

Mr. Mander asked the Minister of Labour whether the Government had now ratified the draft conventions concerning sickness insurance for workers in industry and commerce and domestic servants, and sickness insurance for agricultural workers.—*Miss Bondfield replied: These* conventions were ratified by an Order in Council of Jan. 5th last.

MONDAY, JUNE 8TH.

Tuberculosis among Naval Ratings.

Sir Bertram Falle asked the First Lord of the Admiralty the number of ratings invalided with tuberculosis who were sent sick from H.M.S. *Warspite* during the last commission.—Mr. G. M. Hall (Civil Lord of the Admiralty) replied: The number of cases of tuberculosis which have occurred in H.M.S. *Warspite* since she recommissioned on Jan. 23rd, 1929, is 13, of which 11 have been invalided and two have *died in hospital.*

Sir B. Falle asked Mr. Hall specially to inquire into this matter and ascertain why there had been so many cases, and how many of these men had been pensioned.

Mr. Hall replied that 8 were *pensioned out of* 13. An inquiry had already been held, but unfortunately they were not able to ascertain the actual cause of the very high percentage of cases in 1929.

Child Marriages in India.

Miss Rathbone asked the Secretary for India (1) if he would report to the House what steps, if any, had been taken by the central and local governments of India to carry out the steps recommended two years ago *by the Joshi* Committee as necessary to render effective the administration of the Sarda Child Marriage Restraint Act—namely, a wide publicity campaign aided by State funds; the keeping of marriage registers in a prescribed form with details of age, &c.; universal compulsory notification of marriages and births; the issue *free* of charge of certificates of birth and marriage to the parties concerned; the employment of women police, women jurors and assessors, and medical women in the investigation of sexual offences; and the provision of separate women's waiting rooms at all court houses; and (2) how many complaints of violation of the Sarda Act of Restraint of Child Marriage had been received and dealt with by the courts since the Act came into force on April 1st, 1930, distinguishing between cases prior to *and those subsequent to the formal cessation of the campaign* of civil disobedience.—Mr. Wedgwood Benn replied: The Child Marriage Restraint Act, generally known as the Sarda Act, which was enacted on Oct. 1st, 1929, and came into operation on April 1st, 1930, makes it an offence punishable by fine or, in certain cases, by imprisonment or by both, to contract or arrange a marriage between persons either of whom is below the age of 18 in the case of the male and 14 in the case of the female. The Act further prescribes that to enable the appropriate court to take cognisance of an alleged offence under the Act, a complaint must be laid, within 12 months of the solemnisation of the marriage, in respect of which an offence is alleged. The actual inquiry into the complaint, if one is authorised by the court, is conducted by a magistrate. I am informed that between April 1st, 1930, when the Act came into force and February of this year there were 29 prosecutions under the Act. I have no more recent information, but the number of prosecutions since February is probably very small, if only for the reason that, as the House is no doubt aware, there are a number of private amending Bills which are either already before the Indian Legislature, or of which notice has been given. The Joshi Committee reported on June 20th, 1929, some months before the Sarda Bill was enacted in its final form, and its terms of reference were therefore framed without specific reference to that Act. Several of its recommendations, including those mentioned in Miss Rathbone's first question, have been referred by the Government of India to local governments. Until the views of all of these have been received and considered the Government of India are not able to decide what further steps can be taken in regard to these recommendations.

TUESDAY, JUNE 9TH.

Safety of Life at Sea.

Rear-Admiral Beamish asked the President of the Board of Trade what governments who were represented at the convention of 1929 for safety of life at sea had ratified that convention; *and if any reservations had been declared.*—Mr. W. Graham replied: Up to the present Denmark and the Netherlands only have ratified the convention, with no reservations in either case.

Insurance Chemists and Gifts to Customers.

Colonel Howard-Bury asked the Minister of Health whether the Government had now come to a decision upon the proposal to introduce legislation to repeal the section which prohibited insurance chemists from giving an insured person an inducement by gift or otherwise in consideration of his presenting an order for drugs or appliances on a national health insurance form.—Miss Susan Lawrence *(Parliamentary Secretary to the Ministry of Health)* replied: Legislation is not necessary to deal with this point, but an appeal has been made against the recent decision of the courts in the matter, and until it has been heard my right hon. friend cannot properly make any statement.

Anti-vaccinal Serum.

Mr. Freeman asked the Minister of Health whether his department was taking any action in regard to the adoption of the use of an anti-vaccinal serum as a treatment in cases of post-vaccinal encephalitis which was strongly urged by the Rolleston Committee on page 72 of their second Report.—Mr. Greenwood replied: An anti-vaccinal serum has been made available and *has been employed by the medical* attendant in those cases of suspected post-vaccinal encephalitis which have since been reported and of which sufficiently early information has been received.

Rates on Hospitals.—At the annual meeting of Darlington General Hospital it was stated that the rates upon the building have risen in two years from £15 to £850.

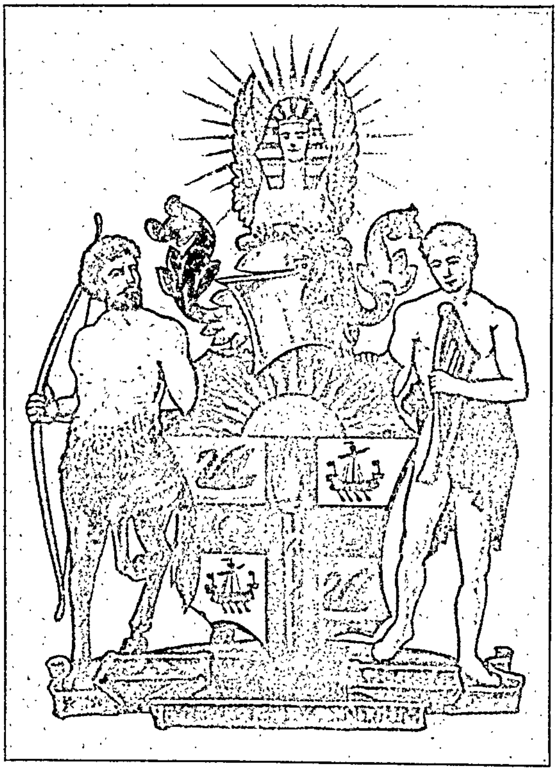
Slippery Hospital Floors.—Dr. Edwin Smith, the coroner for Battersea, recently held an inquest on a female patient of 88 in the Tooting Bec Mental Hospital who, according to the medical evidence, died of pneumonia following fracture of the thigh. It was stated that the patient fell, outside the ward, on a stone floor. The coroner asked "if something could be done to the *floors which* would keep them just as polished but less slippery," and it was arranged that the matter should be brought before the committee.

NOTES, COMMENTS, AND ABSTRACTS

ROYAL COLLEGE OF SURGEONS OF AUSTRALASIA.

OUR last issue contained mention (p. 1256) of the arms lately granted to this College. The accompanying illustration shows the achievement approved by the College of Heralds. The heraldic description is as follows:—

Or and argent between a St. George's cross upon which is imposed a flaming torch or between two serpents each encircled proper. In cantons one and four, a Swan sable; in cantons two and three a Lymphad sable. On a chief azure, a rising Sun in glory.



Supporters: Dexter, Chiron; Sinister, Apollo.

Crest: a female Sphynx affrontée, winged and surrounded by an aureole of sun's rays; on a torse of the colours, Blue and Gold.

The whole standing upon a mount vert, arising from the Southern Hemisphere, in front of which is a scroll bearing the motto: "Fax Mentis Incendium Gloriæ."

Chiron, as the mentor of Nestor, may be regarded as the father of wisdom. He holds a bow as a symbol that he could protect education by force. Apollo, god of healing, holds his best known symbol, the harp, to show he can instil knowledge by gentle means. The lymphad, symbol of discovery by sea, is used in preference to a Viking or long ship, because this latter suggests discovery by Norsemen.

HEROES OF HEALTH.

THE importance of health and the need for prevention of disease are the points chiefly emphasised in a little book [1] designed for children about to leave African schools. The better to secure their interest and fire their enthusiasm the author tells the story of how disease in different forms and in different countries was fought and conquered by the great pioneers of preventive medicine. She describes the achievements of Pasteur, Manson, Ross, and a host of others less well known in simple language which cannot fail to arouse interest. The desire to impress on the young African the value of the scientific discoveries of our Western civilisation is obvious throughout, and she is to be congratulated on the skill and tact with which she attains her objective. "Heroes of Health" is a book which might be read with profit by most lay persons—old or young—and there are many chapters which could be read aloud with advantage to boys and girls in our own schools.

SLEEP.

BOUND in a colour which would keep people awake, and written in a racy, attractive style which would certainly not induce sleep in a reader, an interesting and informative volume [1] on sleep has reached us. It is written in the manner of an educational talkie, but is none the less useful. It deals with the nature of sleep as a biological need, and shows how the organism is only healthy when this periodic rest of all functions occurs regularly and in quantity requisite to the age and occupation of the subject. It deals with the sort of things that make for sleeplessness in everyday life and which more scientific treatises might scorn as beneath contempt. But ordinary people who are harassed by insomnia are not interested in scientific theories, but are prepared to take any advice which will bring them the balm of sleep. After discussing the sort of surroundings, the sort of people, the sort of occupation, and the manifold anxieties apart from physical disease which rob us of our sleep, the authors give amusing but none the less very sensible advice on the rooms we should sleep in, the source of light, and even the size and consistency of the bed. Persons of all ages from babyhood to old age are given sensible words of advice, and few medical men would fail to gain oddments of useful information from reading the book through.

ROYAL MEDICAL BENEVOLENT FUND.

At a recent meeting of the committee 59 grants were made, amounting to £1311. The following are particulars of a few cases helped.

Dr. X., aged 65, married. At the special request of the hon. secretary of the local British Medical Association Division an emergency grant of £10 was given, also an annual grant of £10, payable in four instalments. Owing to being crippled with rheumatism, the applicant has been unable to carry out his professional duties, and he and his wife were known to be nearly destitute and suffering from lack of food.

Widow, aged 78, of M.R.C.S. When her husband died in 1911 she went to live with her only son who had a dental practice. When the son married ten years ago his mother continued to live with him, for she had no home of her own nor the means to support one. The son died three weeks ago, and the applicant was stranded; the furniture and little else went to his widow. The applicant suffers much from chronic asthma, and at her age (78) it is impossible for her to follow any remunerative occupation. The Fund voted an annual grant of £26, and is endeavouring to obtain further help from other societies.

Widow, aged 70, of M.R.C.S. Has maintained herself since 1899 by working as a companion housekeeper. Her employer died August, 1930. She is now too old to obtain other employment and her income consists of the old age pension of £26 and a grant of £25 from the Indigent Gentlewomens Society, making £51. She feels her position very acutely, and it was only with a great deal of persuasion that she would consent to an application being made to the Committee. Fund voted £26.

Daughters, aged 76 and 69, of M.R.C.S. These two sisters who, on the death of their father in 1871, were left comfortably off, now, through the reduction of dividends, were found to be sharing a total income of £89 a year out of which they have to pay rates of £12. Fund voted annual grant of £20 to each sister.

Dr. Y., aged 75, married. Gave up practice in 1927 to undergo a serious operation from which he made a good recovery. Since then he has been doing locum work from time to time. His last employment was for 13 months, which ended in September, 1930. Since then he has been unable to find work and has been drawing on his capital, which is now reduced to £45. His wife was trying to find employment but recently met with an accident and is in hospital. Fund voted £10.

Subscriptions and donations should be forwarded to the hon. treasurer of the Fund, 11, Chandos-street, London, W.1.

ADDRESSES AND ORIGINAL ARTICLES

THE NEUROLOGY OF OLD AGE.*

BY MACDONALD CRITCHLEY, M.D. BRIST.,
F.R.C.P. LOND.,

JUNIOR NEUROLOGIST TO KING'S COLLEGE HOSPITAL; ASSISTANT PHYSICIAN TO THE NATIONAL HOSPITAL, QUEEN SQUARE.

LECTURE III.

Psychological Aspects.

ONE of the greatest problems in psychiatry concerns the nature and genesis of the various disorders of the mind associated with old age. Whether the analysis be carried out along pathological or clinical lines, it soon becomes apparent that numerous subgroupings are necessary.

In the briefest of descriptions, one may attempt some sort of classification as follows: simple senility (psychic senescence); senile dementia; arterio-sclerotic dementia; and the various presenile dementias.

A discussion of senile hysteria and other neuroses and psychoneuroses of advanced life would tempt us beyond the time at our disposal.

1. Lhermitte and Nicolas [137] apply the term *psychic senescence* to the pattern of psychological processes which is to be expected in healthy old age. The outstanding features include diminished acuity of memory, or better a loss of adherence to recent events; impaired faculty of rapid evocation of events; loss of fluidity; and weakness of creative imagination. Savage [138] adds the symptoms of restlessness and of disturbed sleep. In more severe forms, egocentricity, depression, and hypochondriacal tendencies may develop.

2. *Senile dementia* in its broadest sense may be best described in the words of the definition proposed in the manual of the American Psychological Association:

> "A well-defined type of psychosis which as a rule develops gradually, and is characterised by the following symptoms: impairment of retention (forgetfulness) and general failure of memory, more marked for recent experiences; defects in orientation and a general reduction of mental capacity; the attention, concentration, and thinking processes are interfered with; there is a self-centering of interests; often irritability and stubborn opposition; tendency to reminiscences and fabrications. Accompanying this deterioration there may occur paranoid trends, depression, confused states, &c. Certain clinical forms should, therefore, be specified but these often overlap."

These clinical variants are usually described as the confusional, maniacal, melancholic, and paranoid subtypes, in addition to the uncomplicated dementia senilis simplex.

Concerning the pathology of senile dementia, it must be admitted that there is no characteristic histological counterpart so that the diagnosis cannot be made with certainty upon microscopical examination alone. On the other hand, certain anatomical findings are commonly encountered although also occurring in conditions other than senile dementia. The characteristics of a senile brain will here be present but in a greater intensity. Brain atrophy, fatty and pigmentary degeneration, glial overgrowth are usually demonstrable to a marked degree. In particular senile plaques and Alzheimer's intracellular fibrillary changes are seen in profusion, to a much greater extent than in the brains of healthy old age. Exceptions to this general picture may be found and will be discussed more fully hereafter.

3. The *arterio-sclerotic dementias* differ radically from the senile deteriorations in ætiology, clinical aspects as well as in pathology. They do not necessarily belong to the senile age and may occur in unmistakable form in early adult life. Efforts have been made at various hands, to isolate clinical subtypes, each associated with a distinctive pathological process. Rhein, Winkelman, and Patten,[139] for instance, speak of arterio-sclerotic deterioration, progressive arterio-sclerotic psychosis, and arterio-sclerotic dementia, which they couple with a sclerosis of the larger vessels, of the smaller vessels, and of large and small vessels respectively. Other variants have been described at different times, so that such terms as "subcortical encephalitis" (Binswanger), "hypertensive encephalopathy" have arisen.

4. Scarcely any study has been made of the problem of the combination of senile with arterio-sclerotic dementia, although cases of such must actually outnumber the pure varieties. Whether the mental symptoms of cerebral arterio-sclerosis differ when they arise in youth, maturity, or old age; whether the presence of long-standing arterio-sclerosis favours the early and severe development of senile change are problems which are rarely discussed. Kraepelin, on histological grounds, has indeed suggested that arterio-sclerosis may facilitate involutional processes in the brain, and this suggestion is rather borne out by some of Grünthal's cases.

PRESENILE DEMENTIAS.

5. The various presenile dementias are very important in their possible bearing on the ætiology of the senile psychosis. Three well-defined types can be isolated—namely, Pick's disease, Alzheimer's disease, and presbyophrenia.

Pick's disease [140] is a slowly progressive dementia starting usually in the sixth decade and accompanied by focal manifestations; it is characterised pathologically by circumscribed and symmetrical areas of cortical brain atrophy.

Alzheimer's disease [141] is another example of dementia with focal signs, appearing usually between the ages of 40 and 60. The anatomical picture differs from that in Pick's disease in that brain atrophy is less intense and more generalised; the histological characteristics are those of an intense senile process greater as a rule than would be expected in a senile dement of a very advanced age.

Presbyophrenia.—This term was applied by Kahlbaum [142] to a special clinical variety of presenile dementia in which confusion, defective memory with confabulation, restlessness with euphoria, were prominent symptoms. The status of this disorder has been much discussed; some authors regard it as indistinguishable from Alzheimer's disease; others—basing their arguments upon the resemblance to Korsakow's psychosis—consider it a variety of polyneuritic mental disorder. Fischer and others believed that there was a particular pathological correlate to presbyophrenia and they associated this psychosis with the presence of senile plaques. Subsequent research has shown, however, that there is no direct connexion between this disease and the demonstration of plaques in the cerebral cortex, and indeed no clear-cut pathological picture has yet emerged.

* The Goulstonian Lectures delivered before the Royal College of Physicians of London on March 10th, 12th, and 17th, 1931. Lectures I. and II. appeared in THE LANCET of May 23rd and June 6th respectively.

have been afflicted with a symptom of similar appearance, but developing earlier—in some members in maturity or late middle life, and in others in youth. In one family it may be possible to quote examples of each type.

Premature and Precocious Senility.

Although the problems attendant upon old age in general have been somewhat neglected, no lack of interest has been displayed concerning the premature appearances of the senile state. Indeed it has always been a topic of popular appeal especially in regard to the possibilities of treatment or prevention.

We may differentiate two chief groups of cases according to the age at which the marks of senility appear, thus "premature senility" may be applied to those examples of physical involutional changes coming on in the middle period of life, while to the rarer cases of senile appearances in youth or childhood the term "precocious senility" or "senium præcox" may be restricted.

The ætiology and manifestations of premature old age need not be detailed; the factors which seem to be important may be mentioned only. Thus, we recognise in some families an inherent resistance as it were against general involutional processes so that certain families are known to show the marks of old age at an unusually early date—just as other families are characterised by a vigorous longevity. Racial factors are extremely important and the resistance to old age changes displayed by many of the African negroes is striking. External circumstances are perhaps the most significant, however, in determining a premature senility so that a man's real age is determined less by the numerical passage of time than by the aggregate of his past illnesses. Chronic visceral disease is, in the majority of cases, an important factor in producing an early dissolution. Cardiovascular disease—and arterio-sclerosis in particular—can obviously be quoted in support of this view.

Another striking example of the premature entry of senile changes is seen in pituitary cachexia or Simmonds's[159] disease. As the result of disease of the anterior lobe of the hypophysis, there develops an extreme degree of wasting and asthenia, anæmia, loss of hair from the body and greying of the scalp hair, sexual hypoplasia, and changes in the skin, teeth, and nails. The general impression is one of advanced senility, occurring at a premature age. Other examples of endocrine disease are on record in which the premature development of senile changes is striking. Following the early descriptions by Claude and Gougnot, a syndrome of "pluriglandular insufficiency" is sometimes recognised, being characterised by cachexia, genital atrophy, stupor, depression, hypothyroidism, and premature senility.

In precocious senility we are dealing with a problem which might—if adequately studied—throw much light on the causes and processes of normal old age. Unfortunately, our knowledge of senium præcox is very meagre and is riddled with lacunes.

It is useful to distinguish three clinical subgroups—namely, (1) cutaneous geromorphism, (2) congenital ectodermal defects, and (3) progeria.

CUTANEOUS GEROMORPHISM.

Souques and Charcot,[160] in 1891, applied the term "géromorphisme cutané" to a condition in which the skin shows at a very early age the characteristics of advanced life. Thus, changes set in at puberty, whereby the skin of the face, neck, the upper thorax, and the proximal portions of the limbs become atrophic and inelastic, hanging in folds over the deeper tissues. The superficial aspect is that of an aged individual. It is noteworthy that the various cutaneous appendages remain unaltered so that there is no whitening or falling out of the hair and no changes in the teeth or nails. Nor are the viscera or the blood-vessels in any way diseased; there is merely a process of senium præcox strictly limited to the dermis over certain bodily areas.

CONGENITAL ECTODERMAL DEFECTS.

Parkes Weber[161] has familiarised us with the clinical features of the so-called congenital combined ectodermal defect, which includes various abnormalities in the hair, teeth, nails, and sweat glands. The general appearances are those of advanced senility, and other hypoplastic changes may be demonstrable at times in the skin, mammæ, bones, and sex glands.

The earliest reference to this type of case I have succeeded in tracing was made by Easton in 1799.[162] He quotes a Polish woman who died in Koninia at the age of 108. When 94 years old she married a man of 105 by whom she is said to have borne three children. In each case the infant's hair is described as grey; there was a vacuity in their gums like that which appears after the loss of teeth, though they never had any. Their backs were bent and their complexions sallow, and, in short, they presented all the other symptoms of decrepitude. The accuracy of these statements is supported—we are told—by the local parish registers.

Another early case of similar nature has been recorded by Thurnham in 1848,[163] in the *Transactions* of the Medico-Chirurgical Society.

PROGERIA.

Closely analogous to these cases of combined ectodermal defects are the instances of precocious senility supervening upon a state of infantilism. There is almost certainly a close association with the cases of ectodermal defect, and it is probable that transitional cases link up the two conditions. One of the earliest cases of this type was recorded in 1886 in the *Med.-Chir. Transactions* by Jonathan Hutchinson.[164] Under the title of "Congenital Absence of Hair and Mammary Glands, with Atrophic Condition of the Skin and its Appendages," he recorded a boy of three and a half years whose wrinkled and old-mannish appearance suggested senilism. From the account of his case one would have relegated it to the class of combined ectodermal defects, but we learn that 12 years later the same patient was studied and described by Hastings Gilford,[165] who gave the title "progeria" to this condition of premature senilism. Since that date other cases have been put on record so that we can recognise a common picture. In the general attitude and bodily conformation, in the facial appearance with the atrophic wrinkled skin and emaciation, the baldness or greying of the scalp hair, the degenerative alterations in the cardiovascular system, we see a typical case of senility in miniature.

Despite the superficial resemblances to the processes of normal old age shown by these three groups of cases we cannot, on the slender data available, pursue the analogy very far. Until we have considerably more information, especially of a pathological nature, we cannot draw any helpful conclusions. Possibly the resemblance is merely superficial and not an index of a far-reaching relationship. We need information as to the type of intercurrent illness to which these individuals are liable; as to whether such typical old age affections as senile tremor, paralysis agitans, cerebral softenings are ever encountered. Further examinations of the nervous system, as well as psychological investigations, are urgently needed in such patients.

Still more striking is the lack of pathological research in cases of senium præcox; as far as I can gather only one autopsy has been made and no histological examination of the nervous system has ever been carried out in a case of progeria. It would be obviously of value to determine whether or not the characteristic findings such as we have detailed are demonstrable in the brain and spinal cord; whether senile plaques or Alzheimer's intracellular changes are present or not. On these points one must simply wait for information which would probably throw light upon the nature of so-called physiological old age.

One final point arguing that the analogy between precocious senility and normal old age is not far-reaching, lies in the traits of infantilism which are demonstrable in the former. The child with progeria is not so much one which has run through the gamut of the years with astonishing rapidity, but rather one who has, in some respects, never grown up. In many ways the patient has skipped an epoch or a decade. These are points which are readily demonstrable clinically—not only in the physical examination but also in the execution of the Binet-Simon intelligence tests. From an anatomical standpoint they have been demonstrated by Keith[166]; from his most detailed study of the skeleton of an individual dying at the age of 18 of progeria, he was able to point out that most of the osseous abnormalities betrayed a state of infantilism while others were the index of a premature development.

Relationship of Arterio-sclerosis to Senescence.

When one considers the various neurological syndromes common in old age, it is found that many of them can be directly attributed to lesions of the cerebral blood-vessels. Thus, the hemiplegias and paraplegias of old age, possibly also senile tremor and epilepsy, are associated with areas of ischæmia within the central nervous system. Possibly some of the minor signs of so-called healthy old age—such as alterations in the tendon reflexes, loss of vibratory sensibility, slowness of movement, inelasticity of gait, and so on—are also produced by slighter degrees of chronic malnutrition.

Even when there is no macroscopical evidence of arterio-sclerosis or concomitant lesions, it is at least possible that a condition of capillary fibrosis may exist causing a prolonged circulatory inadequacy. It might also be suggested that no primary neuronic decay can be recognised in the senile brain which is strictly independent of vascular degeneration.

Can we extend this conception and argue that the ageing of the nervous system depends upon vascular deterioration? In other words, is Cazalis's aphorism . . . "a man is as old as his arteries" strictly true? If this view is correct, then the symptomatology of cerebral arterio-sclerosis should be identical with that of senility. There should exist no senile manifestation which is not also seen in cerebro-vascular disease, and, conversely, no sign or symptom in the arteriopath which may not also occur in the aged. Moreover, this parallelism would be independent of the age of the individual, and we should expect the marks of senility in the arterio-sclerotic of middle life. This, of course, is not altogether the case. In those rare cases of senile vascular disease in childhood (Hughes and Perry[167]) there is not necessarily a precocious senility. There are numerous differences between the clinical aspects of the aged and the arteriopathic, although the superficial resemblance may be great. The psychiatrist will confirm this in pointing out that arterio-sclerotic dementia and senile dementia are not identical.

Pathological study of the brain in cases of diffuse cerebral arterio-sclerosis emphasises the distinction. We do not encounter senile plaques, Alzheimer's tangles, diffuse parenchymatous atrophy with pigmentary degeneration of the nerve-cells unless the individual happens to have been aged as well as arterio-sclerotic. The histology of the two conditions is distinct.

In theory, therefore, there are two separate conceptions, the neurology of old age and the neurology of cerebral arterio-sclerosis, each with its own clinical picture, and its own pathology. We must imagine a hypothetical senile brain without vascular disease, just as we often see arterial degeneration in the brain of a young subject.

At the same time we must admit that the distinction is more academic than practical, since in the great majority of cases the processes of ageing operate simultaneously on both parenchyma and blood-vessels of the brain.

Nature of Old Age Considered from a Neurological Standpoint.

From earliest times writers on the subject of old age have debated whether involution and decay are to be regarded as physiological or pathological processes. It may be convenient to approach this question from the viewpoint of the neurologist and to determine what light is afforded by a study of the senile nervous system.

The argument of those who maintain that old age is an inevitable and essentially normal phenomenon, can be stated in the words of Prof. Warthin[168]:—

> "The senescent process is potent from the very beginning," he says . . . "involution is a biologic entity equally important with evolution . . . . its processes are as physiologic as those of growth . . . . It is, therefore, inherent in the cell itself, an intrinsic, inherent, inherited quality of the germ plasm, and no slur or stigma of pathology should be cast upon this process . . . . Senescence is due primarily to the gradually weakening energy charge set in action by the moment of fertilisation."

Or, to quote Prof. Marinesco[169]: " . . . All living matter obeys the universal law of evolution. . . . Cells appear, multiply, increase, decay, and die."

Instances of longevity occurring in certain families or in particular races support this view, and suggest that there is normally a certain expectation of life which in exceptional cases is extended a little. Ophthalmologists tell us that the crystalline lens of the eye diminishes in elasticity with advancing years. This constant and slowly progressive change commences in the second decade of life, indicating that involution sets in at a very early date.

The opposing view regards old age as a disease in itself, and looks upon the senile histological changes in the various organs as evidences of multiple traumata. These represent scars, as it were, indicating the ravages of previous infections, disease, toxins, faulty habits, and so on. Such an opinion is centuries old; Cicero[170] declared "that every decay and strength (in old age) results more often from the vices of youth than from age, for a licentious and unbridled youth bequeaths a worn-out constitution to old age." Sir Clifford Allbutt[171] said: "In medicine we do not count the ages of people by the revolutions of the earth around the sun, but we measure them by the revolutions of their own morbid processes."

Metchnikoff has familiarised the laymen with this hypothesis, but one of the most eloquent advocates of this view is Prof. Tilney.[172] In a recent and most inspiring address he takes up the standpoint that the old brain is actually a diseased brain.

> "No evidence thus far adduced," he says "is sufficient to convince us that there is such a thing as a strictly old brain. The brain in aged people may present certain morbid changes, but these are in their turn incident to many pathological assaults upon the tissues sustained during life which, in some individuals more, in others less, are in all alike the consequence of infections, intoxications, or other morbid influences . . . All of this is a strong argument in favour of the theory which holds old age in the brain, as in other organs, to be the result of life's successive and cumulative intoxications," and later . . . . "According to this view, old age has a pathological background. It arises from definite conditions which may be combated or corrected."

I have stated the two divergent viewpoints and have quoted freely from the opposing advocates. As in most cases where opinions are diametrically opposed, the truth is probably a compromise between the extremes. Even if it be true that the "aged brain is one which has been diseased, abused, or neglected" (Tilney), one must admit a limited span of life to every living cell and organism. Otherwise a perfect prophylactic régime, capable of excluding every noxious influence, would confer immortality. Almost certainly the two factors are mutually operative, the inherent span of existence and the devastating influence of exogeneous factors.

It is impossible at present to decide which factor is the more powerful. An investigation into cerebral pathology offers, however, a hope of throwing some light upon this problem. I would suggest three avenues along which research might be helpful.

(1) Certain pathological features which are commonly held as characteristic of old age—such as senile plaques, Alzheimer changes, axonal swelling of the Purkinjé cells—are very occasionally seen in the brains of young subjects. These exceptional cases should be studied with the greatest care as suggesting that these so-called "senile changes" are merely the index of a particular type of tissue reaction.

(2) The tissue reaction of the senile brain to known toxins should be studied and compared with the response of a mature tissue against the same toxin. A comparison, for example, of the histology of general paralysis of the insane in the adult, in the child and in the aged, offers an admirable opportunity of contrasting the reactions of a mature, immature, and senile tissue respectively.

(3) Further histological examinations should be made of the brains of normal old people and comparison made with the changes in senile dementia. The object of this should be to determine, not how much histological change is present, but how little. It is highly important to discover the minimum change that can be encountered in the brain of a healthy centenarian.

It may be asked whether such investigation is worth while or if the problem is not merely academic. The research is essentially practical in its bearings, for by determining which histological features are indicative of exogenous influence and which are the expression of a simple involution, the date of onset of old age may be determined. The span of life may well prove to be far beyond the estimate of the Psalmist, as judged by the inherent viability of the tissues. Moreover, by determining the exact part played by external influences in shortening life, steps may be essayed to prevent or to counteract these factors. Old age, in fact, may be the result of two processes, one endogenous and inevitable and the other exogenous and avoidable. Histological research may determine the importance of the latter.

It is interesting and somewhat chastening to recall that this was precisely the conclusion arrived at by Andreas Laurentius.[173] In 1599 he wrote . . . "The causes of our dissolution are either inward, or outward: the inward are borne with us, abide with us dailie, and accompanie us even to the grave. The outward doe spring and rise from without, compasse us on every side, and though a man may keepe himselfe from some few, yet there are an infinite number besides, which cannot be avoyded. Those which are borne and bred with us are two, the contrariettie of the elements, whereof our bodies are framed, and the working of our own naturall heate."

I may perhaps be allowed in conclusion to quote from Tilney once more: "Some day, people will awaken to the fact that they have been missing the greatest constructive opportunities. . . One liberally supported and effective brain institute would prove an incomparably more profitable investment for civilisation than the most powerful battle-fleet that ever sailed the seas. The political party which will have the foresight and humanity to introduce into its platform an article advocating and supporting the longer and better use of the human brain will offer a worthy issue to its electorate."

I beg to acknowledge my indebtedness to Dr. P. M. Turnbull, the medical superintendent, and to Dr. C. J. C. Earl, late assistant medical officer of Tooting Bec Mental Hospital, for their unfailing kindness in permitting me to visit their wards and to examine their valuable pathological material; to Dr. W. D. Wiggins, Dr. Humphrey Nockolds, and Dr. N. S. Craig, of St. Alphege's Hospital, Lewisham Hospital, and St. Mary Abbott's Hospital. My grateful thanks are due to the Commissioners of the Royal Hospital, Chelsea, for their kind permission to visit their patients, and to the medical officers, Major E. A. Strachan and Major F. M. Lipscomb, for their constant assistance. To Dr. J. G. Greenfield and my other colleagues at Queen-square I am indebted for encouragement and advice. To the courtesy of Prof. J. Lhermitte of the Hospice Paul Brousse, Paris, and of Prof. P. Schuster of the Hufeland Hospital, Berlin, I am under deep obligation, for permitting me to work in their valuable clinics. My gratitude is to be extended to the Medical Research Council who have defrayed the cost of my work.

ON ACUTE RHEUMATISM FOLLOWING TONSILLITIS.

BY WILFRID SHELDON, M.D., M.R.C.P. LOND.,
PHYSICIAN TO THE CHEYNE HOSPITAL FOR CHILDREN, CHELSEA.

FOR many years it has been recognised that there is a close association between infection of the throat nd acute rheumatism—that is to say, acute rheu-atic inflammation of the heart or joints. An nportant contribution to this subject has recently een made by Schlesinger,[1] who in a series of 22 hildren under his care at the West Wickham Con-alescent Heart Home made the observation that a efinite interval intervenes between the onset of a roat infection and the reappearance of acute eumatic symptoms—an interval of approximately 0-21 days. During this interval the throat symptoms ibside and the child seems to have made a complete ecovery from the throat infection, but this is shown ot to be the case when in two or three weeks fresh eumatic manifestations arise. A proper under-anding of the changes that are taking place in the hild during this "silent" interval would almost rtainly reveal much of the pathogenesis of rheumatic eart disease.

Sore-throats in Two Institutions.

One of the advantages of a convalescent home over hospital is that the patients can be kept under edical observation for periods extending over any months, and incidental sore-throats and their sequelæ can be studied. In the ordinary hospital children are not admitted to the wards because of sore-throats, and generally do not come under observation until the rheumatic inflammation which follows the sore-throat has already developed. Furthermore, the throat infection is often a mild affair; there may be no complaint of sore-throat, and only the fact that the temperature rises two or three degrees for a day or two for no obvious cause leads to an examination of the throat. These mild pyrexias would usually be missed at the child's own home, but at a convalescent home the daily temperature record directs the attention of the doctor to them.

During the last two years the opportunity has arisen of observing children with rheumatic heart disease over prolonged periods. This has been possible at the Cheyne Hospital for Children, Chelsea, where one ward of 25 beds has been devoted to cases of this nature, and also at the Lancing Convalescent Heart Home, where the 60 beds are filled from the rheumatic clinic at the Hospital for Sick Children, Great Ormond-street, with cases of early and mild cardiac rheumatism. During this period 34 children have suffered from sore-throats or rheumatic relapses at these two institutions, and the salient features of these cases are presented in the Table.

Before proceeding to analyse the contents of this Table, that part of the history of the first case which is germane to this paper will be given in more detail, since it affords a good example of a rheumatic relapse following upon a sore-throat.

CASE 1 was a boy, aged 11 years, who when 8 years old had rheumatic fever, followed by aortic and mitral disease. His tonsils had been thoroughly enucleated some time before his attack of rheumatic fever. He was admitted to the Cheyne Hospital when 10 years old, and made steady progress, so that by February, 1929, he was getting up preliminary to going home. On March 4th he complained of a sore-throat and had a temperature of 102° F. The routine throat-swab for diphtheria bacilli proved to be negative, and the temperature settled back to normal in 24 hours. The boy remained quite well for a fortnight, but on March 18th the temperature rose again, and four days later pericardial frictions became audible. The boy's condition steadily became weaker, and he died on April 2nd. The temperature and pulse chart is reproduced (Fig. 1) in order to demonstrate the evanescence of the sore-throat, and the apparently normal period which followed for two weeks before the onset of the fatal pericarditis.

Returning to the Table, the first 29 cases comprise all the instances of sore-throat which have arisen at the Cheyne Hospital during the last two years, and also all the cases of rheumatic relapse at that hospital, whether or not they were preceded by clinical evidence of sore-throat. Of these 29 cases, 19 suffered from a rheumatic relapse which was preceded in 14 instances by a brief febrile disturbance, lasting as a rule about 48 hours, and occurring at an interval which varied from 9 to 25 days before the rheumatic relapse. This preliminary febrile disturbance I have called the "initial fever." The initial fever was accounted for in five cases (6, 9, 14, 24, 27) by follicular tonsillitis, in five others (1, 7, 19A, 20, 29) by a sore and reddened throat, while in four cases (4, 5, 10, 28), although an initial fever occurred, no obvious cause could be found on clinical examination to account for it. Of the remaining five children who suffered from an acute rheumatic relapse, three (8, 13, 21) began their relapse by suffering from a sore-throat, but the rheumatic relapse occurred synchronously with the throat infection. In one child (23) the relapse consisted of the development of rheumatic nodules five weeks after the initial fever due to sore-throat, but this child received aspirin grs. 30 daily for a month after the sore-throat, and as will be shown later the

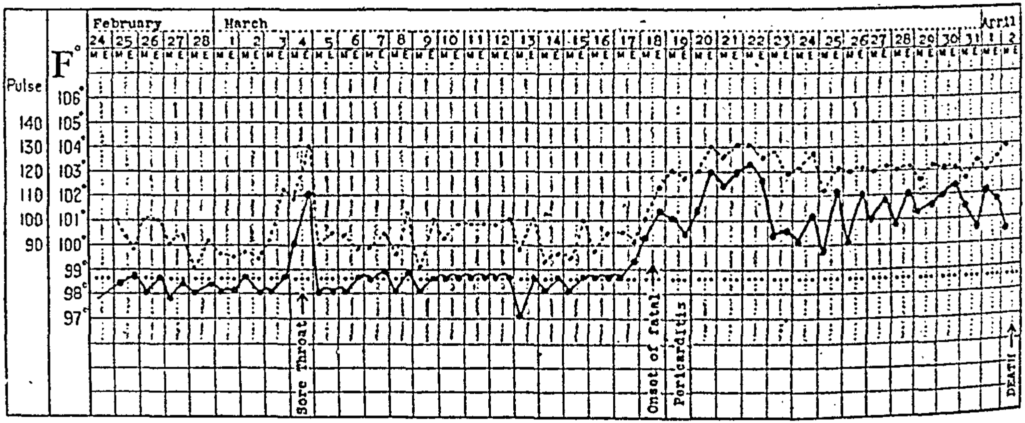
use of this drug may have delayed the relapse or so modified it as to make it uncertain how long after the initial fever the rheumatic relapse began to develop. The other child (Case 25) suffered from a relapse of rheumatic pancarditis, which proved fatal, but in her case there was no initial fever nor any evidence of infection of her throat. Except for the fact that this child's last illness happened while several other children in the ward were suffering from an epidemic of sore-throat, her rheumatic relapse seemed to arise without cause.

The last five cases of the Table are children who had sore-throats while at the Lancing Heart Home. Three of these children experienced an acute rheumatic relapse which began 14, 18, and 24 days respectively after the initial fever.

Analysis of the 34 children in the Table supports Schlesinger's observation that if a child has already had a rheumatic infection, then the occurrence of an acute infection of the throat is likely to be followed by a rheumatic relapse in roughly 10 to 21 days.

FIG. 1.



Temperature and pulse chart in Case 1. (Mitral stenosis and aortic regurgitation. Tonsils removed.)

With the exception of the three cases in which rheumatic relapse coincided with the throat infection, the silent period between the initial fever and the rheumatic relapse lay, in my cases, between 9 and 25 days. It is interesting to note in passing that of the 44 instances of acute rheumatic relapse compiled from Schlesinger's cases and those in this paper, not once did the relapse after the throat infection take the form simply of chorea, an observation which suggests that although throat infection is a factor in the production of rheumatic carditis and arthritis, it is of less importance in producing chorea.

Tonsillectomy and Rheumatic Relapses.

In the third column of the Table is set out the state of the tonsils before the initial fever took place, and it will be seen that relapses occurred whether the tonsils had been removed or not. Of the 19 children at the Cheyne Hospital who suffered a rheumatic relapse, 6 (31 per cent.) had previously undergone complete tonsillectomy, 2 (11 per cent.) had obvious tonsillar remnants, and the remaining 11 (57 per cent.) had not had their tonsils operated upon. These percentages may be compared with those obtained from an analysis of the throat condition in all the rheumatic children admitted to Cheyne during the last two years. During this period 89 children have been admitted; of these, 30 (33 per cent.) had previously undergone complete tonsillectomy, 7 (9 per cent.) had obvious tonsillar remnants, and 52 (58 per cent.) had not had their tonsils operated upon. Although the number of children is small, the percentages approximate so closely that the evidence seems to indicate that previous tonsillectomy is of no value as a safeguard against rheumatic relapses.

Aspirin as a Prophylactic against Relapses.

It is well known that an injection of horse serum in man may be followed in ten days or so by the appearance of serum sickness, the symptoms including urticaria and a transient non-suppurative arthritis. Derick, Hitchcock, and Swift[2] have shown that if aspirin or neocinchophen (Tolysin) is given in sufficient amount over a period of ten days or so immediately following the administration of horse serum, the subsequent serum sickness can be modified to the extent of preventing the arthritis, although the urticaria is not affected. The dose of aspirin employed amounted to 5 or 6 g. daily—a dose which would be very large for an adult, and certainly more than one would give to a child. The explanation which the authors advance is that the antirheumatic drugs prevent the formation of *circulating* antibodies normally produced by the presence of a foreign serum, the arthritis of serum sickness being held to be due to the clash between these two substances. The urticaria is not affected because it is due, not to *circulating* antibodies, but to antibody produced within the reticulo-endothelial cells of the skin.

An analogy between the administration of serum and the development of serum sickness on the one hand, and sore-throats and rheumatic relapses on the other hand has been drawn by Schlesinger, and following the work of Derick, Hitchcock, and Swift, he has attempted to prevent rheumatic relapses by giving aspirin as soon as the sore-throat has appeared, continuing the drug for a month or so. In 16 cases of tonsillitis in rheumatic children treated in this way, he states that no serious rheumatic relapse followed.

Hoping for the same beneficial results from aspirin, the drug has been given to seven rheumatic children at Cheyne, beginning its administration as soon as the initial fever and sore-throat appeared. The dosage and duration of administration of the drug are

Table showing the Relationship between "Sore-throats" and Rheumatic Relapses in 34 children, all of whom had already shown evidence of rheumatic infection. Cases 1 to 29 occurred at the Cheyne Hospital, Chelsea, and Cases 30 to 34 at the Lancing Convalescent Heart Home. Cases 1, 9, 10, 6, and 7 have previously been quoted in Schlesinger's article (Arch. Dis. Child., 1930, v., 411).

y. = years; *m. = months*

shown in the fourth column of the Table. In Case 13, although aspirin was given at the onset of the sore-throat, rheumatic pericarditis developed at the same time as the tonsillitis, leaving no time for the aspirin to prevent the rheumatic relapse, and this case may therefore be disregarded. Case 24 was generally sick once a day while on aspirin, and probably did not absorb more than about two-thirds of the amount of aspirin given in the 24 hours, but with that exception the drug was tolerated perfectly well.

In three children (Cases 14, 23, 24) aspirin seemed to modify the rheumatic relapse, but did not prevent it. Thus in Case 14, pyrexia appeared for 24 hours on the twelfth day after the beginning of aspirin therapy; otherwise this child seemed to have avoided a relapse, but within a fortnight of the discontinuance of aspirin it became evident that the aortic valve was affected, and it is probable that the rheumatic process was attacking the aortic valve while the child was under the influence of the drug. In Case 23 no signs of rheumatic relapse appeared while aspirin was being given, but five days after the drug was stopped rheumatic nodules were found—the child had been under observation for six months previously and had never had nodules. In Case 24 pyrexia appeared for 24 hours on the eleventh day of aspirin therapy, and a fortnight later, while still receiving aspirin, the child developed rheumatic pericarditis, which proved fatal.

Three of the "aspirinised" children (Cases 11, 15, 16) remained free from rheumatic relapse after their initial fever. It must, however, be pointed out that in nine other children (Cases, 2, 3, 12, 17, 18, 22, 26, 32, 33), although no antirheumatic drug was employed, the sore-throat was not followed by a rheumatic relapse. From these few cases it is impossible to draw a conclusion. It may be that those children who relapsed after receiving aspirin did not receive a large enough dose of the drug. The first indication of the beginning of a relapse is a rise of temperature and pulse-rate, but in the aspirinised children the temperature remains at about 97° F. even in the face of acute rheumatic carditis. The temperature chart in these cases may lull one into a sense of false security, later events showing that while the child was under the influence of aspirin the rheumatic lesion was progressing. The prophylaxis of rheumatic relapses, by giving a course of aspirin after sore-throats, seems to offer a promising field of research.

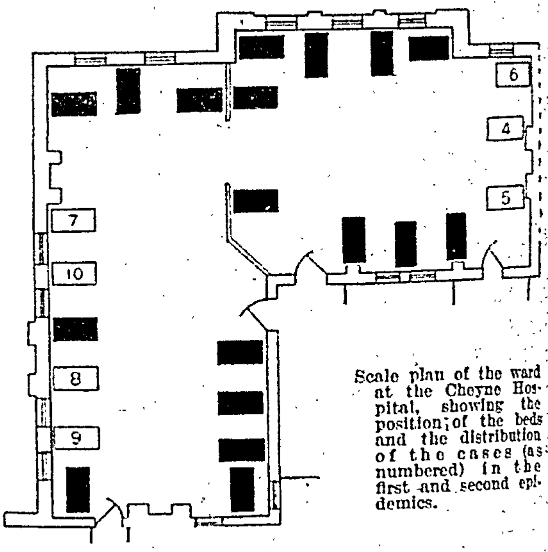
Epidemics of Sore-throat and Rheumatic Relapses.

The cases in the Table have been tabulated in the chronological order of the initial fever, in order to demonstrate that sometimes the initial fevers and the rheumatic relapses constituted small epidemics.

The first epidemic at the Cheyne Hospital was composed of Cases 4, 5, and 6. Case 4 developed a temperature on May 5th, 1929, and began pericarditis on May 31st. On the next day the child in the next bed (Case 5) developed a temperature of 102° F. for 24 hours, and two days later, on June 3rd, the child in the bed on the other side of Case 4 developed tonsillitis (Case 6). Case 5 went on to suffer from acute rheumatic arthritis, and Case 6 from fatal pericarditis. Fig. 2 is a scale plan of the ward at Cheyne and shows the position of the beds. It can be seen that in this first small epidemic the affected children were congregated closely together.

A second similar epidemic occurred in October, 1929, affecting Cases 7, 8, 9, and 10. Case 7 began a sore-throat on Oct. 7th, and died from a relapse of pericarditis. Four days later, on Oct. 11th, Cases 8 and 9 developed sore-throats, followed by acute rheumatic arthritis, and in Case 9 by carditis as well. Six days later, on Oct. 17th, Case 10 had pyrexia, and three weeks later was ill with acute carditis. The beds which these four children occupied are indicated in Fig. 2, and it can be seen that they were in close proximity to each other. Judging from the proximity of the children in each of these little epidemics, it seems likely that an organism, responsible for the sore-throat, was passing from child to child, conveyed possibly by droplet infection with or without the aid of a carrier.

FIG. 2.



Scale plan of the ward at the Cheyne Hospital, showing the position of the beds and the distribution of the cases (as numbered) in the first and second epidemics.

One year after the second epidemic, on Oct. 11th, 1930, Case 19 developed tonsillitis, which recurred on Oct. 31st. During the next two months ten other children suffered from pyrexia with clinical evidence of acute throat infection, giving rise to a somewhat protracted epidemic. Of these 11 children, in eight the throat infection was followed by an acute rheumatic relapse. The bacteriology of the preliminary throat infection was investigated by Dr. W. R. F. Collis, whose paper is published with this one, but it may be mentioned here that an organism common to all the 11 cases was obtained from the throat cultures. The same organism was also recovered from a nurse who developed follicular tonsillitis on Nov. 21st, three weeks after the epidemic had commenced. It is likely that she acted as a carrier of the organism, since the children affected after she was taken ill were scattered throughout the ward.

Papers describing epidemics of acute rheumatism have appeared from time to time, and are summarised in a paper by Boas and Schwartz [3] in 1927. Grenet[4] as a result of his experiences in five epidemics in the French forces during the war, concluded that acute articular rheumatism was a contagious disease. Hiller and Graef [5] described an epidemic occurring in a convalescent home for rheumatic children near Chicago in 1927. In the Milroy lectures in 1930, Glover [6] adduced evidence to show that acute rheumatism could be regarded as an infectious disease, the virus being conveyed by droplet infection.

Evidence has been advanced in this paper to show that acute rheumatic relapses are often preceded at a definite interval by sore-throats, and that the sore-throats may sometimes assume epidemic characters.

It is the preliminary sore-throat which properly should be regarded as the infectious element in acute rheumatism, the sore-throat spreading from case to case probably by droplet infection; but the development of acute rheumatism after the initial throat infection appears to depend upon some altered condition of the individual which enables products from the sore-throat to set going an acute rheumatic reaction. The rheumatic reaction, whether arthritic or cardiac, has no more claim to be considered infectious than has, for example, post-diphtheritic paralysis.

Conclusions.

(1) Relapses of acute rheumatic arthritis or carditis are often preceded by an initial fever—usually demonstrably due to nasopharyngeal infection—at an interval of one to four weeks beforehand. Occasionally the rheumatic relapse occurs synchronously with the throat infection. (2) The removal of the tonsils does not influence the likelihood of a rheumatic relapse. (3) The use of aspirin as a prophylactic measure against rheumatic relapses after throat infections is mentioned. Further investigation on this point is required. (4) The element of infectiousness in acute rheumatism lies in the preliminary throat infection, and these throat infections may assume epidemic proportions.

ACUTE RHEUMATISM AND HÆMOLYTIC STREPTOCOCCI.

BY W. R. F. COLLIS,* M.D. CAMB.,
M.R.C.P. LOND., D.P.H.,

ASSISTANT PATHOLOGIST AND RESEARCH FELLOW AT THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET.

IN 1900 Poynton and Paine[1] isolated a streptococcus from the throat of a patient suffering from acute rheumatic fever accompanied by tonsillitis and with this organism produced experimental arthritis. This pioneer work served to emphasise the association between acute rheumatic fever and throat infection, but it is only recently that this association has been studied from the epidemiological point of view. Glover,[2] in his Milroy Lectures of 1930, described various epidemics of tonsillitis and rheumatic fever in semi-isolated communities at Army and Air Force establishments. He showed that the peaks of the tonsillitis epidemics were followed after some two weeks by the peaks of the rheumatic fever epidemics. At Halton, out of a total strength of 3530, 427 boys got acute tonsillitis, and of these 41 showed subsequent symptoms of acute rheumatic fever. He found that there was a correlation between overcrowding, tonsillitis, and rheumatic fever.

Schlesinger,[3] while in charge of a large group of rheumatic children at the West Wickham Home during the last few years, has made some very important and original observations on the epidemiology of acute rheumatism. Each winter an epidemic of nasopharyngeal infection occurred in the wards of this home among the convalescent children. Recovery from these attacks of sore-throat was apparently complete, but after a "silent" period of 10–21 days a certain percentage (36 per cent.) of cases developed acute rheumatic cardiac relapses. It was observed also that if aspirin was given in large doses at the time of the initial sore-throat and continued for some weeks subsequently relapses did not occur.

Sheldon (in the paper preceding this) confirms the general principles of these observations. He describes similar epidemics of sore-throat which have occurred among rheumatic children in different convalescent homes, and has noted in most of his cases the same silent period before the appearance of rheumatic symptoms.

Tonsillitis has long been recognised as an important factor in the ætiology of acute rheumatism, and it has been surmised that the tonsil is one of the principal foci of entry of the rheumatic virus. Though the hæmolytic streptococcus is the chief cause of acute tonsillitis the possibility of this organism being associated with rheumatic fever was not definitely raised until Coburn's[4] work appeared in January of this year, though Dr. F. Griffith[5] investigated in April, 1930, an outbreak of tonsillitis at a public school which was followed in several instances by primary acute rheumatism. Griffith found that a hæmolytic streptococcus of a well-defined serological type was responsible for the cases and suggested (private communication) that there might be direct ætiological connexion between this streptococcal infection and rheumatic attacks. There were various causes which tended to divert suspicion from the hæmolytic streptococcus. Owing to what has been referred to as the silent period between the throat infection associated with rheumatic fever and the subsequent development of rheumatic cardiac symptoms, most cases of acute rheumatism reaching the hospital no longer show any demonstrable throat infection, nor does a bacteriological examination as a rule reveal a preponderating growth of the causal organism of the previous throat infection. (I have, however, been able to demonstrate the presence of the hæmolytic streptococcus in the throats of over half the rheumatic children who have been admitted to the Hospital for Sick Children, Great Ormond-street, during the past few months.) Moreover, the throat infection may be slight and give rise to few general symptoms, so that no history of tonsillitis or sore-throat is obtained from the parents. Swift,[6] writing in 1926, recognised this difficulty in studying the cause of the throat inflammations generally spoken of as associated with acute rheumatic infection.

The recognition of the full significance of the silent period and the provision of special homes for rheumatic children have recently facilitated investigations in this country. That these investigations have not hitherto implicated the hæmolytic streptococcus may be attributed to the fact that attention was generally focused on organisms found irregularly in the blood of patients with acute rheumatism, such as the various types of non-hæmolytic streptococci. In consequence work on throat cultures has been directed largely to search for similar organisms associated with the tonsillitis, &c.

Hitchcock,[7] in New York, and Nabarro and MacDonald[8] in London, studied throat cultures from rheumatic children, not at the time suffering from acute upper respiratory infections, and failed to find any one type of *viridans* or other non-hæmolytic streptococcus predominating in the throats of

---

rheumatic cases. In a series of epidemics at the West Wickham Home, Schlesinger made throat cultures at the time of the initial sore-throats and reported as follows :—

> "During the 1927 epidemic special search was made for the streptococcus which Birkhaug has reported to be so frequently present in the throats of rheumatic children . . . we were unable to isolate this organism. It was noticed that many of the streptococci were hæmolytic on blood-agar plates and the rest, cultured on boiled blood-agar, were chiefly of the *viridans* type commonly found in the throat."

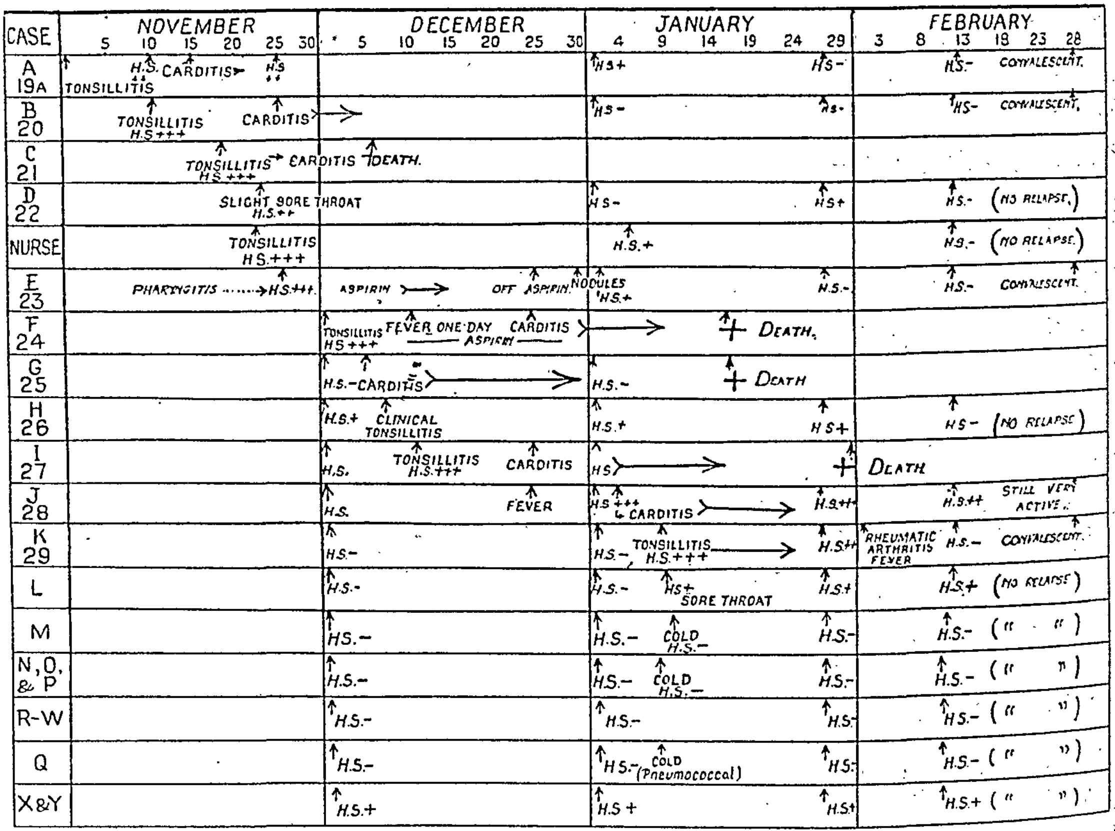

Chart showing incidence of rheumatic relapses and association of hæmolytic streptococcal infection during an outbreak of tonsillitis among rheumatic children in a ward at the Cheyne Hospital from November, 1930, to February, 1931. The 25 children in the ward are here called A to Y, but the 11 cases A to K are those numbered 19A to 29 in Table I. of Dr. Wilfrid Sheldon's paper, published herewith. H.S. = hæmolytic streptococci obtained from throat swab; + + + = pure culture; + + = fairly numerous colonies; + = sparse colonies; − = no colonies on plate.

In later epidemics similar results followed similar procedure, and Schlesinger came to the conclusion that no causal organism could be associated with these epidemics. He himself, however, regarded them as epidemic clinically, since "infection" appeared to spread from case to case. Though its possible significance was not recognised, the fact that hæmolytic streptococci were observed to predominate in the cultures where blood-agar was used suggests that this organism was responsible.

Present Investigation.

This investigation deals with the bacteriology of an outbreak of tonsillitis in Dr. Wilfrid Sheldon's ward for rheumatic cases at the Cheyne Hospital for Children. Its clinical aspect is described in Dr. Sheldon's communication.

The first case of tonsillitis was observed on Oct. 31st, 1930, and the bacteriological investigations were begun on Nov. 10th, when the second case appeared. Subsequent cases occurred at intervals during the months November to February inclusive, a detailed study of the throat flora being undertaken during this period. Throat swabs were obtained at definite intervals from every child, irrespective of its clinical condition at the time, and a more intensive investigation was made of the children who were affected by the serious outbreak of throat infection which was associated in almost every case with subsequent acute rheumatic relapse.

The results of this study are set out in the accompanying chart. Only the presence or absence of hæmolytic streptococci is indicated, except in the case of a group of colds which were of pneumococcal origin, for no other organism was found to account for the clinical symptoms of tonsillitis and pharyngitis. The throat infection is referred to for simplicity in the chart by the word "tonsillitis" when the infection was associated with inflamed tonsils or large tonsillar remnants, and by pharyngitis when previous tonsillectomy had been complete. When the heart has been involved in the rheumatic relapse this is termed "carditis" and where arthritis occurred without cardiac involvement this is stated briefly. A correlation between the throat infection and the subsequent secondary attacks of acute rheumatic fever is shown by the chart, and the epidemic nature of the infection is demonstrated by the succession of cases.

The organism causing the epidemic was the hæmolytic streptococcus, and it is shown that only after infection with this organism did relapses occur during these four months. A small epidemic of upper respiratory infection termed on the chart "colds" and associated with the pneumococcus produced no after-effects.

A silent period of over ten days is shown in all but two cases. In one of the latter cases (C), who had already a very much damaged heart, a very severe throat infection accompanied by a temperature of 104° lasting for four days was followed after a period of only two days by an attack of fulminating carditis. In the other no prior sore-throat was observed, nor did a throat culture five days before the relapse reveal the presence of hæmolytic streptococci. The relapse occurred, however, in the course of the epidemic, and some site of infection other than the throat was possibly responsible. Seven cases in which an almost pure growth of the organism was obtained during the throat infection had a subsequent secondary acute rheumatic attack. One similar case treated by aspirin showed no symptoms till the drug was discontinued when 35 days after the initial throat inflammation nodules appeared and the pulse-rate increased. In two cases (D and L) with slight sore-throats which were associated with the appearance of only a few colonies of hæmolytic streptococci on the plate culture from the throat no relapse occurred. Three cases (H, X, and Y) showed a few colonies on the plates at each culture, and as their throats appeared normal at the time must be regarded as casual carriers. One of the latter (H) developed clinical tonsillitis on Dec. 8th, but no culture was taken on that date and no relapse occurred subsequently. A nurse who also suffered from acute tonsillitis during this period and from whose throat a hæmolytic streptococcus was obtained, made an uninterrupted recovery.

The remaining 11 children had no infection with hæmolytic streptococci during this period, though five suffered from the "colds" already referred to, and none experienced rheumatic relapses.

POST-MORTEM EXAMINATIONS.

On the four cases which came to autopsy the macroscopic and microscopic appearances confirmed the clinical diagnosis of acute rheumatic carditis. Pericarditis was found in every case; it was associated with perisplenitis in two cases and recent endocarditis in every case. Cultures taken from the centre of the tonsils gave an almost pure growth of hæmolytic streptococci in three cases (the fourth case had had tonsillectomy). Hæmolytic streptococci were cultured in one case from an enlarged gland behind the pericardium, in another from the spleen, but in none of the four fatal cases could growth be obtained from the heart's blood post mortem.

BLOOD CULTURES.

Fifteen blood cultures were made from 11 of these patients—six during the tonsillitis, three during the silent period, and six during the acute cardiac relapse. Twelve cultures remained sterile, one was contaminated, and two grew a small diplobacillus. In no case was a hæmolytic streptococcus cultured from the blood.

The method of blood culture employed was a modification of that recommended by Cecil, Nicholls and Stainsby—e.g., 25 c.cm. of blood are withdrawn from the arm and placed in two sterile tubes, the serum subsequently removed, and 50–100 c.cm. glucose phosphate broth added. Subcultures were made every week for six weeks. This method had previously proved efficient both in routine hospital blood cultures and in cases of infective endocarditis where the organism was difficult to grow.

INTRA-CUTANEOUS TESTS.

Below are submitted some preliminary observations which have been made on the skin reactions with the products of the hæmolytic streptococci responsible for the Cheyne epidemic of tonsillitis.

Two preparations have been used. One was the exotoxin which consisted of the filtrate of a 24-hour broth culture. This filtrate was found to contain a toxin capable of producing positive skin reactions in susceptible individuals in a dilution of 1/1000. These reactions took 12–24 hours to develop and when compared side by side with Dick reactions gave similar appearances and results in nearly every case.

The second preparation, which may be termed the soluble "endotoxin," was an extract from the bodies of the cocci obtained in the following way:

The cocci were centrifuged from 100 c.cm. broth culture, washed with salt solution and heated to 60° C. for half an hour. They were *dried* in a vacuum over phosphoric pentoxide and were ground in a microbe-mill for several days, at the end of which very few intact cocci could be found in smear preparations. The ground-up bodies were then extracted with salt solution in the proportion of 10 c.cm. to the deposit from 100 c.cm. of broth culture. This suspension in turn was centrifuged until quite clear and the supernatant fluid removed and carbolised (0·5 per cent.). From this concentrated solution dilutions of 1/100 and 1/500 were made for actual use in the skin tests.

All the children in Dr. Sheldon's ward at the Cheyne Hospital were skin-tested to the exotoxin and to the soluble extract. In the chart and in Table I. are recorded the results of the tests on all the cases, except those with fulminating carditis, together with control tests on 20 non-rheumatic children from the Hospital for Sick Children, Great Ormond-street, suffering from other diseases and belonging to the same age period.

TABLE I.—*Skin Reactions with Exotoxin in Cases at the Cheyne Hospital.*

—	Cases.	Positive.	Negative.
Rheumatic cases	22	2	20
Controls	20	7	13

All cases giving positive reactions reacted to 0·2 c.cm. 1/1000 dilution and those considered negative gave no reaction to 0·2 c.cm. 1/100 dilution. It was observed that one of the cases reported above as positive became negative six weeks after an attack of acute tonsillitis associated with the hæmolytic streptococcus.

TABLE II.—*Skin Reactions with Soluble "Endotoxin" in Cases at the Cheyne Hospital.*

—	Cases.	Strongly positive.	Moderately positive.	Negative.
Rheumatic cases.	22	16	6	0
Controls	20	3	2	15

I have found it more difficult to arrive at a suitable skin test dose for the soluble extract than for the exotoxin. The cases in Table II. were tested with 0·2 c.cm. 1/100 and 0·2 c.cm 1/500 and the results read at the end of 24 and 48 hours. Reactions were considered strongly positive if they fulfilled three conditions: (*a*) the erythema at the site of an injection of 0·2 c.cm. of 1/100 dilution measured more than 20 mm. at 24 hours (read in two directions and the mean taken); (*b*) if it did not fade or if it increased in 48 hours; and (*c*) if œdema was present around the site of inoculation. In such cases the 0·2 c.cm. of 1/500 dilution gave smaller but similar readings. Reactions were considered moderately positive if, at the site of inoculation with the 1/100 solution there was an erythema of 12 mm. or more with slight œdema which persisted for 48 hours.

In many of the rheumatic cases the reactions were severe, an erythema appearing of more than 40 mm. This was accompanied by œdema and followed by the formation of a central necrotic area which resembled in appearance a strong Mantoux reaction. In one case the erythema round the site of inoculation with the weaker solution resembled that of erythema marginatum.

Some observations were also made on ten cases skin-tested during acute fulminating carditis. In these very sick children a greatly reduced sensitiveness to the "endotoxin" was observed during the most acute phase of the relapse. Some of these cases, observed throughout their illness, were shown to be positive both before and after the acute relapse. This phenomenon is probably merely a temporary inability of the body cells to react; a similar loss of skin sensitiveness is often observed in fulminating tuberculosis and typhoid fever and has been described by Mackenzie and Hanger[9] and others.

These skin tests show that there is a marked difference between the toxic action of the exotoxin and that of the endotoxin; while the exotoxin gave fewer reactions in the rheumatic cases than in the normals, the soluble endotoxin reacted in 100 per cent. of rheumatics and in only a quarter of the controls. It must be remembered that this group of rheumatic children were all cases who had suffered from previous attacks of acute rheumatism associated with carditis and had probably had previous streptococcal infection.

A number of experiments were performed to ascertain as far as possible some of the properties of these two streptococcal products. Some cases which had previously been proved to give positive reactions to the exotoxin or to the soluble endotoxin were retested with solutions of these substances which had been placed in a boiling water bath for one hour. The exotoxin was found to be inactivated by the heat while the reaction to the endotoxin was unaltered.

Neutralisation experiments with the serum from persons giving negative skin reactions showed that the exotoxin was completely neutralisable while the endotoxin tended to give conflicting results with similar experiments. It seemed, however, clear that the degree of skin sensitivity to the latter did not depend on a simple toxin-antitoxin balance, but on a sensitivity of the cells themselves. The above results show that the exotoxin is neutralisable and heat-labile and probably identical with the Dick toxin, while the endotoxin is heat-stable and probably unneutralisable by serum.

Some further preliminary experiments were done with a view to finding the chemical compositions of the active principle in the soluble endotoxin:—

(*a*) 5 c.cm. of the original saline extract were dialysed for over 100 hours till the dialysate no longer contained any trace of salt when tested with a few drops of silver nitrate. At the end of the experiment the amount of the fluid in the sac was found doubled and a precipitate had formed at the bottom. The precipitate was redissolved, and both it and the supernatant fluid from the dialysis were made up to dilutions calculated as 1/100 of the original extract. Both gave strongly positive skin reactions on known sensitive cases, though the supernatant fluid appeared to be the more potent.

(*b*) 5 c.cm. of extract were precipitated with decinormal acetic acid at a pH 4. (Both supernatant fluid and redissolved precipitate gave positive reactions and again the former was the more potent.)

(*c*) 5 c.cm. of extract were saturated with ammonium sulphate; tests showed that both deposit and supernatant fluid contained the active principle.

These experiments demonstrate that the active principle of the endotoxin is not dialysable. The fact that it was present in both supernatant fluids and precipitates suggests that it is a very soluble substance which probably adheres to the precipitates and is carried down with them.

Swift, Wilson, and Todd[10] have demonstrated marked hypersensitiveness of rheumatic fever patients to "nucleo-proteins" prepared from all types of streptococci but most marked to those from hæmolytic types. Coburn,[4] to whom further reference is made below, has also shown supersensitiveness in 00 per cent. rheumatic fever patients, to "nucleo-proteins" obtained from the hæmolytic streptococcus but not to those from a *viridans* strain. There are many references in the literature of the last five years to skin tests on rheumatic cases to filtrates and autolysates prepared from any different types of non-hæmolytic streptococci, by Birkhaug[11] and others.

However, the number of cases reported in this paper is not sufficiently numerous to warrant a comparative discussion of these works at present. A further study with purified extracts from other strains of hæmolytic streptococci and from non-hæmolytic streptococci is at present being undertaken and will be reported in another communication.

Discussion.

In Coburn's[4] work referred to above there is presented a most formidable array of facts in support of his view that the hæmolytic streptococcus and no other organism, culturable by ordinary means, causes the upper respiratory infections associated with acute rheumatism. He brings forward evidence to show that—

> *hæmolytic streptococci are but rarely found in the tropics* where acute rheumatism is almost unknown. In a group of children whom he transported to Porto Rico from New York all symptoms of active rheumatism disappeared in a short time along with the coincident disappearance of the hæmolytic streptococcus from their throats. On subsequent return to New York hæmolytic streptococci appeared once more and their appearance was followed by rheumatic relapses.
>
> The throat flora of a group of ambulatory rheumatic children were kept under observation for over a year and the effect of upper respiratory infections watched. Although epidemics of nasopharyngeal infection occurred with the pneumococcus, Pfeiffer's bacillus, the hæmolytic staphylococcus, and the hæmolytic streptococcus, it was only after infection with the latter that rheumatic relapses tended to recur. He also observed a very high degree of sensitiveness in rheumatic cases to "nucleo-protein" prepared from the hæmolytic streptococcus.

The facts presented in this paper were obtained by the study of an epidemic of rheumatic fever following the recognition of the silent period and offer a different approach to the subject than that pursued by the last author, yet the results are in remarkable agreement with his findings. They deal only with rheumatic relapses in association with acute hæmolytic streptococcal infection of the throat. However, these relapses, studied from the clinical point of view, show all the symptoms of second acute attacks of rheumatic fever rather than the mere lighting up of a subacute focus; they would be better described as acute secondary attacks of rheumatic fever, since in every instance where relapse occurred the disease was inactive at the time of the acute nasopharyngeal infection.

So far as present knowledge goes there does not appear to be any essential distinction between primary and secondary attacks of acute rheumatic fever. Scarlatina may, for example, give rise to an attack of acute rheumatic fever in cases with no previous history of rheumatism and it commonly causes a relapse in children with a rheumatic history. In both cases the phenomenon of the silent period is similar—i.e., a period of 10–20 days elapses between the onset of infection and the appearance of the rheumatic symptoms.

In spite of the difficulty of getting a clear history of sore-throat and obtaining satisfactory throat cultures in many cases arriving at hospital with primary attacks of rheumatic fever such cases as the following are not infrequently met with in the wards of the Hospital for Sick Children, Great Ormond-street:—

Boy, aged 7 years, admitted to Dr. Hutchison's ward complaining of pain in the chest and shortness of breath.

Past history: Frequent attacks of acute tonsillitis.

History of present illness: Four weeks ago had acute tonsillitis associated with fever; 14 days later pains commenced in muscles and joints, later increasing in intensity and being associated with general malaise. Shortness of breath developed gradually from this date.

Physical examination on admission: This revealed acute pericarditis, the tonsils were large and red and showed signs of recent acute inflammation. On admission throat culture gave a still predominant growth of hæmolytic streptococci. Five weeks later the throat infection appeared to have cleared up and hæmolytic streptococci could no longer be demonstrated by throat culture. The tonsils were enucleated five and a half weeks after admission. They were large but not unhealthy and contained no pus; cultures made by direct smear on blood-agar plates from the centre of the tonsil grew only two colonies of hæmolytic streptococci. Skin tests with hæmolytic streptococcal "endotoxin" gave strongly positive reactions.

I wish to thank Dr. Hutchison for allowing me to publish this case.

This case demonstrates how the infection soon disappears from the throat in rheumatic fever and is an example of acute hæmolytic streptococcal tonsillitis followed, after a silent period of 14 days, by the appearance of symptoms of acute *primary* rheumatic fever; it affords additional evidence in support of the view that the essential mechanism is the same in primary and secondary attacks.

The case quoted above also brings out another point of considerable importance. The clinical notes give a history of repeated attacks of acute tonsillitis. This is a very constant finding in the histories of cases of acute rheumatism. Often a history of previous scarlet fever is also obtained. This fact suggests the possibility of an altered body reaction being produced in persons who have had previous streptococcal infections. Clinically an early rheumatic state has been described. While no very clear picture of this state can be given, every children's physician constantly sees children complaining of vague limb and joint pains or slight choreic movements.

It is in this connexion that the discovery of a soluble extract from the body of the hæmolytic streptococcus to which rheumatic cases are particularly sensitive is of interest. The skin sensitiveness is such that the inoculation of 0·2 c.cm. of a dilution of 1/500 of the extract will cause an erythema of 35 mm. an inner area of œdema of 20 mm. and a central area of necrosis of 7 mm. in a hypersensitive rheumatic case, while 0·2 c.cm. of 1/100 extract injected into a non-rheumatic insensitive case will produce no reaction at all. This is indeed a very profound change in tissue reaction.

But it must be clear to anyone who has studied the clinical phenomena of the acute rheumatic state characterised by such different manifestations as arthritis, rheumatic nodules, carditis, chorea, and skin eruptions, that the dissemination of a soluble poison from a single focus of infection can hardly be the sole factor in the production of all these conditions.

The fact that 15 blood cultures during life and four cultures from the heart's blood at autopsy, reported on in this paper, did not reveal the presence of the hæmolytic streptococcus in any case would suggest that this organism had not at any time produced a *septicæmia.* The discovery, however, of the hæmolytic streptococci in foci so far distant as the spleen and the pericardial glands does indicate at least a transient bacteræmia with the organism causing the upper respiratory infection.

The observations recorded in this paper show: (1) that an acute infection of the throat with hæmolytic streptococci may cause secondary attacks of acute rheumatic fever in children who have already suffered from one or more attacks of acute rheumatism; and (2) that such children are highly sensitive to intracutaneous injection of a soluble extract of the bodies of the hæmolytic streptococci. The precise bearing of these findings on the pathogenesis of rheumatic fever requires further investigation, and there are many questions upon which information must be sought before the part played by the hæmolytic streptococcus can be defined.

Summary.

1. An epidemic of tonsillitis in a ward occupied by cases of rheumatic heart disease at the Cheyne Hospital for Children was shown to be caused by the hæmolytic streptococcus. 2. Rheumatic relapses occurred in 9 out of 11 children who developed acute streptococcal infection, while similar febrile disorders not associated with the hæmolytic streptococcus caused no relapse. 3. In addition to the throat cultures 15 blood cultures taken in 11 cases during life and four cultures from the heart's blood after death failed to reveal the presence of the hæmolytic streptococcus in any case, though the organism was cultured at autopsy from the centre of the tonsils in three cases, the spleen in one, and the glands draining the pericardium in another. 4. Intracutaneous tests were made with the exotoxin and a soluble "endotoxin" from the hæmolytic streptococcus causing the outbreak. 5. Rheumatic subjects were found to be very sensitive to the endotoxin while they gave fewer positive reactions to the exotoxin than a similar age-group of controls. 6. The association of throat infection with hæmolytic streptococci and rheumatic fever is discussed and a possible causal relationship suggested.

This paper was written in conjunction with Dr. W. Sheldon, without whose help and the splendid coöperation of the sister of the ward at the Cheyne Hospital the work could never have been done. I wish particularly to thank Dr. F. Griffith for his help and advice throughout the whole of the work. Many of the extracts were prepared in the pathological laboratory of the Ministry of Health. I should like to thank Dr. J. A. Glover for his advice and Dr. W. W. Payne and Mr. P. Bruce White for their help in connexion with the chemical analysis of the extracts. The work was done in the Research Department of the Hospital for Sick Children, Great Ormond-street, under the direction of Dr. D. Nabarro, to whom and to the medical staff of the hospital my sincerest thanks are due.

PERMANENT SEPARATION OF THE EPIPHYSIS FOR THE CAPITELLUM.*

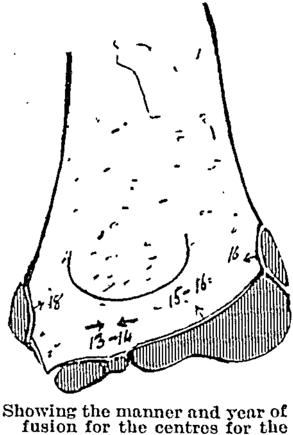
BY PAUL BERNARD ROTH, M.B.ABERD., F.R.C.S. ENG.,

ORTHOPÆDIC SURGEON, WITH CHARGE OF FRACTURES, TO THE MILLER GENERAL HOSPITAL, GREENWICH.

THE manner of ossification of the lower end of the humerus is variously described in papers and text-books. This is because the centres appear at varying ages, not always at one particular date. I have taken the earliest age at which any centre has been noticed as present and adopted it as the basis of the following description. I do not assert that this is the age at which the centre appears, but it is the age before which it is not found. All writers agree as to the order of appearance of the centres: capitellum, internal epicondyle, trochlea, and, if present, external epicondyle. The last-named is surgically of no importance. Most writers agree also as to the order in which these centres fuse with each other and with the shaft, but disagree by as much as three years on the age at which these fusions take place.

The earliest age at which these centres have been found is: capitellum, 1 year; internal epicondyle, 3 years 9 months; trochlea, 8 years; external epicondyle, 9 years. The last three may not appear until two or three years later than the age indicated, but the centre for the capitellum is almost always present at 1½ years. The centres for the capitellum and trochlea (that for the latter consisting of two nuclei placed side by side) (Fig. 1) unite in the thirteenth or fourteenth year and join the shaft in the fifteenth or sixteenth year; the two remaining centres join up a little later, the outer fusing equally with the capitellum and the shaft, the inner joining the shaft separately at a higher level, last of all. At 19 years it is unusual to find any epiphyseal lines showing.

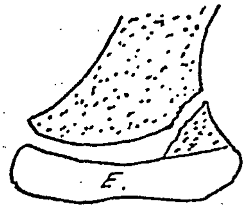
FIG. 1.



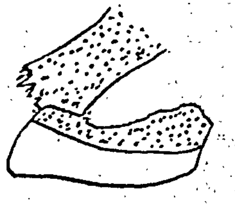
Showing the manner and year of fusion for the centres for the lower end of the humerus. The curved line indicates the position of the olecranon fossa, through which transverse fractures take place.

At birth the lower end of the humerus consists entirely of a cap of cartilage, and it is possible, though extremely rare, for this to be torn completely away from the shaft. There is a specimen very nearly showing this in the Museum of the Royal College of Surgeons (Fig. 2) and Mouchet[1] has described a case. On the other hand, the inner end of this cap, containing the centre for the internal epicondyle, is frequently torn off. In out-patient work this is the condition known as "injury to the lower epiphysis," and usually nothing is done for it. It should be replaced by open operation. When the child is a few years old, it is not at all unlikely to sustain a transverse fracture through the olecranon fossa, often with gross displacement of the fragments (Fig. 3). Though this is a break in the bone and the line of cleavage is some distance away from any epiphyseal line (see also Fig. 1), it has in the past been described as a separation of the lower epiphysis. The true separation which does occur is a tearing away from the cap of cartilage of practically its outer half, containing the centre of ossification for the capitellum. This centre is D-shaped and can be seen displaced in the lateral radiogram; normally the plane of its axis as mentioned by Cohn[2] should intersect that of the shaft at an angle of 60° (Fig. 4). The part displaced is much larger than the part seen in the radiogram, for the D-shaped part is only the bony nucleus or kernel. It is also much more than the part destined to be the capitellum, for it extends inwards to include half the trochlea (Fig. 1). In the two following cases this accident occurred in early life, and the torn off part has remained as a separate bone.

FIGS. 2 3



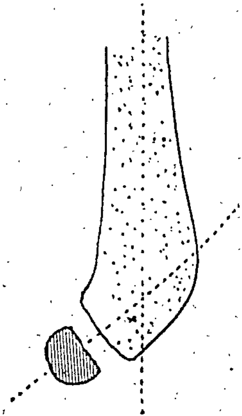
Child, aged 2. Separation of epiphyseal cartilage (E) of humerus.



Child, aged 2. Transverse fracture through olecranon fossa, formerly described as a separation of epiphyseal cartilage.

Both these drawings are from specimens in the Museum of the Royal College of Surgeons, numbered respectively 3579.1 and 3396.1.

FIG. 4.



The D-shaped bony centre or epiphysis for the capitellum, as seen in a lateral radiogram. The plane of its axis should intersect that of the shaft at an angle of 60°.

CASE 1.—A jar washer, aged 22, was sent to me on May 3rd, 1928, by Dr. R. H. Evans, complaining of pain in the left shoulder, which she had had on and off for years. On examination she was found to have a marked deformity of the left elbow; there was cubitus valgus, the "carrying angle" being 135° instead of the normal 105°. She said she had broken the left elbow when 4 years old, and that it had been crooked ever since. The radiogram showed that the outer half of the lower end of the humerus was lying separate from the rest of the bone (Fig. 5). Though separate, it has retained fairly well its correct shape and the radius articulates normally with it. There is a considerable gap, however, between it and what is left of the trochlea. The radius and ulna form a very oblique angle with the humerus.

The function of the elbow is perfect, except that its shape renders some movements very awkward. I suggest that the pain in the shoulder may be due to commencing osteo-arthritis, caused by abnormal strain because of the awkward elbow. As pointed out by Lane and others, when one joint of a limb is thrown out of line, the other joints eventually become affected.

CASE 2.—A hand driller in the Royal Arsenal, aged 18, was sent to me on August 9th, 1928, by Dr. C. Kingsley Carroll, complaining of pain in his left elbow when carrying heavy weights. On examination I found a similar deformity of the left elbow, with a similar "carrying angle"; and there was a history that when 6 years old he had dislocated it and had the dislocation reduced. The radiogram (Fig. 6) showed a distorted elbow, with complete separation of the capitellum from the humerus. There is a large gap between it and the latter bone and between it and the radius; again part of the trochlea is missing, and again the radius and ulna form a very oblique angle with the humerus. The capitellum has been twisted through 90°, its radial surface pointing directly outwards instead of downwards. The radial head has tried to reach the capitellum, as shown by its very marked hypertrophy. Though there is full movement of the elbow, the articulation of the head of the radius is peculiar; for the capitellum is movable, and when the radius rotates the former rotates with it, so that part at least of the movement takes place between the capitellum and the humerus. There must be a fibrous band joining the capitellum to the radius.

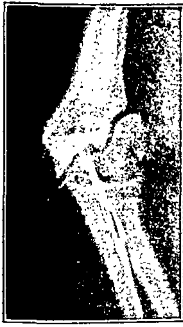
---

* Based on a paper read before a meeting of the British Orthopædic Association held in London on Nov. 29th, 1930.

[1] Mouchet, Albert: Presse Méd., Nov. 10th, 1928.

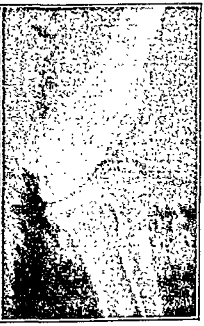
[2] Cohn, I.: Arch. of Surg., 1921, ii., 455.

FIGS. 5



Permanent separation of the epiphysis for the capitellum, without displacement.

6



Permanent separation of the epiphysis for the capitellum, with rotation through 90°.

These cases are presented as examples of true separation of the centre for the capitellum, and differ from the Royal College of Surgeons' case and from Mouchet's case, in both of which the whole cartilaginous cap was involved. They demonstrate the result of non-operative treatment. In the second patient, the rotation through 90° and the wide displacement account for the non-union, but in the first, where the separated portion appears to be accurately opposed and in proper line, one must suppose that the gap is due to the intervention of tags of torn muscle or capsule.

The correct treatment of this injury, if met with directly after the accident, is open operation and replacement of the separated fragment by suture. I propose to do a transverse osteotomy of the humerus in the first case, and to replace the fragment in the second. In the first I attribute the pain to secondary osteo-arthritis of the shoulder-joint; when the humerus is put straight the pain will go. If I am wrong, the patient will be no worse off, and will have a straight arm. In the second, the pain is due to the insecure arrangement of the radio-humeral articulation, and this must be put right. If the patient wishes, an osteotomy can be done later.

After reading my paper, I had a letter from Mr. G. H. Stevenson, of Glasgow, enclosing notes of a case similar to Case 1. The radiogram, except that it is of the right arm instead of the left, is identical with that of my patient. His case concerned a woman aged 40, complaining of severe pain in right arm, with wasting of all the ulnar intrinsics. There was marked "cubitus valgus," and she gave a history of a fall on the right elbow when a child. He operated and transposed the ulnar nerve to the front of the elbow, *with excellent result*. This case suggests the possibility of both of my cases developing nerve symptoms in later years.

THE ZONDEK-ASCHHEIM REACTION.

BY WILLIAM STEWART, M.D. GLASG.,
ASSISTANT PATHOLOGIST TO THE ROYAL HOSPITAL, WOLVERHAMPTON.

WITH the introduction of the Zondek-Aschheim reaction all other biochemical tests for the diagnosis of early pregnancy were superseded. As workers over a wide area were obtaining excellent results it certainly seemed worthy of investigation; some of the results of 12 months' study here are given below. The method employed was a slight modification of that introduced by H. Allan and F. Dickens.[1] The mice received the injection over a period of three days, morning and evening of each day; it is not essential to keep to the exact time each day. They were killed on the morning of the fifth day.

Results.

Group A.—Physiological Pregnancies.

Normal uncomplicated pregnancies	18
Hyperemesis	4
Pregnancy and heart disease	1
Pregnancy, pyelitis, and albuminuria	6
Pregnancy and epilepsy	2
Pregnancy and syphilis	2
Pregnancy and gonorrhœa	1
Pregnancy and pulmonary tuberculosis	2
Pregnancy and excessive obesity	2
Pregnancy and uterine fibroids	2

All gave a positive reaction.

Group B.—Abnormalities of Pregnancy.

	Cases.	Pos.	Neg.
Hydatidiform mole	9	8	1
Carneous mole	2	2	0
Dead fœtus	1	1	0
Ectopic pregnancy	3	2	1

Group C.

	Cases.	Pos.	Neg.
Amenorrhœa	9	0	9

200 days to full time	11 "

The only fallacy was a case of hyperthyroidism in a female aged 19, both lobes of the thyroid being enlarged, the basal metabolic rate being plus 43, and menstruation regular. The specimen of urine was obtained two days before menstruation was due and gave a positive reaction. This was followed two days later by normal menstruation. In such cases hypertrophy of the anterior pituitary gland has been noticed. In the case of hydatidiform mole which gave a negative reaction, the specimen of urine was obtained five days after parturition; this might explain the negative reaction.

---

[1] THE LANCET, 1930, i., 39.

A case of dead fœtus.—There had been amenorrhœa of 233 days, before which menstruation had been regular. The reaction was done because, on physical examination, the clinical findings did not agree with the patient's history, but suggested a pregnancy of three months. The patient herself thought there was something wrong; it was a second pregnancy. Twenty-seven days after a positive result had been sent a macerated fœtus was evacuated. The estimated age of the fœtus was 2–3 months.

Cases of ruptured ectopic gestation.—Case 83 was a patient admitted as a case of acute appendicitis; no menstrual period had been missed, and previously menstruation had been regular. The condition proved to be a tubal abortion. The reaction obtained was negative.

In Case 116, 32 days had elapsed since the last menstrual period. The time of rupture as judged by the onset of pain and abdominal symptoms preceded the specimen of urine obtained by 31 hours. This case gave a positive reaction.

Case 123 had had 58 days' amenorrhœa; at operation a large quantity of clotted blood was found in the pelvis with the remains of the fœtal tissues. The urine gave a positive reaction.

TRANSITION FROM NEGATIVE TO POSITIVE.

Three cases illustrated the transition from the negative to the positive reaction during pregnancy.

CASE 1, a school-teacher by profession, had obtained a post at some distance from her home. She was extremely anxious to have a child, but there had been two miscarriages in the past. She was athletic, and the abortions had been attributed to this. She visited her doctor to see if he thought she might be pregnant; if so, she was willing to give up her intended post in the hope that her pregnancy might terminate successfully. Her menstruation was of the 28-day type, and was not due until five days after the visit to her medical adviser. There had been no interruption of menstruation. The urine was obtained on the Tuesday, Wednesday, and Thursday, menstruation being due on the following Friday. This specimen of urine gave a positive œstrin reaction only. The menstrual period was missed. Another specimen of urine was obtained on the Tuesday, Wednesday, and Thursday of the following week. This specimen gave a positive reaction. She gave up her intended post and I assisted at the circumcision of the offspring in the early part of this year.

CASE 2, an unmarried girl, had had her last menstrual period on August 14th, 1930. Coitus, which only occurred once, took place on Sept. 1st. The menstrual period due in the middle of September was missed. The urine was examined on Sept. 22nd and gave a positive œstrin reaction only. A second specimen was obtained from that passed on the morning of Oct. 1st, and this specimen gave a positive reaction.

CASE 3, a patient admitted as a case of acute appendicitis, had not missed a period, and previously menstruation had been regular. A specimen of urine was obtained before the patient was sent into the theatre. Laparotomy showed a tubal abortion. The reaction was negative.

These cases show a definite negative reaction at the commencement of pregnancy. The transition occurred in the first case between the twenty-first and twenty-eighth day of pregnancy, and in the second case between the twenty-second and thirtieth day of pregnancy.

THE REACTION IN THE PUERPERIUM.

How long does the reaction remain in the puerperium? One case gave the following result:—

10 hours after labour	result positive.
20 hours after labour.. ..	„ „
34 hours after	œstrin reaction only.
44 hours	reaction negative.
60 hours	„ „

OTHER CASES.

Normal pregnancy	51 hours after labour..	reaction negative.
	77 „ „ „ ..	„ „
Carneous mole	3 days after	„ „
Hydatidiform mole	36 hours after	„ positive.
	3 days after	„ negative.
Hydatidiform mole and pulmonary tuberculosis 18 days after		.. reaction negative.

DEATH OF THE MICE DURING THE TEST.

This has been a considerable factor in the work of others; some have had to abandon the test altogether. This has not been my experience. It has been overcome by the following methods: (1) using the blood-serum; (2) centrifugalising the urine; (3) treating the urine with ether.

Where the urinary tract is infected, this difficulty may be overcome by using the blood-serum. It can be used in doses of 0·1 c.cm. at each injection. The urine may be centrifuged and the supernatant fluid only used. Treatment of the urine with ether has been found most satisfactory. In no specimen of urine received has the result been vitiated by reason of the toxicity of the urine. The method used is as follows. The urine is shaken up with a small quantity of ether and allowed to stand. As the ether is of lower specific gravity than the urine it rises to the surface, and is allowed to evaporate. Evaporation may be hastened by incubation at 37° C. in an evaporating dish. Nothing is extracted from the urine, and a sterile urine is left behind. I have successfully used this method where the urine had been kept over an interval of 23 and 47 days. Further observations have shown that where acetone is not present in the urine the separation may be hastened by using a separating funnel. If acetone be present and the separating funnel be used, some at least of the active principle is extracted. It is apparently immaterial whether the acetone is already present, as in hyperemesis, or is added.

Various other methods have been tried, among them the Zeitz filter, which removed not only the organisms but also the active principle. The other treatment is useful for specimens sent by post.

Discussion.

This was an entirely impartial investigation into the Zondek-Aschheim reaction, and the results obtained show it to be a definite and reliable one. The urine from cases in which the products of conception are present contains an active principle which acts as a specific stimulus to the ovary of the immature mouse. There is apparently a definite negative reaction at the commencement of pregnancy and the chorionic villi are developing about the time that the reaction becomes positive. It is probably from these that the stimulus comes for the over-production of the anterior pituitary hormone. Chorionic tissue is the only tissue that is common to all the above conditions. Death of the fœtus has apparently no effect on the reaction. So long as there is living chorionic tissue present a positive reaction is to be expected. It is immaterial whether this chorionic tissue is physiological or pathological. Macroscopic examination of the ovaries is sufficient; in no case has this finding been reversed by section of the ovaries.

SUMMARY.

1. This reaction is a reliable test for pregnancy. 2. The only fallacy in this investigation was in a case of Graves's disease. 3. The mortality in the mice can be overcome by treatment of the urine with ether. 4. Ether in the absence of acetone does not extract the active principle, but if acetone be present the active principle is extracted. 5. The reaction becomes positive at about the twenty-fifth day after conception. 6. The reaction disappears from the urine about 30 hours after parturition.

This work has been carried out in the pathological laboratory of the Royal Hospital, Wolverhampton. I am much indebted to Dr. S. C. Dyke, director of the department, for originally suggesting this subject, and for the admirable facilities which he has afforded me; also to the governors of the Royal Hospital. I am also much indebted to the coöperation of my medical colleagues, Mr. S. W. Maslen Jones and Dr. N. Wilkes, of the Women's Hospital, Wolverhampton; to Dr. G. Mitchell, director of the venereal diseases department, the Royal Hospital, Wolverhampton; to Dr. S. J. Cameron, consulting physician; and to Dr. D. M. Hart and Dr. M. Gilchrist, of the resident staff of Royal Maternity and Women's Hospital, Glasgow; to Prof. Beckwith Whitehouse and Dr. A. P. Thomson, of Birmingham; and to Mr. R. Stanley Lee, medical superintendent of the Municipal Hospital, New Cross, Wolverhampton.

CLINICAL AND LABORATORY NOTES

GONOCOCCAL POLYARTHRITIS IN A NEW-BORN CHILD.

BY A. D. C. BELL, B.M. OXF.,
MEDICAL REGISTRAR AND TUTOR, CHILDREN'S DEPARTMENT, ST. THOMAS'S HOSPITAL;

AND

P. A. CLEMENTS, M.B. DURH.,
SENIOR MEDICAL OFFICER, VENEREAL DISEASES DEPARTMENT, ST. THOMAS'S HOSPITAL.

THE case here reported is that of a female infant born at term after a normal labour and weighing at birth 8 lb. 8 oz. The mother, aged 38, had had five other children all of whom were said to be alive and well. As a result of the infant's developing an acute ophthalmia in the right eye the mother was examined and found to have gonorrhœa, gonococci being found in cervical and urethral smears. The blood, examined by Dr. T. E. Osmond, gave a positive reaction to the gonococcal complement-fixation test, but a negative to the Wassermann.

The infant, born on Oct. 4th, 1930, was reported to have been quite normal until the fourth day when, as noted above, a purulent ophthalmia was discovered, and on the eighth day it was noted that she had swelling of the middle joints of the left forefinger and the right third finger, which was followed on the next day by a similar condition of the metatarso-phalangeal joint of the right great toe and of the ankle.

She came under our care when 16 days old. The general nutrition was fair and she was apparently free from pain except on movement of the affected joints. The temperature was 101° F. The joints above mentioned were swollen and the skin over them hot, red, and shining. No active inflammation of the conjunctiva was present and there was no discharge. On aspiration of the affected joint of the left forefinger, flaky pus was withdrawn containing numerous gonococci, which were demonstrated both in smears of the fluid and in culture on hydrocele agar. Prolonged search on numerous occasions failed to reveal any active focus until the eighth day after admission, when a scanty purulent discharge was noted in the right eye, and in this were numerous extracellular gonococci. A slight vaginal discharge was noted two days after admission, but no gonococci were found in it, and it disappeared in a few days under irrigation with a weak solution of chloramine-T.

The mild conjunctivitis was treated with boric acid irrigation every four hours, and daily painting of the everted lids with 2 per cent. solution of $AgNO_3$, followed by ung. hydrarg. oxid. flav. applied to the lids. After ten days' treatment gonococci still persisted in the slight conjunctival discharge, and instillations with 5 per cent. protargol were substituted for the silver nitrate, but gonococci continued to be found for another four days. The joints were treated by protection from the weight of the bedclothes, no splints being applied, and gradually improved until, on the twenty-seventh day after admission, only a little peri-articular thickening of the ankle and the middle-joint of the third finger of the left hand remained; five days later radiography showed no articular changes. The complement-fixation reaction carried out by Dr. J. Oliver was negative on admission and a month later. The patient was discharged practically recovered five weeks after admission, and when seen 11 weeks later was in good condition, gaining weight normally, and showing no sign of disease.

Gonococcal arthritis in infants appears to be a rare condition, for we have discovered reports on only 43 cases, and in many of these the causative organism was not identified. The arthritis in this case was apparently secondary to a gonococcal conjunctivitis which subsided as the arthritis developed, and relapsed as this improved. The reappearance of gonococci in the conjunctival sac and their persistence after relapse, though this was accompanied by only slight signs of irritation, is of interest, as is also the fact that the gonococcal complement-fixation reaction remained negative in the presence of a well-marked gonococcal arthritis, such as in an adult would almost certainly have given rise to a positive reaction. That the mother's infection was discovered only by the fact of the child developing ophthalmia shows the importance of careful ante-partum examination.

For permission to publish this case we are indebted to Colonel L. W. Harrison.

A CASE OF PAROTID CALCULUS.

BY D. M. SUTHERLAND, M.D. MANCH., F.R.C.S. ENG.,
HON. ASSISTANT SURGEON TO THE ROYAL MANCHESTER CHILDREN'S HOSPITAL; HON. SURGEON TO STOCKPORT INFIRMARY.

IN April of this year a woman, aged 48, presented herself with a diffuse swelling of the left parotid gland. She stated that about 10 years previously she began to experience a feeling of fullness in the gland with swelling which appeared at meal-times and subsided about half an hour after a meal. The swelling did not appear each day and after five months the trouble disappeared. Eight years later the condition recurred and she noticed that pus was exuding from the inner side of the cheek. The swelling of the gland persisted and she began to suffer severe dyspeptic symptoms. She developed symptoms of hyperthyroidism, the toxic symptoms of which she still displayed at the time of operation. On examination the entire parotid gland was enlarged and the anterior portion showed a softened area with a hard centre suggestive of the presence of calculus. Radiography however gave a negative result.

The history of the case seemed to point so definitely to the presence of calculus that it was decided to explore the gland. The hardest and most prominent portion of the gland was explored by a needle and a calculus was felt. A horizontal incision was made into the gland directly over the prominence, a small abscess cavity opened, and a calculus about ¼ in. in length and ⅙ in. in thickness removed. Within 48 hours of the removal of the calculus the discharge of pus into the mouth had ceased. Although the wound was slightly inflamed for several days a fistula did not ensue. The general enlargement of the gland has subsided gradually but the immediate relief of the dyspepsia was remarkable. There was no sign of injury to the facial nerve.

The stone proved to be only slightly opaque to X rays. It did not show the presence of any foreign body.

There has been much discussion concerning the ætiology of calculus formation in the salivary glands. It has been suggested that the cause may be the entrance of a foreign body into the duct of a gland or that it may be infection of the gland with bacterial decomposition of the secretion and precipitation of its colloid and inorganic constituents. In the case reported neither of these two factors appeared to be the cause. The calculus was in the gland and not in the duct as would have been expected if a foreign body had been the cause. The parotid duct runs forwards from the gland upon the masseter muscle to its anterior edge where it turns sharply inwards through the cheek piercing the buccinator muscle, and then runs forwards between this muscle and the mucous membrane; it opens into the mouth by a minute orifice. From anatomical considerations it would appear difficult for calculus in the gland to be due to a foreign body. The fact that the parotitis and abscess formation disappeared after the removal of the calculus suggested that the infection was secondary and not the cause of the calculus.

It must be remembered also that bacterial infection of the parotid gland is much more common than that of any other salivary gland and yet calculus formation is rare. The above case suggests that the calculus was due to the precipitation of the constituents of the parotid secretion caused by some unknown alterations in the reaction of the gland. Two other points brought out by the case are the value of probing the gland by means of a fine needle, which does no harm, and the fact that a negative radiographic examination does not disprove the existence of a stone.

REVIEWS AND NOTICES OF BOOKS

Florence Nightingale, 1820–1856.

By I. B. O'MALLEY. London: Thornton Butterworth, Ltd. 1931. With 24 illustrations. Pp. 416. 21s.

Florence Nightingale, a national heroine, is already the subject of a complete biography by Sir Edward Cook, while estimates of her character and summaries of her life-work have won places in much general literature. But Mrs. O'Malley's book is none the less wanted, for it enables us to appreciate the intimate motives of Florence Nightingale's conduct, her hesitations and doubts and their origins, the interplay upon her feelings and her actions of her home environment and the influences of her few but intimate affections. The author's attempt has been to give a representation of things that might have been—indeed certainly would have been—in an autobiography, and then to depict Florence Nightingale's early years to the reader, as they might have appeared to Florence herself. In a generous preface, Mrs. O'Malley urges that all should read Sir Edward Cook's book, or, at any rate, the abridged version of this book which appeared in revised form in 1925, written by Mrs. Vaughan Nash, but she makes no attempt to compete with either work.

The record leaves off at the end of the Crimean war, when Florence Nightingale was 36 years old. It is divided into two equal parts, the first dealing with the early life and the second with the Crimean war, and in each case, wherever possible, Florence Nightingale is made to speak for herself and to observe and record her own experiences. This has been possible because a large number of personal notes, journals, and letters, written by Florence Nightingale, and now in the hands of the Nightingale family, were entrusted to Mrs. O'Malley for the purposes of her undertaking, and she has made excellent use of this material. The first part consequently is very detailed—too much so, it may seem. But as we proceed we are able to see that the story as told, whether the episodes are pathetic or amusing and whether they bring associations with a great world or with the peasants of a small community, does more than make good reading. It forms an astonishingly accurate introduction to what happened in 1854–56, when a cultured young woman, self-trained (and that only partially), and surrounded by every barrier of social restriction, left the drawing-room and the park for the battlefield and the sick ward to strive against revolting realities, supported by little but high dreams of duty. From the very beginning we seem to see that Florence Nightingale was fulfilling a destiny. At the age of 9 she began to write her life—La Vie de Florence Rossignol—when already she "desired to be useful to sick persons," and family letters to which Mrs. O'Malley has had access, especially letters to her cousin and friend Hilary Bonham Carter, show that always this urge to devote herself to the solace of suffering was with her. When Florence Nightingale was 17 years of age the Nightingale family went abroad, and for the next two years she kept a journal, from which it is clear that she became generously fired with the cause of a united Italy, and developed more interest in social questions than in the splendid displays of art. The Nightingales were wealthy and the continental tour was intended as a prelude to the entry of Florence and her elder sister into fashionable life. But the intention failed as far as Florence was concerned. On return to England, Mrs. Nightingale's own social ambitions, which were acute, were gratified, but by this time Florence had arrived at the conclusion that "the only way to make life real is to do something to relieve human misery." She refused a brilliant offer of marriage; further trouble in Greece and Egypt did nothing to reconcile her to society; a visit to a German orphanage confirmed her intention to be a nurse, and at last, just a year before the outbreak of the Crimean war, she got definitely free from the shackles of home life, obtaining a post as superintendent of a nursing home.

From this point Mrs. O'Malley tells the story of Florence Nightingale's experiences in the Crimea relying for the facts upon public documents, but throwing searching light upon them all by the use of Florence Nightingale's correspondence, and that of a few friends who accompanied her to the seat of war. The various adventures—for much of the hospital work in the Crimea was a series of adventures—are told very simply in those side-lights on history; there is not the slightest attempt to magnify horrors, and full play is given wherever possible to the lighter side of things, the author following here Florence Nightingale's own method of narrative. And throughout all the second part of the book the feeling grows that Florence Nightingale was fulfilling a destiny; that the advantages and disadvantages of her early life had equally prepared her to answer a terrible call, and further that there was no one else who could have answered it.

Mrs. O'Malley has produced a fine work. The enjoyment of extraordinary opportunities for obtaining the material would have served her little if she had not known how to deal with it. She has recognised and laid stress upon the relevant things, and has thus produced what is practically an autobiography of Florence Nightingale's early years, much as the author of La Vie de Florence Rossignol might have written it.

The Treatment of Schizophrenia.

By LELAND E. HINSIE, M.D., *Professor of Clinical Psychiatry, Columbia University.* London: Baillière, Tindall and Cox. 1930. Pp. 206. 13*s.* 6*d.*

THIS book seems to be intended for the average psychotherapist of moderate attainments rather than for the research worker or the well-informed specialist. It contains a straightforward account of the treatment of early schizophrenia by means of free association, in the light of psycho-analytic theory. As a scientific contribution to the literature the book is negligible. It lacks adequate clinical data; the number of patients treated, the history and state of each, the period of treatment and of subsequent observation, the precise method of coping in these cases with the technical difficulties that arise in the psycho-analytic procedure—all these are lacking. One finds instead much knocking at open doors, robust attacks on positions long since surrendered, and summaries of points of view which are now familiar. The book, moreover, is loosely constructed, and the form of expression at times is not clear. However, the author has enthusiasm, and concludes that careful and patient treatment of early schizophrenia can do much good—an unexceptionable view, but one that is not yet widespread in this country, where orthodox opinion is pessimistic about the course of dementia præcox however it is treated. This little book is therefore welcome, and may stimulate much useful effort; its directions to the psychiatrist on general management and diagnosis are sound, and the Freudian views of the author do not lead to irrelevant speculation or unintelligibility. The final chapter, a survey of the literature of the subject, is wide and critical, though by no means exhaustive.

Il Colera.

By G. SANARELLI, *Director of the Institute of Hygiene in the Royal University of Rome.* Milan: Soc. An. Instituto Editoriale Scientifico. Viale Romagna 58. 1931. Pp. 559. 90 lire.

THIS work is one of the most comprehensive monographs we have seen on Asiatic cholera. Prof. Sanarelli is well known for his extensive researches into the pathogenesis of this disease published largely in the Annali d'Igiene. The book is divided into three parts. The first treats of the medical and historical geography, the nosology, pathological anatomy, bacteriology, experimental pathogenic action of the cholera vibrio, the presumed choleraic poison, and the pathogenesis of the disease. Attention is drawn to the work of Filippo Pucini of Florence, who in 1854 described the presence in the fæces of cholera patients of extremely mobile microbes having the shape of an *S*; in 1879—i.e., four years before Koch's researches—the results of Pucini's observations on the same organism were published in a review on the "Morbid Process of Asiatic Cholera." Later, Metchnikoff, from his experimental work, drew the conclusions that Koch's vibrio was the sole agent of Asiatic cholera, and might infect the water and persist there for many years after the cessation of an epidemic, preserving its virulent properties; also that the susceptibility of man to cholera has no constant relation to the virulence shown by the vibrio in laboratory animals. In the chapter dealing with pathogenesis Prof. Sanarelli has incorporated his own work which demonstrated the presence of vibrios in the gastric parietes as well as the intestinal, and the phenomenon of "epithallaxis" (Sanarelli's phenomenon) is fully discussed. The second parts of the book treat of the epidemiology of cholera, chapters being devoted to the predisposing factors, determining causes, bacteriological diagnosis, carriers, therapeutics, and preventive vaccination. The method of treatment by hypertonic intravenous injections devised by Sir Leonard Rogers is stated to have proved highly successful during the epidemic of 1911 in Italy, but other therapeutic measures are also fully described. The third part of the book deals with the propagation of cholera, the Indian and Mohammedan pilgrimages, the methods of protection to be used by local authorities in dealing with epidemics, and international methods of defence, with special reference to the Mediterranean and Egypt. The book is enriched with numerous woodcuts and admirable reproductions of histological specimens, mainly from Prof. Sanarelli's own collection. An extensive bibliography is attached to this excellent book.

Breast-feeding.

By MARGARET EMSLIE, M.B., Ch.B., *late Senior Assistant Medical Officer for Maternity and Child Welfare, County Borough of Croydon; formerly Senior Clinical Assistant, Hospital for Sick Children, Great Ormond-street, London; Medical Officer, Southfields Centre.* London: Humphrey Milford, Oxford University Press. 1931. Pp. 142. 5*s.*

ARTIFICIAL feeding has of recent years become so widely adopted that much of the lore of Mother Gamp with regard to the natural feeding of the normal baby has to be sought from pædiatricians. It is an unfortunate fact that breast-feeding has been more assiduously preached than conscientiously practised, and Dr. Emslie examines at some length the probable causes for this state of affairs. She begins her book with two clearly written and well-illustrated chapters on antenatal preparation for breast-feeding and the anatomy and physiology of the breast, particular attention being paid to abnormalities of the nipples. The remainder of the work is devoted to the establishment, management, and difficulties of breast-feeding, and a careful consideration of the ways in which premature weaning may be avoided. The author gives some 60 references, not selected on a very critical basis. In a future edition methods of stripping the breast by other than manual expression might well be dealt with at greater length. Both electric and water-suction breast pumps have reached such a high state of efficiency, although they are not yet much used in this country, that they certainly deserve less cursory reference. The efficiency of these pumps should be made widely known in view of the many occasions (as, for instance, the admission of an infant to hospital) when it is desirable to maintain the milk-supply over a long period, and when the tedium involved in manual expression or the use of the old-fashioned pump frequently leads to abandonment of the struggle. The book provides an up-to-date and practical guide to breast-feeding which should be of real service to physicians and nurses, and could be read with advantage by any intelligent mother.

Text-book of Anatomy and Physiology.

Sixth edition. By ELIZABETH R. BUNDY, M.D. Revised by S. DANA WEEDER, M.D., Assistant Surgeon, Germantown Hospital, Pa. London: J. and A. Churchill. 1930. Pp. 446. 10*s.* 6*d.*

THE aim of this book is to present the more salient features of anatomy and physiology in such a manner that they will be readily grasped by those who do not require too deep a knowledge of the subjects. The book is very well arranged, commencing with an introductory portion dealing with the histology of the tissues, and then proceeding to describe the bones in detail, and the skeleton as a whole. Thereafter the different organs in the body are considered both from their anatomical aspect and their physiology. This combination of "structure" and "function" throughout the book leads to an easy style, and presents a coherent story to the reader. The value of the book is further enhanced by the brief summaries which appear at the end of each section. A helpful feature is the introduction of applied physiology, in the form of "Clinical Notes," which appear throughout the book wherever there is an opportunity of showing the practical application of the points discussed. Very few errors are noticeable, but on p. 175 it is stated that saliva contains two enzymes, ptyalin and maltase; and on p. 178 the phraseology is such as to make one infer that lactase and invertase are the enzymes for the digestion of sucrose and lactose respectively. The section on the sympathetic nerves could be better written. Although the word "autonomic" appears in the index, there is no mention of it in the text; and the parasympathetic nerves are not referred to at all. The book is made more helpful by a plentiful supply of illustrations; and concludes with a brief review of the anatomical relations in the more important regions of the body, and a glossary of anatomical and physiological terms.

Die Funktion der Weiblichen Geschlechtsorgane und ihre Beziehungen zum Gesamt-organismus.

By Dr. ALEXANDER V. FEKETE, Privat-dozent, oberarzt der Graf-Apponyi-Poliklinik in Budapest. Berlin: S. Karger. 1930. Pp. 278. M.12.

THIS book is intended as a supplement to the ordinary text-books of midwifery and gynæcology and deals with subjects usually somewhat neglected in such text-books. The reader will find useful summaries of the German literature on such subjects as the secondary sex characters, the menopause, sterility, dysmenorrhœa, metabolic changes in the maternal organism in pregnancy, the pregnancy toxæmias, the endocrine system, and the female sex organs. English and American work seems to be entirely ignored. To those who wish to have the German literature on the subjects dealt with in handy form the book can be recommended.

Journal of Pathology and Bacteriology.

No. 3 of Vol. XXXIV. (pp. 301–400, March) contains the following: Experimental Tar Tumours in the White Rat, by A. F. Watson (Sheffield). Though it is quite easy to produce epitheliomas of the skin by the repeated application of tar in mice, it has hitherto proved almost impossible to bring off the same result in rats. These animals are now shown to be much less refractory if each application of tar is preceded by one of rat grease.—The Repair in vitro of Embryonic Skeletal Rudiments after Experimental Injury, by Janet S. F. Niven (Cambridge). Up to about five days' incubation injuries to the cartilaginous rudiments of long bones are readily repaired by cartilage; after this, by fibrous and osteogenic tissue. An injured femur continues to develop and differentiate in the normal manner.—Observations on Salmonella Agglutination and Related Phenomena: Fixation of Somatic Agglutinins by Receptors in Solution, by P. Bruce White (London). A technical paper for experts.—The Occurrence of Intranuclear Inclusions in the Nerve Cells in Poliomyelitis, by E. W. Hurst (London). In the early stages of the disease in monkeys and in the only human case examined.—New Lithium Selective and Enrichment Methods for the Isolation of Salmonella Organisms, by J. D. A. Gray (Liverpool). Staphylococci and salmonella are relatively resistant to lithium salts which may be added to media with advantage for their isolation.—Primary Carcinoma of Bronchus, by E. E. Atkin (London). The average age at death of patients with squamous-celled growths is higher than with those of other cell types. Squamous-celled growths are particularly liable to liquefaction and cavitation, and to secondary growths in the other lung.—Tumour Immunity: the Effects of the Eu- and Pseudo-Globulin Fractions of Anti-Cancer Sera on Tissue Cultures, by T. Lumsden (London). The euglobulin fraction contains all the antibodies which are toxic to cancer cells which may thus be concentrated tenfold.—The Effects of Repeated Intrapleural Injections of Electrolytes in the Rabbit—Acquired Insensitiveness of the Lung Epithelium to a Proliferative Stimulus: the Bearing of the Observations on Tissue Resistance, by J. S. Young (Leeds). One intrapleural injection of—e.g., strontium chloride causes a hyperplastic reaction in the epithelium of the marginal alveoli of the lung; a second injection gives no effect. This refractory state wears off in about three weeks.—A Case of Agranulocytosis with Intestinal Changes, by Bo Nordgren (Stockholm).—Capillary Hæmangeioma of Cerebrum, by W. G. Barnard and F. M. R. Walshe (London). These tumours are not uncommon in the cerebellum, but this seems to be the first certain example in the cerebrum where it occurred in the right temporal lobe.—Multiple Teratomata of Peritoneum, by W. G. Barnard (London). A woman of 40 with abdominal symptoms of three months' duration was found at operation to have an ovarian cyst with teratomatous tissue in its wall, and several hundred small teratomatous tumours scattered over the peritoneum, in which nervous tissue was particularly prominent (see p. 1360).—Obituary Notices of A. Leitch (portrait), H. J. B. Fry, Richard Muir (portrait), G. E. Birkett, and A. G. R. Foulerton.

IRRADIATION WITH THE ALPINE SUN QUARTZ LAMP.—In reply to the penultimate sentence of a review of Dr. Hugo Bach's book in our issue of April 25th (p. 921) Dr. R. King Brown writes to say that the translation was prepared from the seventeenth German edition (1927) and brought up to date by the inclusion in an appendix of a recent summary by Dr. Bach on the present position of light treatment, which appeared in *Strahlentherapie.*

GENERAL MEDICAL COUNCIL.

SUMMER SESSION, JUNE 2ND–5TH, 1931.

Committee Business.

EDUCATION AND EXAMINATION COMMITTEES.

Sir Norman Walker presented the report of the Examination Committee. The account it gave of the inspection and visitation of final examinations deserved, he said, close study. The Universities remaining to be visited were mainly on the other side of the Irish Channel; the visitations would probably be completed this year, but not in time for report to the Council's November session. Prof. James Rice, who had been appointed deputy-visitor to the pre-registration examinations, had visited the examinations at Glasgow (Triple Board), London (Society of Apothecaries), and the Universities of Edinburgh, Manchester, Sheffield, and Liverpool. His preliminary reports were being regarded as confidential until he had completed his final report. He had gained a great deal of useful information.

The President presented the Joint Second Interim Report of the Education and Examination Committees on the report by the Departmental Committee of the Ministry of Health on maternal mortality and morbidity. At the last winter session of the Council it had been agreed that the President be requested to write to the Minister of Health pointing out the desirability of providing further accommodation for the teaching of practical obstetrics to medical students. The Minister had replied that none of the hospitals transferred to the London County Council under the Local Government Act possessed a maternity unit large enough for teaching purposes, but that the London County Council were contemplating the provision of a new maternity hospital of 100 beds with facilities for teaching. Provincial medical schools might, the Minister suggested, approach their county borough council to grant facilities in the maternity wards of its hospitals. On the question of a more equitable distribution of confinement cases between medical students and pupil midwives, he referred the Council to the report of the Departmental Committee on the training and employment of midwives, which recommended that pupil midwives in a medical school area should use only material in excess of the needs of medical students. The licensing bodies, replying to the reports, were generally agreed against six months' exclusive instruction in obstetrics, and 30 cases of labour instead of 20, but there was a large measure of assent to the other proposals of the Departmental Committee.

The Joint Committee advised that the Council should delay final action until they received the series of reports by its inspector on the qualifying examinations in midwifery, which were approaching completion.

Sir Robert Bolam, in seconding the adoption of the report, pointed out that some maternity hospitals in connexion with medical schools might find it difficult to do without the grant which they received for pupil midwives.

The President replied that this grant was not payable to all hospitals.

The report was adopted, and the Council directed its circulation to the licensing bodies.

The same committees presented another report on the report by the Society of Medical Officers of Health on the place of preventive medicine in the medical curriculum. The President remarked that the committee sympathised with most of the recommendations of the Society, though some of the details applied to the schools rather than to the Council. The interim report was ordered to be circulated to the licensing bodies. A final report would, said the committee, be presented to the Council on the completion of the series of reports by the inspectors of the final examination.

PUBLIC HEALTH COMMITTEE.

Sir John Moore presented the report of this committee and its recommendation:—

> "That in view of the difficulty which some licensing bodies have felt in putting the new D.P.H. rules into operation by Oct. 1st, 1931, the Council desire to inform the licensing bodies that the standing subcommittee of the Public Health Committee of the Council is authorised to consider any exceptional cases submitted to it as heretofore. Such authorisation would include power to grant permission to continue under the old rules during a year of grace up to Oct. 1st, 1932, or such partial adoption of any, or all of the new rules within the same period."

Mr. Monsarrat desired to postpone the operation of the new rules for a year, saying that some of the teaching bodies were apprehensive lest they should have no chance of putting forward their views.

Sir George Newman said that 22 of the licensing bodies had accepted the very slight amendments to the rules, and only six had found difficulty. The amendments had not been initiated in the Council, but the Council had been approached by licensing bodies. Two or three large schools had already made the necessary arrangements to conform.

Dr. Letheby Tidy thought that postponement would involve the main bodies in serious difficulties. The opinions of the bodies could be collected without postponement.

Sir John Moore and Sir Robert Bolam deprecated any alteration in or postponement of the new regulations now that the schools had taken trouble to conform to them. The latter said that advice had been taken from many important sources throughout the country before the rules were laid down, and Mr. Monsarrat's proposal asked the bodies to do something they were quite entitled to do without invitation. The alterations in the new regulations were not of great moment.

Prof. Sheen said that his faculty regarded the alterations as neither few nor unimportant, and desired an opportunity to express an opinion on them, which they had not yet had. Their professor had never been consulted. What was the good of getting the opinion of the licensing bodies except with a view to amending the rules? The bodies were in a coerced position, but they did not like the rules.

Prof. Johnston said that his faculty had not welcomed the rules at all, but had felt that they had no option save to conform. The only point they had welcomed was the substitution of an academic year for a calendar year. No member of the Council was engaged in training men for the D.P.H., and the teachers ought to be consulted.

Sir John Moore reiterated that the recent revision had not been undertaken on the initiative of the Council, but at the request of certain licensing bodies.

Mr. Monsarrat, proposing

> "That the licensing bodies be invited to express their views on the new regulations regarding the course of instruction for the diploma in public health,"

said that there was a body of important experience in the country of which the Council had not availed itself. When the Council received their opinion it would, of course, consider making use of it.

Sir Robert Bolam moved that the licensing bodies be invited to make any observations they desired to make, as he thought that most of them would not level of 20–40,000 cubic feet per minute to 16,000, for most of the fresh air admitted has been discharged to the outlets without having been any benefit to the occupants of the room. Why Sir FRANK BAINES's memorandum[1] setting out these experiments in detail has only just been presented to Parliament does not appear. The information has presumably been asked for by the committee now sitting of which Dr. ALFRED SALTER is chairman and before which Sir LEONARD HILL has again expressed his views. The proposed changes are so modest and so closely in harmony with all that is modern in the teaching of ventilation that their adoption should be immediate. Warmer feet and cooler heads will be needed this session.

HOSPITALS AND THE EXPENSE OF TRAFFIC CASUALTIES.

THE Minister of Transport has undertaken to remove one of the flaws in last year's Road Traffic Act by repealing subsection (3) of Section 61 which victimised the free conveyance of the local cricket team or school-children's outing. This step, he says, can only be taken by a one-clause Bill treated as non-controversial, and no other amendment of the Act can be undertaken. Otherwise it might have been possible to invite his aid in respect of another part of the Act which was framed to assist hospitals but which is not operating to their proper advantage. Part II. of the Act arranged for the compulsory insurance of the user of a motor vehicle against third-party risks. It has been notorious that the resources and accommodation of our hospitals have been considerably strained by the requirement of treating local traffic casualties. It was felt that, if a patient, injured by a motor accident, recovered compensation under the system of compulsory insurance, the hospital ought somehow to be recouped the expense of his treatment. Section 36 of the Act sought to give a remedy by enacting that, if the insurance company became aware that a person had received treatment in a hospital for fatal or other bodily injuries arising out of a motor traffic accident, the company, when making a payment under the Act, should also pay the hospital the reasonable expenses of such treatment up to a maximum of £25 for each patient. A proviso was added which excluded the application of the foregoing provision where a charge has been made by the hospital for such treatment.

Experience of the working of this enactment is unsatisfactory. It is even possible that in many cases the hospitals would have been better off if the enactment had not been passed, because not a few patients regard compulsory insurance as a complete substitute for voluntary payment to the hospital. Often, of course, the system of compulsory insurance amounts to nothing at all. A motor-coach, let us suppose, runs amok near a crowded pavement and fills the casualty ward of the local hospital. It is ascertained that the vehicle became suddenly unmanageable through a broken axle caused by an undiscoverable flaw in the metal. The accident, say the coach-owners, was not due to negligence but to an act of God; in consequence no payment can be made. Where there is a reasonable prospect of the insurance company making some payment, the settlement may be hung up for a twelve-month while the law courts decide the issue of liability. At the end of that period, if the insurance company succeeds in escaping liability, it is frequently too late to trace the patient and extract from him a voluntary payment; moreover, his sense of gratitude may by that time be less acute. The common-sense practice would be for the patient, when his treatment is ended, to make the hospital such contribution as he can afford, and for this contribution to be deemed a payment on account—an advance which should not prevent the insurance company from making its statutory payment eventually when liability is established. Unfortunately such a practice seems to be ruled out by the proviso (already mentioned) which excuses the company from paying the hospital "where a charge has been made by the hospital in respect of such treatment." The hospital wants three things—first, to recover the expenses of treating the patient; secondly, to recover them promptly; and thirdly, to recover them without endless labour in tracing ex-patients. When a traffic accident brings a patient into the hospital ward, it is easy to ascertain the insurance company concerned, but it is difficult to find out enough about the patient (often a stranger to the district) to ensure the hospital getting into touch with him several months afterwards. The situation seems to call for some amendment of the law. It is for the hospitals to consider what is feasible.

EXPERIMENTAL PRODUCTION OF GALL-STONES.

GALL-STONE formation is generally attributed either to infection, metabolic disorder, or biliary stagnation. Nowadays most clinicians think that a primary gall-bladder infection, probably blood-borne, is the fundamental cause of almost all types of gall-stone, including even the pure cholesterol monolith, which was formerly regarded as of metabolic origin. The factor of biliary stagnation has received less attention of late, although it has often been suggested that the pregnant uterus may predispose to cholelithiasis by mechanical hindrance of the flow of bile.

Since through cholecystography we have come to recognise more fully the concentrating activity of the gall-bladder, it has seemed more likely that a prolonged stay in the gall-bladder may produce a bile so thick that minute solid particles may be precipitated and form nuclei for calculi. Interesting experimental work by WESTPHAL and GLEICHMANN[1] supports this hypothesis, and suggests that, at least in the animals used, stagnation of the bile is the essential cause of gall-stones. These workers used in all 50 dogs for their experiments, but for various reasons they have excluded 10 of these in drawing their conclusions. In 16 dogs the biliary flow was artificially obstructed for periods of from 1 to 11 days; in 22 it was obstructed for periods of from 26 to 235 days. As far as possible an aseptic stagnation was produced, and this was done by ligaturing the bile-duct at various sites and for various lengths of time. In some cases there was total obstruction over long or short periods; in others it was only partial. Further, in some dogs artificial infection of the gall-bladder was carried out in addition, while yet others had excess of cholesterol in their diet. Infection occasionally developed during the experiment as a result of the operation. Always there was a very thorough examination of the bile—removed through a needle—at the beginning and end of the experiment. In a considerable proportion of cases concretions in the bile were produced, varying from almost microscopic particles to the size of large peas or beans, and consisting mainly of pigment. In one case there were definite concentric layers, but in none of them was a definite cholesterol deposit found. A striking feature of the results is that such concretions were produced by simple partial obstruction as frequently as by total obstruction, and that they were apparently independent of any coexistent infection. Indeed, infection sometimes seemed to prevent concentration of the bile and lessen the incidence of concretions. An obstruction of one or two days was enough to produce the first signs of "stone formation," though they disappeared when the obstruction was removed; thus of the 16 dogs in which the obstruction lasted less than 12 days, 13 showed definite naked-eye precipitations in the bile.

[1] Gallenwegsfunktion und Gallensteinleiden (v). Westphal K., Gleichmann, F., and Mann, W. Berlin: Julius Springer. 1931. Pp. 227. R.M.18.

The burden of these results is that bacteria play only a minor and secondary part in the causation of gall-stones, and that infection is certainly unnecessary for their production. Though the conditions are not applicable directly to man without reserve, their significance is clear, and must impress the reader with the importance of an obstructed flow of bile.

◆

PUBLIC HEALTH IN SCOTLAND.

THE Department of Health for Scotland has issued its second annual report, some of the main features of which we summarised recently.[1] The year 1930 is described as a peculiarly difficult one, but the difficulties to be overcome were mainly external: the continued widespread unemployment and the transfer to the new local authorities of poor-law medical service and school health administration. The number of detailed adjustments involved in this transference must have been enormous, and all the while the administrative activities had to go on steadily over the old field. In form the report follows the lines established seven years ago, and adds another to a series which gives a fairly complete picture of the historical growth of public health in a small and well-organised nation. During the year research has been raised to a better plane. The Department set up a scientific advisory committee on medical administration and investigation, with Dr. PARLANE KINLOCH as chairman, representing all the chief departments of medical and biological research. On the advice of this committee, of which Sir WALTER FLETCHER is a member, a report was issued on the Aberdeen investigation into maternal mortality. Early in the year, with the financial help of the Empire Marketing Board, the Department's officers organised a large scale investigation into the effect of raw and pasteurised milk on the growth of 20,000 children in 67 Lanarkshire schools. Research has continued into the importance of the mineral balance in nutrition, the special problem being the mineral differences between human and cow's milk. A special investigation is being made into the incidence of infection in tuberculous milk. Some 10,000 samples are to be analysed biologically at five laboratories by an identical technique, the details of which are to be fixed, with the consent of the Medical Research Council, by the bacteriologists themselves. Not a bad record for the first complete year of a new department. Meanwhile, the staff has been strengthened by the addition of a bacteriologist and a medical statistician. The analysis of tuberculosis returns is correspondingly elaborate; the decline continues to be steady and considerable. In 1920 the death-rate from all forms was 124 per 100,000 of population; in 1930 it was 88. In respiratory tuberculosis the numbers fell from 4194 in 1920 to 3024 in 1930, equivalent to rates of 86 per 100,000 and 62. The decline is steeper than in the general death-rate.

School health administration is 23 years old in Scotland, and the figures recorded show a better standard of cleanliness and a steady amelioration in malnutrition, rickets, and defective teeth. The very large field covered by school treatment can be grasped only when the thousands of cases of eye defects, ear defects, skin diseases, throat diseases, and the like, are scrutinised in the tables. When it can be said that in a total attendance of 741,801 children, 263,334 were examined medically, 82,634 re-examined, and 146,332 subjected to special examination, vigilance may be regarded as fairly effective. Now that the Scottish Education Department has made a medical man a principal assistant secretary and appointed another medical man as inspector of physical education, the integration of the school health service with physical education will no doubt proceed more rapidly. In the Highlands and Islands medical service and in maternity and child welfare the work is now largely organised routine; but the former is still growing, as shown by the appointment of consultant and operative surgeons for the northernmost fringe, including Shetland and Lewis. Under the Housing Act of 1930 leeway is being rapidly made up, and the programme in contemplation almost reaches the figure suggested by the Royal Commission on Housing. Other social services are kept running at full pressure. The poor-law has been lightened by the transfer of 33,000 cases to unemployment insurance, but even so the burden reaches 37 per 1000 of the population.

---

[1] THE LANCET, June 6th, p. 1258.

Unemployment is nearly everywhere worse in Scotland than in England.

In the very full section on national health insurance and pensions a new departure is the chapter on Morbidity in the Insured Population. For nearly 20 years insurance practitioners have made periodic returns of their cases of sickness. Some time ago a departmental committee inquired as to the statistical use to be made of those returns; but, in Scotland at least, the investigation did not lead to any statistical results until now. Within its first year, the Department was able to make arrangement with the approved societies to get periodic information about certificates of sickness. The old system of medical returns has been dropped, and the new system began last July. The chapter containing the preliminary statistical results is worth careful study. In the fullness of time the facts about certification will become an important index of the incidence of sickness in the industrial community. One striking fact is brought out—namely, "that morbidity, so far as concerns mere frequency of certification, is quite at variance with mortality in which increasing age is accompanied by a progressively higher death-rate." In certification "the frequency of a disease is in inverse ratio to its fatality," and this paradox is illustrated by many group facts. The biggest percentage of sickness certificates comes from the age-group 16–19 and, except for the years 50–59, the ages above 19 show a progressive diminution. This is a hint for more intensive investigation of the early ages. The Department is to be congratulated on a well-loaded and well-presented report.

ANNOTATIONS

PHYSIQUE AND HEALTH IN KENYA.

It is often stated that native tribes manifest a much finer physique and enjoy much better health than the decadent inhabitants of civilised countries. Some field work on two native tribes in Kenya[1] suggests strongly that the physique of these people is often inferior to that of Europeans and that disease is quite as prevalent among them as elsewhere.

Among 14,440 native men employed on the Uasin Gisy Railway, the death-rate was 35·4 per thousand, and 5331 were admitted to hospital in a year. The principal causes of death are diseases of the respiratory system, especially pneumonia and tuberculosis. Ulcers of the leg and intestinal disturbances account for much sickness. The investigation here reported was undertaken with the primary object of obtaining more information about the incidence of disease in natives in reserves and their diet. A physical examination was made of 6349 Kikuyu adults and 2500 children and of 1546 Masai adults and 254 children. The Akikuyu are a Bantu tribe, numbering about three-quarters of a million and occupying part of the highlands of Kenya between the Equator and one degree south. Their diet consists chiefly of cereals, plantains, tubers, legumes, and green leaves; 60 per cent. of the diet of the men consists of maize or millet and a further 25 per cent. of sweet potatoes. The women have a virtual monopoly of the green leaves. Very little cow's milk is available and the goats are used mainly as currency instead of as a source of milk or meat. Edible earths are a common article of diet, especially among the women and children. Magadi soda is also largely used as salt. The Masai are a pastoral tribe living on milk, meat, and blood. The non-fighting classes also eat a certain amount of beans, millet, bananas, arrow-root, maize, sugar, and honey. Berries are taken by warriors on hunting expeditions and by pregnant women. An analysis of the chemical composition of the native foodstuffs, earths, and mineral waters showed that the Kenya leaves have a strikingly high calcium and chlorine content; their addition to a diet of cereals and potatoes would therefore tend to correct the calcium deficiency. The manganese content of the leaves and of the plant ash used as salt substitute was also found to be very high. Some of the edible earths are rich in sodium, phosphorus, or iron. The total solids and fat in Masai milk are high. The Kikuyu women's special foods, therefore, increase the intake of calcium and sodium. The diet of the Kikuyu male is adequate in protein but very low in fat and calcium. The Masai diet, in which there is less difference between the sexes, contains a liberal supply of mineral elements and a large excess of protein and fat, but is low in carbohydrates, cellulose, and other indigestible residues.

It was found that the Masai grow more rapidly than the Kikuyu and are on an average 5 in. taller, 23 lb. heavier, and 50 per cent. stronger; they are larger in the chest and smaller in the abdomen. The Kikuyu children commonly showed signs of malnutrition and rickets, a high incidence of dental defect, anæmia, spongy gums, enlarged tonsils, and cervical adenitis. The Masai village children presented a totally different picture, defects and anæmia being uncommon. The adult Kikuyu suffered more from yaws, malaria, conjunctivitis, helminthiasis, and ulcers, but the diseases of the Masai were principally constipation and arthritis. The Masai had no tribal immunity to pulmonary conditions—in gaol they seemed peculiarly susceptible—and their superior resistance under natural conditions was probably correlated with diet and environment. A study of the routine hospital and prison diets in Kenya showed that they were markedly deficient in calcium. The Kikuyu women were healthier than the men.

The committee desire to make it clear that the investigations are only preliminary; nevertheless, some of the problems raised are fundamental. The striking difference in physique between the Masai and the Akikuyu raises the question to what extent diet can affect the stature and physique of a race, and recalls the Scottish experiments in which additional milk for school-children was followed by an increased rate of growth in two successive years. There was, however, nothing to show whether, if the milk had been continued, there would have been an ultimate difference in adult stature. Another most important problem is the possibility that diet may influence susceptibility to certain infectious diseases. This investigation brings forward data to support the suggestion that deficiencies in diet, abnormal composition of the blood, and reduced susceptibility to certain diseases may be correlated. The problem concerns not only public health authorities but also agricultural authorities. A general improvement of agriculture and animal husbandry amongst the Akikuyu would almost certainly be accompanied by an improvement in the health and working capacity of the natives. The problem is not confined to Kenya; it appears to exist in many of our tropical dependencies. The loss of health and efficiency attributable to deficient diet is therefore of considerable economic importance. The Empire Marketing Board is to be congratulated on its foresight in promoting research of this kind.

THE BERCOVITZ TEST IN PREGNANCY.

A YEAR ago Z. Bercovitz[1] described a pupillary test for pregnancy: the instillation into the eye of one drop of a 10 per cent. solution of sodium citrate mixed with five drops of the patient's blood. A positive reaction consisted in a dilatation or contraction of the pupil compared with that of the other side. The reaction has lately been tested by A. J. Gordon and S. W. Emmer[2] on 110 consecutive patients examined at the prenatal clinic of Newark City Dispensary. A number of doubtful reactions occurred in negro women, in whom it is sometimes very hard to read the pupil, but in this series no patient who was not pregnant gave a positive reaction, although several cases of pregnancy gave negative reactions. In the opinion of the investigators the Bercovitz test is a valuable aid to the diagnosis of pregnancy. It is certainly much simpler and quicker than the Zondek-Aschheim test and can be done at once in the consulting-room or clinic.

MENTAL CHANGES IN PERNICIOUS ANÆMIA.

AT a recent quarterly meeting of the Royal Medico-Psychological Association Dr. Norman Phillips, of St. Andrew's Hospital, Northampton, initiated a discussion on the mental disorders associated with anæmia of pernicious type. In his experience these ranged from slight modification of character shown in irritability and unstable moods to definite paranoia with delusions of persecution and suspicion. Such mental states might occur at any stage of the anæmia and Prof. G. M. Robertson recounted a case in which acute mental symptoms developed quite early. Dr. W. F. Menzies remarked that he had seen only four cases of the association at Cheddleton of recent years, but a study of the literature would suggest that if deviation from the normal mental outlook be included such cases are not uncommon. R. C. Cabot noted mental symptoms in 104 (15 per cent.) of 647 cases of pernicious anæmia collected from American sources, and H. W. Woltmann reported[3] that in 1498 cases of this disease treated at the Mayo Clinic between 1917 and 1924, 4 per cent. had definite psychoses whilst 35 per cent. suffered from milder mental disorders. It is therefore rather singular that only one of five text-books on psychiatry published in this country refers to the mental aspect of pernicious anæmia. In a review which appeared not long ago in our own columns[4] Dr. D. McAlpine described varying degrees of mental disturbance in 11 out of 17 cases of pernicious anæmia whose mental condition he had examined. Three showed simple depression with lack of mental energy; one of these committed suicide despite adequate liver treatment. In four cases there was a mild state of mental confusion associated with failure of memory, indifference and a tendency to somnolence. In three the disturbance was more profound and was typical of a toxic psychosis; two of these had begun abruptly with confusion, excitability, amounting in one case to mania, and ideas of persecution and suicide. The majority of Dr. McAlpine's cases showed signs or symptoms of subacute combined degeneration of the spinal cord, but he could establish no direct relationship between the degree of anæmia and the intensity of the mental symptoms. Other writers have described a similar train of symptoms. Sometimes the depression and insomnia have suggested a manic-depressive state, but the recognition of a glossitis or an examination of the blood has led to the correct diagnosis. In the milder cases a diagnosis of neurosis or neurasthenia is apt to be made. Variability in mood, mental as well as bodily fatigue, difficulty in concentration, lack of interest, a sense of apprehension, and a tendency to somnolence are the commoner symptoms, and coincident with this altered mental outlook are frequently found early symptoms of spinal cord involvement, such as paræsthesiæ or referred pains. The blood picture is rarely that of a frank pernicious anæmia; as a rule the degree of anæmia is slight and an ordinary blood count may show no distinctive features. F. W. Langdon has drawn attention[5] to a group of cases in which the nervous and mental symptoms precede the typical picture of pernicious anæmia. His views met with little favour at the time but facts have since come to light in support of them. In Scandinavia for instance, E. I. Warburg and S. Jorgensen have described[6] the association of psychoses and neurasthenic states with achylia gastrica and megalocytosis. They remark that the advent of pernicious anæmia is rather a late stage in this condition; a low colour index may be present at an early stage. The effect of liver treatment on the mental symptoms seem to vary, but as recoveries have been reported the importance of recognising these cases early is evident. At the discussion mentioned Col. J. R. Lord remarked on the importance of a vigorously functioning liver in preserving a cheerful mentality; a morning liver-cocktail might not be an unwise habit. In any case it would be prudent to make inquiry for a history of glossitis and an examination of the gastric contents and of the blood—especially for megalocytosis—in neuroses and psychoses, especially of the toxic type, appearing for the first time in persons over the age of 35.

TENSION OF GASES IN THE TISSUES.

THE tension of the gases in the body tissues generally has not received the same attention as their tension in the blood. The statement has been commonly accepted that in the tissues carbon dioxide, in virtue of its manufacture there, is under a positive pressure; whereas oxygen, because of the demand for it, is at a very low or even negative tension. Dr. J. Argyll Campbell's new investigations[7] are based on the fact that when a gaseous phase and a liquid phase are brought in contact the gases in the two phases commingle with each other, until eventually the pressures of the individual gases in both are equal. In carrying out the observations nitrogen is usually injected into the tissues, and after equilibrium is established the gas is withdrawn and analysed and the pressure of its components is determined. Dr. Campbell says that in no tissue examined was the tension of oxygen below 20 mm. Hg; and it usually varied between 20–30 mm. He concludes that so great is the capillary supply, that even in resting muscle it is not possible to have a zero oxygen tension. In no case was there any evidence of the tension of oxygen in the tissues exceeding that in the arterial blood. A number of observations were undertaken bearing on the controversy on secretion versus diffusion of oxygen through the pulmonary alveoli at high altitudes. Animals were exposed to low pressures of oxygen for prolonged periods and it was found that the oxygen tension in the tissues fell, and remained low even after acclimatisation. From this it was inferred that if secretion was taking place it was not helping the tissues in any way. It was shown also that the coincidently lowered tension of the carbon dioxide in the tissues had no great effect upon ability to tolerate the low oxygen pressure in the inspired air. This was demonstrated by the fact that although cats and rabbits both exhibited the same low CO_2 tension, cats did not tolerate the low O_2, although rabbits did. It was not found possible to lower the O_2 tension in the tissues more than 40 per cent. of normal without the risk of death; hence the idea of a "nil" tension of this gas is held to be absurd. Oxygen was almost absent from the lumen of the gut, this gas being readily absorbed by the mucosa. It was shown that the mucous membrane of the stomach may absorb as much as 12 c.cm. of oxygen per minute. Discussing air swallowing in certain dyspeptics, Dr. Campbell suggests that it is possible that air is swallowed to supply oxygen to an abnormal mucous membrane. The gases in the large intestine, as would be expected, were found to vary with the diet, milk giving a large preponderance of hydrogen, a vegetable diet yielding marsh-gas. The high tension of these gases leads to their absorption, and excretion by the lungs, but the hydrogen being relatively unabsorbable is liable to produce distension. It has been estimated that six litres of carbon dioxide is liberated daily in the gut by the action of acids upon the sodium bicarbonate of the intestinal juices; this gas is readily absorbed, and excreted by the lungs. Dr. Campbell also indulges in speculation about the possible cause of tetany. Having shown that after muscular exertion the oxygen tension in the tissue is 25 per cent. above normal he analysed various predisposing causes of tetany, and found that in 11 out of 14 types experimentally produced there was an oxygen deficiency in the tissues. If one factor alone is responsible, the most constant is oxygen-want. It is suggested therefore that tetany is an effort to raise the oxygen tension.

MULTIPLE TERATOMATA.

TERATOMATA are generally explained as examples either of parthenogenesis or of the inclusion within the body of one of the members of a pair of identical twins arising from the separation of cells in the early divisions of the egg. Certain rare cases occur, however, which cannot with reason be brought within either of these categories, and their existence raises a suspicion that neither hypothesis may be necessary. Such an example is recorded by Dr. W. G. Barnard from University College Hospital.[1] A woman of 40 had ascites and abdominal discomfort for three months. At operation a cyst was found in the left ovary and numerous small tumours scattered about the peritoneum with larger masses in the omentum. She died 12 days later of peritonitis. The cyst, which contained no hair or sebum, was bilocular and in the diaphragm between was well-formed bone. Projecting from the ovarian surface of the cyst and continuous with the diaphragm was a solid lump of tissue which showed the same histological structure as the growths in the omentum and on the peritoneum, of which there were more than a hundred. All were typical teratomas and contained undifferentiated cells, spindle cells in groups and bands, cartilage, bone, a tooth, skin, columnar mucous epithelium and brain, including glia and nerve ganglion cells indistinguishable from the normal. No placental tissue was identified. To explain these facts a great many hypotheses might be made up. But the only reasonable interpretation seems to be that some months before the patient's death the tissues in the ovarian cyst broke out and were disseminated about the abdominal cavity, not as developed teratomata but as single cells or at most small groups of cells, each of pluripotent or totipotent capacities and capable of giving rise to most sorts of tissue. Dr. Barnard's and other cases seem to make it certain that such cells do or may exist or arise in the adult body; they would be more useful if they appeared in amputation stumps and achieved the regeneration of a limb as they do in lizards' tails. And it is plainly possibly that they might be the source of all teratomata.

DRAINAGE OF THE AQUEOUS HUMOUR.

IT is a somewhat humiliating reflection that even now there is no universal agreement among ophthalmologists on some of the fundamental facts of ocular physiology. Especially is this true of problems connected with intra-ocular tension and the circulation of fluids in the eyes. A recent controversy concerns the drainage of the anterior chamber, a matter of the first importance in connexion with glaucoma. What is generally taught is that the normal drainage of the aqueous humour takes place via the spaces of Fontana and Schlemm's canal, a slit-like space encircling the cornea, and connected both with lymph spaces and veins. W. S. Duke-Elder[1] maintains that only where intra-ocular pressure is abnormally increased is there any circulation of the intra-ocular fluid at all, properly so called, but that any change in the composition of the aqueous takes place by dialysis between it and the capillaries of the iris and ciliary body. Only in case of raised intra-ocular pressure can the condition of the venous circulation allow of the actual flow of aqueous fluid into the general circulation via Schlemm's canal. Lately this view has been challenged by Mr. F. Ridley,[2] who maintains that Schlemm's canal has no direct connexion with the venous system, but that there is a constant drainage of aqueous through the cornea into the conjunctival sac and that this drainage takes place chiefly via the filtration angle, where Descemet's membrane is absent. This thesis he supports by experiments on excised pigs' eyes and on the eyes of living rabbits. He maintains that the physiological conditions are such as to determine the constant passage of fluid through the cornea, that the flow takes place chiefly at the filtration angle and that its rate is determined by the intra-ocular pressure. We know by everyday experience that solutions of drugs such as atropine enter the eye from the conjunctival sac. The assumption that the fluid contents of the eye can pass outwards by the same route does not, on the face of it, appear improbable. On the other hand, Mr. Duke-Elder,[3] criticising Mr. Ridley's work, puts forward an experiment which to his mind is conclusive. A solution of methylene-blue is introduced into the anterior chamber of an anæsthetised dog under a pressure not exceeding 2 mm. In a minute and a half the episcleral veins are deeply dyed, whereas there is no coloration of either cornea or conjunctival sac. Mr. Ridley[4] replies that this experiment is irrelevant to his thesis. The methylene-blue, he says, has not reached the episcleral veins via Schlemm's canal, but via the capillaries of the ciliary body and iris by a process of simple diffusion. He objects that a minute and a half is too short a time for diffusion through the cornea into the conjunctival sac to appear. If that is all, however, it would surely be easy for him to repeat the experiment and allow a longer time for the appearance of the blue in the conjunctival sac. It does not appear that Mr. Ridley has succeeded in proving his point that the part played by Schlemm's canal in the drainage of the intra-ocular fluid is negligible. In this connexion we may recall a theory put forward by Prof. Arthur Thomson[5] at Oxford many years ago to the effect that that part of the ciliary muscle which is attached to the scleral spur takes an active part in widening Schlemm's canal, causing a negative pressure in it so that every act of accommodation must tend to facilitate drainage of the aqueous fluid. These physiological problems are not easily solved, but until agreement is reached there seems to be a certain futility about discussion of the pathological problems connected with glaucoma. Meanwhile treatment, and especially operative treatment, must remain largely empirical.

For a summary of the modern views on these physiological problems we may refer readers to an address by Mr. Duke-Elder published in THE LANCET of Jan. 4th, 1930.

ALCOHOLIC FERMENTATION.

EVERYONE is aware that the Lister Institute is doing pioneer work on filtrable viruses and accessory food-stuffs. The report presented to the annual general meeting on June 10th makes it clear enough that there is a similar liveliness in the department of biochemistry. During the year a definite stage was reached in Dr. R. Robison's investigations of the phosphoric esters formed during alcoholic fermentation. The attempt to separate and identify the component esters of hexosemonophosphate was begun some years ago in collaboration with Dr. E. J. King and the isolation of a glucosemonophosphoric ester has already been reported, but the properties of this compound showed that it still contained about 10 per cent. of some other ester of lower reducing power. The final stage in its purification has now been achieved. Evidence of the homogeneity of this ester was given by its behaviour on hydrolysis with acids, while the examination of the products obtained from it by hydrolysis and by oxidation and dephosphorylation have proved that it is a monophosphoric ester of glucose. Further evidence was obtained that the phosphoric acid group is attached to the terminal carbon atom of glucose and this conclusion has been confirmed by the study of its methylated products, carried out by Dr. W. T. J. Morgan, Dr. King, and Dr. R. R. McLaughlin. A second ester also isolated from hexosemonophosphate was shown to be very similar to Neuberg's fructosemonophosphate, while considerable progress has been made towards the separation of the residual fraction, in which at least one unidentified ester is known to be present. It had been previously mentioned that hydrolysis of fructosediphosphate by bone phosphatase does not yield pure fructose but a mixture of sugars containing glucose and fructose. A similar result was obtained on hydrolysis of the pure glucosemonophosphate by phosphatase. This increased lability of the hexose molecule during enzymic removal of the phosphate group is of much interest and may possibly throw some light on the mechanism by which esterification with phosphate facilitates the reactions occurring in carbohydrate metabolism.

Experiments have also been made by Prof. A. Harden and Miss M. G. Macfarlane (Carnegie Fellow) on the reducing properties of yeast with special reference to the alleged need for a co-reductase. Dried yeast which has been so thoroughly washed that it will not ferment a hexosephosphate without addition of coenzyme does not reduce methylene-blue, but can be reactivated by the addition of boiled yeast extract. Such a preparation can also be reactivated by the addition of a lactate, without any other addition. The reduction of methylene-blue which then occurs is accompanied by the evolution of a quantity of carbon dioxide approximately equivalent to the methylene-blue reduced, and arising presumably from the decomposition of the pyruvic acid formed from the lactate by oxidation. This observation affords no ground for the assumption that a co-reductase is required.

UPPER RESPIRATORY INFECTION AND RHEUMATISM.

THE relation of upper respiratory infection to rheumatism in childhood has long been argued over. Their association has indeed been noted for two centuries or more, though it remained until lately in the limbo of "clinical impression." W. P. S. Branson, in 1912, maintained that the mucous membrane of the nasopharynx provides the port of entry of the causative organism, and J. A. Glover in his Milroy lectures of 1930 adduced evidence of droplet infection.[1] Perhaps the most valuable contribution to the subject, however, is B. E. Schlesinger's description[2] of epidemics of nasopharyngeal infection in a convalescent home for rheumatic children. He found that the acute infection was often followed, after a latent period of 10–21 days, by acute arthritic or cardiac manifestations. This latent period suggests an allergic factor in the disease, and Schlesinger's original observation has opened up a new line of rheumatic research. Similar epidemics of upper respiratory infection in wards of convalescent rheumatic children at the Cheyne Hospital and the Lancing Convalescent Heart Home have now been studied in detail by Dr. W. Sheldon, and one of them by Dr. W. R. F. Collis from the bacteriological point of view. Their papers published in this issue show that here, too, there was a latent period between the original infection and the relapse, and the figures, with those of Schlesinger, indicate that while tonsillectomy may give some protection against upper respiratory infection, rheumatic relapses are relatively commoner in children whose tonsils have been removed. Sheldon did not find aspirin an adequate prophylactic against relapses, and points out that these may occur while the temperature is normal.

[2] Arch. Dis. in Childhood, 1930, v., 111.

The bacteriological findings are more controversial. Since the classical work of F. J. Poynton and A. Payne in 1900–04, many investigators have described organisms which they have held responsible for the manifestations of rheumatism and which have sometimes given a high proportion of positive skin tests in rheumatic subjects. Usually the organisms have been streptococci, and attention has mostly been focused on those of the non-hæmolytic group. But there is little similarity between many of the strains described, and arthritic lesions have been produced in rabbits by streptococci unrelated to rheumatism. Many authors on the other hand have found no one type of streptococcus consistently present in cases they have examined, and R. A. Macdonald,[3] reporting recently on a series of tonsils removed at operation, said he found it impossible to distinguish between the cultures from those removed from rheumatic children and those from the controls. In the epidemic at the Cheyne Hospital, Collis has isolated hæmolytic streptococci from the throats of patients in whom relapses occurred and has carried out skin tests with a soluble endotoxin and an exotoxin prepared from this organism. He finds rheumatic subjects highly sensitive to the former except during fulminating carditis. Control tests showed a high proportion of negative results. Further investigations on these lines will be awaited with interest, but at present the number of cases studied is small.

LOW BACK PAIN.

PAINS and disabilities centring in the lower back are often exceptionally difficult to diagnose and treat. At a lecture-demonstration at the British Red Cross Clinic for rheumatism on Tuesday, Dr. C. B. Heald classified the chief causes of low back pain into four groups: the "injury" group; the "constitutional disease" group (e.g., rheumatism, arthritis, gout); the "toxic" group, where the cause is constipation, appendicitis, or gonorrhœa; and the "congenital defect" group, where the pain springs from some anatomical abnormality, especially in a vertebra. Each of these groups has roughly its own diagnostic language, though of course most cases are to a certain extent mixed, but the clinician is often able to form fairly sound suspicions of the ætiology from a consideration of the physical type of the patient. According to Dr. Heald, patients can be divided broadly into the long-backed, the florid, the asthenic, and the healthy normal types. The possessors of long backs are, he says, especially liable to pure trauma, for they are working against an especially unfavourable leverage. Patients with a florid stout appearance should suggest arthritis or gout as the chief enemy. The toxic group of low back disabilities is chiefly made up of patients of the asthenic type, who show lordosis and kyphosis. The congenital defect is elusive, and its diagnosis depends largely on the elimination of other causes and an X ray.

Dr. Heald demonstrated tests of value in diagnosis and in the control of treatment. Mennell's test determines any inflammation or irritation of the roots of the sciatic nerve; the psoas and sacro-iliac joint are tested by the leg-lifting test, compression and separation of the iliac crests, arching the back in the prone position, and passive hyperextension of the hip-joints. Specific injury, if it does not fracture a transverse process, mostly tears fibres in the common aponeurosis or the ilio-lumbar ligament, and the patient will be able to lift one leg but not both when separated. Mennell's test will often find out the "constitutional disease" type, in which the arthritic or rheumatic lumbar spine irritates the sciatic nerves, while the patient will lift both legs and submit to having the iliac crests firmly handled. Moreover, he cannot stand hyperextension of the hips. Patients in the toxic group are also likely to show a positive Mennell's test on the painful side from sciatic involvement, and a slackness of the common aponeurosis which hinders leg-lifting. Their sacro-iliac joints are tender from loss of tone rather than acutely painful from definite injury. Trunk-lifting generally leads to dismal failure through rapid muscular fatigue, and hyperextension of the hips may be painful but full or excessive. The congenital-defect patient, whose defect is unmixed with other causes, may pass all the tests.

In discussing treatment, Dr. Heald laid stress on the value of extensive lumbar strapping for aponeurotic tear. He showed a patient in whom this method had relieved serious pain of ten years' standing, and in whom it had been replaced by a celastoid belt for permanent wear. The constitutional disease type, he said, benefits from physiotherapeutics and exercises, and its lordosis should be given special attention. The badly toxic patient should be immobilised as for a fracture until the muscles can be restored by rest, regulation, and the removal of foci. The congenital defect can sometimes be removed by operation, but is only too apt to cause further trouble.

JESSE BOOT OF NOTTINGHAM.

Lord Trent, who died in Jersey last Saturday, will be chiefly remembered as a Freeman of Nottingham who earned vast wealth and put it to worthy ends. Grandson of an agricultural labourer and son of a herbalist, he was born 81 years ago in Nottingham, and at the age of 13 took control of his father's shop in Goose Gate. Spending his spare time in studying pharmacy he opened 14 years later a chemist's shop in a working-class neighbourhood of Nottingham, which was the forerunner of a retail chemists' undertaking employing 13,000 people. Under his direction the firm of Boots soon began to manufacture their own drugs and were in the position to supply to the troops during the war a hundred millions or more of water-sterilising tablets, while Sir Jesse himself in collaboration with Colonel E. F. Harrison devised the box respirator for which the firm supplied all the chemicals required. On his native city Sir Jesse spent nearly a million pounds, his greatest gift being the new University College at Highfields in which he endowed several scientific chairs. His wife and he also built hostels for students on a lavish scale. To ensure a noble appearance for the East Midland university, which he saw in imagination, he laid out a broad street a mile long bordered with rhododendrons to be named the University Boulevard. His benefactions in his wife's home of Jersey to which he retired were of similar intent and on a like scale. He initiated a scheme for coöperative marketing by Jersey farmers and built schools and workmen's houses. This achievement is the more remarkable when it is remembered that for 30 years he had been completely crippled by myositis ossificans.

ON June 8th Surgeon Rear-Admiral Reginald Bond was received by the King upon his appointment as Medical Director-General of the Navy from July 1st.

SPECIAL ARTICLES

HARVEIAN SOCIETY CENTENARY.

LAST week the Harveian Society of London celebrated the conclusion of its hundredth session by recalling scenes in William Harvey's life and assembling many of those who honour his memory. The celebration opened with the delivery of an oration, published in our columns last week, by Dr. Raymond Crawfurd, on the place of medical societies in the progress of medicine.

EXHIBITION OF RELICS.

Members of the society were entertained to tea on Thursday in the Great Hall of Harvey's hospital, where an attempt had been made to arrange an exhibition of Harveian relics. It must be admitted, however, that in spite of Harvey's long association with St. Bartholomew's practically nothing has survived which can be regarded as having a personal connexion with Harvey himself. The nearest approach is the fine pewter inkstand, given to the hospital by Martin Bond in 1619. This almost certainly was used by Harvey when he attended at the hospital, and it still stands on the table in the Treasurer's office, though a replica has been made for his use. The other treasures in the exhibition dated from the earliest days of the hospital down to the end of the seventeenth century. They included a deed making a grant by Rahere to Hagno in 1137; a deed of covenant signed by Henry VIII. in 1546; and the well-known Cartulary of John Cok, 1456–68. Other manuscripts were the volumes of the hospital ledgers and journals covering Harvey's time, and another of definite Harveian interest was the repertory book, with the plan of the hospital as it was in 1617. Harvey never actually lived in the hospital, but this plan was made during the period of his service, his appointment as physician to the hospital dating from 1609. The hospital silver was also exhibited, the earliest piece, a tall cup with a baluster stem, having been given by "John Jones, Cittizen and Marchant Taylor of London." in 1639. In addition to these relics there were shown reproductions of all the known portraits and busts of Harvey, and an almost complete range of the editions of his three books: *De Motu Cordis, De Circulatione Sanguinis, De Generatione Animalium.* A few of these were from the St. Bartholomew's College library, but the first edition (1628) of *De Motu Cordis* was lent by the Royal College of Physicians of London, together with the editions of 1639 and 1643. The Royal College also lent the two editions of the *De Venarum Ostiolis* by Fabricius published in 1603 and 1624, the plates in which were the source of the famous engraving in Harvey's work. The first edition of *De Circulatione Sanguinis* was lent by the Royal College of Surgeons, together with the first English translation of *De Generatione* (1653), a copy on fine paper with the engraving by Faithorne. Another fine example of this engraving was lent by Sir D'Arcy Power. It is regarded as probably being the best representation of Harvey in existence. Another book of extraordinary interest was the copy of the first edition of *De Generatione Animalium,* containing notes upon Aristotle in Harvey's own hand on the fly-leaves. This had afterwards belonged to Harvey's brother Eliab, and contains his signature. It was lent to the exhibition by Mr. F. C. Pybus, of Newcastle. Other examples of Harvey's crabbed and difficult handwriting were two brief signed notes. One of these belongs to the hospital; the other was lent by the Wellcome Medical Historical Museum, together with a number of paintings and other objects of interest. Among the books were some very uncommon editions, notably those of *De Motu Cordis,* published at Padua in 1689, and at Bologna in 1697, of each of which only one other copy has been recorded.

BUCKSTON BROWNE DINNER.

A festival dinner was held at the Grocers' Hall on Friday evening when Prince Arthur of Connaught was the principal guest. Sir Thomas Horder, president of the society, who was in the chair, announced the election of Prince Arthur to honorary membership of the society, handing him a gold medal specially struck to commemorate its centenary.

Prince Arthur, in proposing "The Society," spoke of its endeavour to maintain the spirit of Harvey. As chairman of the Middlesex Hospital he was, he said, deeply interested in all that related to the progress of medicine, and he regarded societies like the Harveian as assisting greatly in the expansion of medical science and the development of medical services.

Sir Thomas Horder, in reply, greeted Prince Arthur as a Freeman of the Worshipful Company of Grocers, in whose beautiful hall the feast was being held. Although William Harvey was not a Grocer himself, three of his six merchant brothers belonged to the Company, an association which had no doubt influenced the Master and Wardens in their decision to offer hospitality on this occasion. The Harveian Society, he said, had not departed from the spirit of its eponym. In its presidential chair had sat physicians like Richard Quain, William Broadbent, Hughlings Jackson, Thomas Buzzard, John Williams, James Goodhart, and Malcolm Morris; surgeons like John Erichsen, Henry Thompson, Thomas Bryant, Watson Cheyne, C. B. Lockwood, Henry Power, and his equally distinguished son D'Arcy Power. Harveian lecturers such as Jonathan Hutchinson, Francis Champneys, Buckston Browne, Almroth Wright, StClair Thomson, Arthur Keith, and Berkeley Moynihan had made evident the society's efforts to search out the secrets of nature. It was, he said, difficult for us to speak of William Harvey in moderate language. He was so easily the central figure in our annals and the founder of scientific medicine in this country. As Cæsar appeared to Cassius in relation to the Roman republic, so Harvey appeared to us in relation to British medicine—"He doth bestride the narrow world like a Colossus; and we petty men walk under his huge legs, and peep about to find ourselves dishonourable graves." Harvey had done a much greater thing for medicine than to establish beyond all doubt the physiological principles governing the circulation of the blood. He introduced rational and scientific methods into the chaos of empiricism, speculation, and wild hypothesis. Imagination boggled at the thought of what medicine was before Harvey. A friend of his, speaking of to-night's engagement, had said "Harvey? that was the man who discovered the circulation of the blood, wasn't it?" adding, after a pause, "I think they really must have known about it before." A few days ago, Sir Thomas went on, he had joined in a search for those caves in the garden at Coombe Lodge, Croydon, where, said Aubrey, Harvey was wont to sit and meditate. He did not find them, but was able, nevertheless, to capture something of the Harvey atmosphere in the old garden where Dr. George Ent had sought out Harvey and induced him reluctantly to part with his book *De Generatio Animalium*. He concluded by thanking Prince Arthur for his good wishes and assuring him that the society would strive to justify the distinction which his name had given to its roll.

Sir StClair Thomson, as an honorary member and one of nearly 40 years' standing, bade the guests welcome. He quoted a saying about Sir Astley Cooper that he had passed "through the hearts of the poor into the pockets of the rich," adapting it to apply to Prince Arthur who, as treasurer of the Middlesex, had passed "through the pockets of the rich into the hearts of the poor." Prof. W. H. Welch replied for the Harveian Society of New York as one who occupied the chair of medical history at Harvard. "Permit me to say," he kindly remarked, "you do these things extremely well." He described the effect of anniversary celebrations of this kind in stimulating the advancement of medical knowledge. Lord Dawson, who also replied, spoke with feeling of the ties of medical comradeship. In no other field, he said, do we work in such harmony. Dr. D. Elliot Dickson, representing the Harveian Society of Edinburgh, was induced to tell a story.

The guests included Dr. R. A. Young (President of the Medical Society of London), Dr. Raymond Crawfurd, the Archdeacon of London, Sir Farquhar Buzzard, the Master of the Apothecaries, Prof. W. Blair Bell (President of the British College of Obstetricians and Gynæcologists), Sir Arthur Gaskell, the Master of Caius College, Sir Dudley Ridout, and Dr. H. B. Brackenbury.

PILGRIMAGE TO HEMSTEAD.

The centenary celebrations ended auspiciously in a summer day's pilgrimage on Saturday to Hempstead Church where William Harvey and many of his family are buried "lapt in lead" in the Harvey Chapel. His remains were transferred in 1883 from the vault beneath the church, at the charge of the Royal College of Physicians. The journey was made by road and the party, which included a large number of ladies, was received by the vicar, the Rev. Conyers Barker, at the church where a short service was held, the address being given by the Right Rev. T. A. Chapman, D.D., Bishop of Colchester, and a collection was taken in aid of the fund for rehanging the bells when the new tower is built to replace the one that collapsed in 1882. Sir Thomas Horder then offered, on behalf of the Harveian Society, a silver paten, which was received and consecrated to the use of the church. The party inspected the Harvey relics contained in the church and its vault, and took luncheon in the vicarage garden. The members then proceeded to Rolls Park, Chigwell, near Loughton, where they were received by Lady Francis Lloyd, and Sir D'Arcy Power gave a short account of William Harvey in his family relationships.

CONTRIBUTORY SCHEMES AND PUBLIC ASSISTANCE. The Leeds public assistance committee has adopted a scheme for providing hospital treatment for the contributors to the Leeds workpeople's hospital fund and their dependants. A payment of twopence per week will entitle the beneficiaries to treatment at the hospitals of the public assistance committee or at the public dispensary and nursing societies of the city. The workpeople's fund will pay to the Leeds corporation £1 5*s*. for each in-patient within the city—tuberculous, mental, chronic, maternity, and notifiable diseases cases excluded. The full rate of maintenance and treatment will be paid for patients outside the city area.

ROYAL INSTITUTE OF PUBLIC HEALTH.

ANNUAL CONGRESS AT FRANKFORT-ON-MAINE.

THIS congress was held from May 19th to 24th. From Frankfort opportunity was taken to visit the spas of Nauheim, Homburg, Wiesbaden, Kreuznach, and Munster a. St., and on the outward journey most of the visitors called at Aachen to see the Quellenhof and the Landesbad with its baths for insured patients. The sessions of the congress were held in the lecture rooms at the Städtisches Krankenhaus, a hospital of some 3000 beds. Of the numerous papers read at the six sections only a few notes can be given here.

Section of State Medicine.

DIABETES.

Dr. G. SINGER (Vienna) said that the increase in the extent of diabetes and the peculiar difficulties of dealing with this disease have brought it within the sphere of public health activity in Vienna. The discrepancy between our considerable scientific knowledge of the disease and the results of treatment are most marked in the age-group 25–55, the most productive years of man's life. In Vienna a welfare centre has been set up confined to the very poor; it has been so successful that doctors are anxious to send both private and insured patients to the centre. In 1930 2000 patients attended; those requiring hospital treatment were recommended to go to hospital; the bulk were dealt with at the centre. The installation of special kitchens for diabetes is an important advance. Dr. Singer considers that many diabetics can be efficiently treated and more cheaply without insulin.

Dr. L. R. GROTE (Frankfort) pointed out that in the German public hospitals the number of patients admitted for diabetes had increased by 80 per cent. from 1924 to 1927; the increase is due to treatment by insulin and to the diminution of the mortality in children which can now be reduced to nil. The treatment of diabetics is usually extended over too long a period; they ought to be treated intensively either in a special clinic or in a special division of a hospital. In the Carl von Noorden Clinic at Frankfort, the severest cases are made fit for work in about 18 days. Subsequent treatment and advice could well be given at special welfare centres. Dr. Grote also advocated the institution of homes for diabetic children where they would be instructed on diet.

CANCER.

Herr GRUNEISEN, general secretary of the German Society for Combating Cancer, pointed out that owing to better methods of treatment in the last 20 years there had been a lessening of mortality from cancer during the middle period of life. For the diagnosis and treatment of cancer centres should be established in connexion with university clinics and the large hospitals. A concentration of all the cases of cancer in such centres is not desirable or necessary; the cost of the apparatus and the difficult X ray and radium technique, however, compel a certain amount of concentration. An important duty of the cancer centres would be the following up of all patients treated for at least five years. No effort must be spared to prevent sufferers being treated by quacks.

VENEREAL DISEASES.

Dr. ROESCHMANN, general secretary of the German Society for Combating Venereal Disease, gave an account of the working of the law relating to the prevention of venereal disease passed by the Reichstag in 1927. This requires that anyone knowingly suffering from venereal disease or having reasonable cause to believe themselves to be infected must submit themselves to medical treatment by a qualified medical practitioner. Parents and guardians must similarly see that children under their care so suffering are treated. The competent sanitary authority may require persons whom they have reason to believe are suffering from and disseminating venereal disease to produce a medical certificate as to their health. Persons suffering from and suspected of disseminating venereal disease may be subjected to curative treatment and may be detained in a hospital if such detention appears to be necessary to check the spread of the disease. Medical treatment involving serious danger to life shall only be undertaken with the consent of the patient. Any person cohabiting while knowingly suffering from contagious venereal disease or having reasonable cause to believe himself infected shall be liable to imprisonment; a similar penalty can be enforced if any such person marries without informing the other party to the marriage of such infection. Only qualified medical practitioners may treat venereal diseases and diseases of the genital organs; the treatment given must be more or less orthodox. This section also requires examination of the patient by the doctor; there must be no treatment by correspondence (absentee treatment). The giving of advice by lectures and so forth on self-treatment is also prohibited. Anyone who medically examines or treats a patient with venereal disease must inform him of the nature of the disease and the danger of spread and give him a copy of the official memorandum on the danger of venereal disease. Any patient under observation or treatment who fails to attend or who in consequence of his occupation or other circumstances is especially dangerous to other persons must be notified by the doctor in attendance to the sanitary authority. Secrecy is ensured by the infliction of a legal penalty on any employee of a sanitary authority or venereal disease centre who discloses information acquired in the course of his duty as to the existence of venereal disease in any person or its source. Such disclosure may, however, be made by a medical practitioner in the service of the sanitary authority or venereal disease centre or with the consent of such medical practitioner to a public authority or to any person who is entitled to such information in the interests of his own health. The advertising or recommending to the laity of any drugs or treatment for venereal diseases is forbidden under a penalty. The Government may test drugs intended for use as preventives of venereal disease and, if necessary, may stop their sale. Regulations may also be made as to the display, advertising, and recommendation of any approved drug. The law also deals with the prevention of spread to or by babies and children.

In the course of discussion Dr. Roeschmann said that in Germany brothels were being gradually closed. He thought that accosting could be controlled by the police; this had been effected in Hamburg where, shortly after the war, it became so intolerable that the public complained, also in Carlsruhe where the Minister concerned had investigated the matter personally and ordered the police to take action.

CRIMINAL ABORTION.

Dr. V. BORLAND and Councillor BENNETT (Bethnal Green) in a joint paper stated that the traffic in "female remedies" is very considerable; practically every pharmaceutical chemist stocked one or other of these preparations as a regular line: they were even more prominently displayed by the herbalist and "hygienic store." An ergotin and aloes compound pill sold virtually to secure abortion could be freely obtained from any wholesale patent medicine house; the cost was high—*2s. 6d.*, *3s. 6d.*, or even more a box. "Orange pills," in regular demand in the East End of London, were sold by unqualified drug stores at 1*s.* for six pills; they contained aloes, liquorice, and colocynth, and are no more than a strong laxative. These fraudulent preparations are sold to women who are in a state of the direst poverty. During 1930 66 cases of abortion occurred in Bethnal Green: five of the women died. Nineteen deaths from childbirth occurred in the last two years, seven of these being due to septicæmia following abortion. The taking of pills and drugs was definitely ascertained in two cases; in three other cases there was reason to suspect instrumental interference.

SCOLIOSIS.

Mr. G. R. GIRDLESTONE (Oxford), in an account of the English orthopædic schemes, referred to the insidiousness of scoliosis which when once established cannot be completely cured and which is often progressive throughout childhood and again after middle life, yet no parent is prepared to take a child to a distant hospital even once for a defect which is so intangible until well established; only when there is an orthopædic clinic nearby with its consequent automatic instruction of the mothers in the vicinity will such defects, easily cured in their early stages by remedial exercises, be prevented.

DISINFECTION.

Dr. ROSENHAUPT (Mainz) regretted that the disinfestation of dwellings by hydrocyanic gas liberated from zyklon was not allowed in Germany; its use is permitted in Scandinavia, Austria, and Hungary. In Germany, however, zyklon may be used for premises other than occupied dwellings. He described a hydrocyanic gas chamber which can be charged and emptied without anyone having to enter it. For the disinfestation of dwellings he recommended the use of diametan, a mixture of sulphur with an oxidising agent; this liberates sulphur trioxide at high pressure.

Section of Industrial Hygiene.

ENGINEERING RISKS.

Dr. A. MASSEY (Coventry), dealing with the health of workers in the engineering industry, said that some 50,000 persons in the city of Coventry were engaged in the engineering trades. The health of workers in an industry depends not a little on the health of the industry itself; good trade means regular employment, decent earnings, and relief from mental anxiety attendant upon economic stress. Home conditions are of basic importance; it is very little use to work in a hygienic factory if the worker has to live in a slum. Many engineering processes tend to eliminate the physical misfits at an early stage; at a later stage there is also a selective transfer from engineering to other vocations when advancing age finds engineering too exacting; the proportion of workers over 50 years of age in this trade is considerably less than that of workers in all occupations collectively. In engineering shops heat is often a detrimental factor; this has to be countered by the cooling powers of adequate ventilation. The dangers to health from sand-blasting, the process used for cleaning the surfaces of castings and heat-treated machine details by impinging sand under high pressure, are somewhat difficult to counter. Some of the fine particles of silica penetrate the fabric of the helmet or gain access under the cape attachment; although the *maintenance* of a positive air pressure inside the helmet is of service, the use of shot instead of sand should be considered; the shot do not fracture or become pulverised. Even then the danger from silica is not entirely removed: the rough castings before treatment are coated with sand burnt on during the moulding; shot-blasting breaks off these particles producing a fine silica dust which must be guarded against. Respirators are unfortunately not ordinarily employed during the sieving of used mould sand. Chromium plating has been increasingly used of late to render bright motor-car and cycle fittings untarnishable. The worker is very apt to inhale chromic acid fumes; the respirators supplied are often only used when the men are under direct supervision. In cellulose spraying the emanations in the spraying chamber and its immediate vicinity are very pungent; they contain certain benzene derivatives which are occasionally the source of benzene poisoning and at times include amyl nitrite as a decomposition product; the inhalation of this substance may conceivably bring about cardiovascular changes. Oil dermatitis and boils cause much trouble among operators of turret and automatic machines; for cooling these during metal-cutting operations large quantities of a special expensive oil are used. It is used over and over again and soon swarms with micro-organisms especially streptococci; other impurities and metallic particles are present. The addition of a bactericidal fluid miscible with oil serves to prevent boils, but oil dermatitis caused by the action of the metallic particles and other impurities continues to be not uncommon.

Dr. H. L. Garson (Port Sunlight) set out his nine years' experience of the medical examination of employees at a food factory employing some 500 workpeople. The employees are examined before being accepted for work; in order to be certain of excluding workers with septic cuts or sores on the hands and arms it is made a condition of employment that the employees shall submit to re-examination if so required. Of 475 girls examined between the ages of 14 and 18, 54 were rejected; 49 of these owing to lack of personal cleanliness, but only 5 on account of physical defect. Any defects found in those passed as fit for work are noted and treatment secured: girls under 18 who have dental caries or a defect of vision must submit to treatment. Smaller employers by combining among themselves could do much to reduce the cost of medical treatment, some of which can be given under the panel system. In answer to a question Dr. Garson stated that during nine years' work in the food factory he had not come across a single case of enteric fever or dysentery among the employees.

MOUNTAIN SICKNESS.

Prof. Koelsch (Munich) addressed visitors to mountainous resorts. He considers that when climbing mountains, possibly carrying a load—in other words, a rücksack—persons especially sensitive may be attacked by mountain sickness even at a height of 1000 to 2000 metres. When the ascent is passive—i.e., riding a horse or mule or by mountain railway—the critical altitude is about 3000 metres. The rapidity with which height is attained comes into play; the longer the time taken the longer have the body mechanisms to accommodate themselves to the altered conditions. The Austrian Zugspitze railway takes only 20 minutes to ascend about 1900 metres, whereas the Bavarian electric railway requires an hour to reach the same altitude. The authorities of mountain railways going up to great heights should be required to put up a notice at the starting station giving advice to elderly and delicate persons, especially to invalids with heart or lung complaints or with high blood pressure, marked anæmia, and possibly ear troubles. Notices should also be posted in the carriages and at the various stations advising passengers, especially elderly and delicate persons, on alighting to rest in order to become acclimatised. It is also advisable that the rate of ascent should be fixed at 20–30 mins. per 1000 metres difference in altitude. An acclimatisation station between the second and third part of the journey would be useful; persons feeling discomfort on the way up could alight in time.

EXHAUST GASES.

Prof. Gross (Ludwigshafen) did his best to dispel any fear of the danger of exhaust gases from motor traffic in streets. He found that when the engines are running at full speed the exhaust gases contain only a small percentage of carbon monoxide, 0·1 per cent. by volume as opposed to 6·8 per cent. when running light; similarly unburnt motor spirit is much more abundant when the engine is running light. But much dilution of the exhaust gases occurs even at a distance of one metre from the car; with increase of the velocity of the motor-car further dilution takes place. In a car standing still there was 3 per cent. of carbon monoxide in the exhaust and less than 0·1 per cent. at a distance of a metre. Travelling at the rate of 10 kilometres an hour there was 6·5 per cent. of carbon monoxide in the exhaust and less than 0·1 per cent. at a distance of one metre; when the speed was increased to 20 kilometres there was 9·6 per cent. of carbon monoxide in the exhaust and less than 0·1 per cent. at the distance of one metre. No danger is to be apprehended from the air in well-ventilated tunnels; in the tunnel under the Elbe at Hamburg, which is provided with adequate natural ventilation, the percentage of carbon monoxide was found to vary from 0·005 to 0·023. The results of 101 analyses of air collected in streets mostly during rush hours under varying conditions of temperature and meteorological conditions at the level of the head of a policeman on six occasions only gave a percentage exceeding 0·015, the highest being 0·023; the air examined at the same spot a few minutes later contained far less carbon monoxide. Seeing that danger only arises from breathing 0·02 per cent. of the gas for several hours even persons stationed on duty in streets run no danger of carbon monoxide poisoning. There is also no danger from unburnt motor spirit in the exhaust gases liberated in the streets; experiments on animals showed that 10 to 15 times the amount present in exhaust gases must be reached before such unburnt spirit could cause trouble.

Section of Women and Children.

Prof. Grotjahn (Berlin) pointed out that in the last decade the birth-rate has fallen to 16 per 1000 in England and 18 in Germany; half of what it has been. Unless steps are taken the birth-rate will fall further. States which depend on commerce and industry require a certain density of population and must guard against dwindling. A diminution must occur if families are to consist of two children only; for maintenance of the number each family must have on the average three children, and as this will not occur in each individual family it is essential for the State that there should be many families with more than three children. Dr. Grotjahn considers that the time has come for an appeal to parents to beget children; the burden should be adjusted by making family allowances to those drawing regular wages and by compulsory insurance for parenthood for others.

Prof. E. Schlesinger (Frankfort) said that during the last few months a retrogression had occurred in the state of nutrition of the children of the working classes. Too little milk and milk foods were consumed and in the winter months too little vegetables; the cheaper kinds of meat and sausages were being used. Very valuable is the milk breakfast with its 260 calories and the dinner with its 500-600 calories and abundant vegetables provided by the schools.

Section of Tuberculosis.

THE GERSON DIET.

Discussion on the influence of diet on tuberculosis was stimulated by the presence of Dr. Gerson, one of the originators of the salt-free diet. Opinion among those present was, on the whole, averse to its use—at least, for cases of pulmonary tuberculosis. Dr. G. Schröder (Schömberg) considered such a diet dangerous to some patients. Dr. O. Amrein (Arosa) held that patients treated for tuberculosis could not all be given the same diet; differences in national dietaries stood in the way. Although he had seen astonishing results obtained by Prof. Sauerbruch at Munich in cases of surgical tuberculosis, and especially in patients with lupus given a salt-free diet, he had given it up himself in pulmonary tuberculosis. Prof. L. Brauer (Hamburg) had caused consecutive patients admitted to his institution to be sent alternately to one pavilion when they were given salt-free diet, and to another when they were given the ordinary full diet; no difference could be detected in the results. Prof. F. Volhard (Frankfort) explained that in the treatment of pulmonary tuberculosis by a salt-free diet Gerson holds that the diet should be largely vegetarian with but little meat, and the body should be saturated with vitamins, whereas Herrmannsdorfer allows food rich in protein and not so restricted as to meat. Both have prescribed a so-called "Mineralogen," a mixture of calcium salts and phosphorus with cod-liver oil; this is, however, apparently no longer considered an essential part of the treatment. Common to both diets is the increasing restriction of sodium chloride. Although he had found no benefit to tuberculous patients by giving them a salt-free diet he was certain that such a diet was of benefit to patients suffering from other diseases. The salt in the food should be limited so that the chloride excretion in 24 hours does not exceed 1 g. The kidneys are saved work, the quantity of circulating blood is lessened; blood pressure often falls, and attacks of angina pectoris cease.

EARLY SIGNS.

Dr. J. Strasburger (Frankfort) reported that examinations of contacts with tuberculous patients carried out at the University polyclinic at Frankfort, in which X rays had been largely employed, showed that in 2·6 per cent. there was a manifest lesion of the lungs. All these contacts were apparently healthy and would not have sought medical advice. Control examinations of about 1400 students and nurses resulted in the discovery of only one case of tuberculosis. The form taken by the disease in the contacts was the *Früh-infiltrat*, which usually can only be detected by X ray examination.

Dr. J. Rennie (Sheffield) emphasised the importance of dealing with cases of pulmonary tuberculosis before they became sputum-positive. In Birmingham, London, and Sheffield a rough comparison of the percentage of sputum-negative cases treated in sanatoriums is 30·3, 20·5, and 81·7 respectively; these figures indicate that in Sheffield for every infectious case of pulmonary tuberculosis treated in sanatorium four non-infectious cases are so treated. The position to-day is that no physician can guarantee a complete cure to an infectious case of pulmonary tuberculosis however localised the initial lesions may be. Of 7231 sputum-positive cases recorded in Sheffield since 1911, 80·4 per cent. have died of pulmonary tuberculosis; 2 per cent. have died of other causes. In no area can the death-rate be appreciably lowered by curing infectious cases of pulmonary tuberculosis; to effect this it is necessary to diagnose and treat the disease before the sputum-positive stage. He holds that where definite infiltration is shown by radiographic examination physical signs are present. Whether such patients are in the active stage of the disease or not can only be determined by admitting them for observation.

COLLIERS AND SILICOSIS.

Prof. S. Lyle Cummins (Cardiff), speaking on coal-miners and tuberculosis, said that coal-miners, although so constantly exposed to the inhalation of both coal dust and stone dust, are notoriously less liable to pulmonary tuberculosis than the rest of the adult male population in Great Britain. There is, however, a high death-rate of colliers from bronchitis. A large proportion of elderly coal-miners are affected with a degree of silicosis which though not sufficient to prevent them from working is sufficiently advanced to give rise to the radiological appearances characteristic of lung fibrosis; such men tend to be short of breath on exertion and are liable to have a cough and bring up rather copious sputum, often black in colour; they are also subject to fairly frequent attacks of catarrh. Apart from the stone dust used to prevent explosions there is also present in the air of coal-mines stone dust from the ripping of the roof, the repairing of the walls and road, and from the coal face when the seam has to be reached by drilling "hard headings." Prof. Cummins believes that fine particles of silica are taken up by alveolar phagocytes and carried into the intercellular spaces of the alveolar walls. Thence the dust-laden cells enter the lymphatic vessels; the silica particles undergo slow solution and the silica sol thus produced causes a fibrosis to be set up. The dust cells agglutinate in the lymph channels obstructing the circulation, ultimately causing local stasis; around these accumulations of cells fibrosis also occurs. The presence of coal dust in the lungs of experimental animals has been found to have a definite protective effect against tuberculosis; its anti-tuberculous properties may depend upon its well-known powers as an adsorptive agent.

MEDICINE AND THE LAW.

Coöperative Drug-supply: Unsuccessful Action against the Minister of Health.

The difficulty of obtaining any remedy against a Minister of the Crown was shown last month by an unsuccessful action against the Minister of Health. The third schedule of the Medical Benefit Regulations governs the supply of drugs and appliances under the national health insurance system; its provisions are part of the terms of service agreed a few years ago with representatives of the pharmacists. If the Attorney-General is correctly reported, he stated that "it was understood or agreed that the terms should apply for a period of six years." In the schedule it is stipulated that no chemist shall give or offer to any person any gift or reward "whether by way of a share of or dividend on the profits of the business or by way of discount or rebate or otherwise" as an inducement towards, or in consideration of, such person presenting an order for drugs or appliances on a prescription form under the regulations. It is easy to imagine the kind of abuse at which the stipulation was aimed. But the result was to make a coöperative society unable to pay dividends on health insurance prescriptions dispensed in coöperative drug stores. The societies not being entirely devoid of influence, the Minister of Health proposed to cancel the obnoxious stipulation. The proposed change affected the prospects of some 10,000 retail pharmacists throughout the country who objected to the deletion. They applied to the Chancery Division for a declaration that the Minister was not entitled thus to alter the terms of their contracts with the insurance committees, and for an injunction to restrain him from carrying out his intention. The Minister, of course, has large powers of making and altering regulations under the National Health Insurance Acts, but the plaintiffs argued that his present proposal was not a bona-fide exercise of such powers. Appearing on behalf of the Minister, the Attorney-General contended that the plaintiffs' action was misconceived, that it disclosed no consideration for the alleged agreement, and that the bargain was legally invalid. He applied to strike out the claim on the ground that it did not disclose any reasonable cause of action; the proper remedy, if any, was by way of petition of right. The court agreed; it would be a waste of time and money for the plaintiffs to continue their action in the present form; the action was therefore dismissed with costs.

The Crown is notoriously a well-equipped and relentless opponent. The almost archaic procedure by petition of right, which the Pharmacists' Union has now been told is its only method of attack, is something of a scandal. It is slow and costly. The legal advisers of the Crown can hamper the petitioners at every turn. The petition cannot be set down for trial until it obtains the "fiat" of the Crown ("that right be done"); the granting of the "fiat" is an act of grace. In several ways the rights of an ordinary plaintiff disappear when the Crown is defendant. The Crown can obtain discovery of documents in support of its case; the petitioner has no such right against the Crown. In other respects (counter-claim, pleading, and amendment) the Crown enjoys technical privileges which have long ceased to exist as between ordinary litigants. The unfairness of the procedure against government departments was fully illustrated in the years following the termination of the war. The experience led to the setting up of a Crown Proceedings Committee; but there were unaccountable delays in its deliberations, and ultimately Lord Haldane bade it formulate legislation on the express assumption that reform was essential. Some years after the committee was set up it produced a well-drafted bill to make sweeping changes. The ancient principle that the King could do no wrong (originally, perhaps, based on the difficulty of suing the King in his own courts) was to be abolished, as has already been done in the Dominions overseas. The Crown could then be sued in damages if the servants of the Crown were guilty of negligence or other misconduct. Nothing, however, has been done to carry out the committee's proposals, though both branches of the legal profession have publicly demanded that this reproach to English justice should be removed. At least one eminent judicial authority has attacked the evils of bureaucracy. Here is an evil with the cure ready to hand. The law is amply represented in both Houses of Parliament. Its representatives would serve their country well by pressing for the consideration of the Crown Proceedings Bill. If, as in the present instance the retail pharmacists have no valid legal grievance against the Minister, it should be possible to establish the fact without recourse to procedure which expert opinion condemns as unfair.

THE SCOTTISH CENSUS OF 1931.

(FROM OUR EDINBURGH CORRESPONDENT.)

IN answer to a question in the House the Secretary of State for Scotland has issued the provisional summaries of the recent Scottish census. The population of Scotland shows a fall from 4,882,497 in 1921 to 4,842,554 in 1931; a decline of 39,943, or 0·8 per cent. At the last census the increase of population was trifling, and the present decrease is hardly a surprise. The causes cannot be fully analysed until the detailed returns appear, but at least some of the causes are easily guessed. The census of 1921 had, on account of the coal strike of that year, to be taken in June instead of in April. This affected the local populations and made some confusion for the administrative bodies, especially those of the small summer holiday resorts; but this could not touch seriously the total for Scotland. Two main causes of the decline are suggested: the drift of industry southwards to England, a theory that cannot be verified until the English figures are ready, and the falling birth-rate, which is true of Scotland as of England. Emigration was mounting in the early days of the decade, but it has recently fallen materially. This should count towards an increase of the population, and yet the population has fallen.

TOWNS AND RURAL AREAS.

The 24 towns over 20,000 at last census show a net increase of 65,810; 15 of them show an increase of 84,818, but 9 of them (coal, iron, and shipping) show a decrease of 18,908. Glasgow has increased by 36,890, or 3·5 per cent., now standing at 1,088,417; Edinburgh by 18,734, or 4·5 per cent., now standing at 438,998. The two cities of Dundee and Aberdeen show increases of 7268, or 4·3 per cent., and 8298, or 5·2 per cent. respectively.

Of the rural areas, some show very serious decreases. Argyllshire declined from 78,862 to 63,014, or 18 per cent., but this was, at least in part due to the "holiday" factor. Bute, another "holiday" area, fell from 33,711 to 18,822, or 44 per cent. In both these extreme cases, however, there was probably a more fundamental drift from the "land" to the town. Caithness, an agricultural and fishing county, fell by 2629, or 9·3 per cent. Ross and Cromarty, which includes the island of Lewis, fell by 8016, or 11·3 per cent. This is almost entirely an agricultural, fishing, and sheep county. The biggest decline in a purely rural county, except Argyll, is shown in Wigtownshire, which fell by 1484, or 4·8 per cent. Of the northern island groups, the county of Orkney shows a decline of 2036, or 8·4 per cent., and Shetland, 4110, or 16·1 per cent. The populations of these two are now 22,075 and 21,410 respectively.

As to sex, males declined from 2,347,642 in 1921 to 2,325,867, a fall of 21,775; females, from 2,534,855 to 2,516,687, a fall of 18,168. In 1921 the excess of females was 187,213; it is now 190,820. It will be interesting to see how the transfer of industry affects men and women and whether the decline in the birth-rate is due, in any material proportion, to a decline in the marriage-rate.

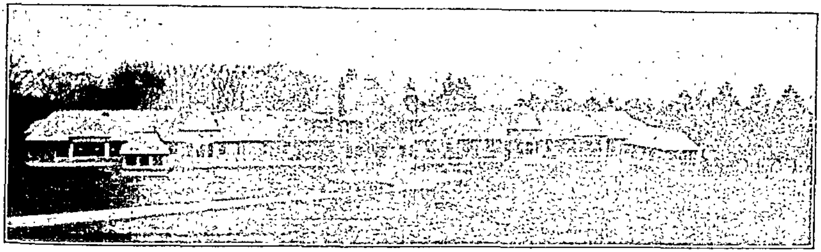
EFFECTS OF DEPRESSION IN INDUSTRY.

In no previous census have the effects of industrial depression been so manifest, whether we look to Shetland, in the extreme north, or to the industrial belt of the midlands, which holds about three-fourths of the Scottish population, or to the agricultural areas of marginal counties of the highlands and lowlands. But the analysis of these redistributions, which are so obvious in a small nation like Scotland, must await the completed returns and then we shall be enabled to judge whether a trifling decrease of 40,000 in some four and three-quarter millions is any indication of vital decadence or only represents a passing phase of industry.

GILGAL HOSPITAL, PERTH.

THIS hospital has been designed and erected by the directors of James Murray's Royal Asylum, Perth, to meet a special need. It became apparent during recent years that more accommodation of the hospital type for acute and recent cases and those requiring medical and nursing treatment was required, and after consideration of the various possible means of expansion it was decided to erect a self-contained hospital block of 40 beds on an adjacent site. This building is intended to be reserved solely for voluntary patients and especially for those whose standard of behaviour and habits is high, whose malady is slight or of short duration, who are sensitive and fully appreciative of their surroundings and company, and who may be apprehensive of possibly harmful or painful contacts with invalids of a more confirmed or different type.

The property named Gilgal, on which the new



View of the hospital.

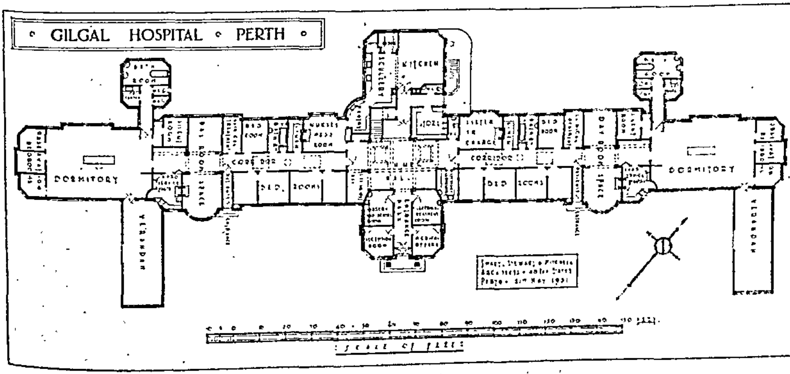
hospital has been built, extends to about ten acres. It is situated on the slopes of Kinnoull Hill about 200 feet above sea level, and is about one mile from Perth, on the east side of the river. The private rooms, verandahs, and garden face south and west, and it commands to the north a magnificent view of the valley of the Tay and the mountains beyond.

The hospital consists of two wards and a central admission block. The latter contains on the ground floor a medical office, reception room, surgery and dental room, electrical treatment room, dispensary and laboratory, and office of matron, all connecting with the main entrance hall. At the back are the kitchen and store, nurses' mess room, and service pantry. On the first floor of the central block are the staff quarters, including detached rooms for night nurses and in the basement, with access only from outside, is the central heating and domestic hot water plant. Under the entrance hall is the meter room and a compartment for luggage. The surgery and dental room is fitted for minor surgery, surgical examinations, and for dental treatment. It contains a gas-fed sterilizer, wash-hand basins and sinks, a dental chair, and instruments for emergency surgery. The electrical treatment room contains an ultra-violet projector, radiant heat lamps, and apparatus for faradic, galvanic, and Schnee baths. The laboratory is fully equipped for investigation of the body fluids.

The hospital is a self-contained unit and all cooking is done by gas, the plant consisting of two Falcon ovens, a Richmond boiler, a Main grill and toaster, and a Main hot closet. The total consumption when the hospital is nearly full is expected to be 50,000 to 60,000 cubic feet of gas per month. Oil-fuel is used for both the central heating and the supply of domestic hot water. The plant for the former consists of two (one being a reserve) Britannia boilers fired by Oil-O-Matic burners. The latter is a Rapid-Heater fired by a similar but smaller unit. All the burners are entirely automatic in action. The oil tank (which is filled from outside the building) has a capacity of 1000 gallons of oil (4 tons), being about 21 days' supply in cold weather.

Heating of the rooms is by the Panel system, designed by Messrs. G. N. Haden and Sons. The heating elements on the ground floor consist, not of the usual type of exposed radiator, but of grids or panels of high-grade steel tubing of half-inch bore, which are attached to the lower edges of the rafters in the ceilings and being buried in the plaster are invisible. For large bedrooms as much as 120 ft. of tubing is used in one panel and for dormitories, corridors, &c., a series of panels is employed. All joints are welded and each section is tested to withstand 300 lb. pressure. Each panel is fed by a buried pipe which can be controlled in the same way as a radiator. The advantages of this heating system are the absence of cumbrous radiators, the avoidance of convection air currents and dust, with its disastrous effect on decorations, the high proportion of radiant heat, and the much slighter drying effect on the air. Owing to the narrow channels the water must circulate in, a half h.p. electric Rotary Impeller pump is inserted in the return main, near the boiler. On the first floor, heating is by the usual Ideal radiators in each room and corridor.

Each ward unit consists of a dormitory (8–11 beds), a day-room or lounge and dining-room, six private bedrooms, three observation private bedrooms, two bathrooms, a clinical treatment room, a service pantry, a verandah, three w.c.'s, a slops room, linen store and cupboards. The dormitory and corridor have controllable ceiling extractor ventilators, and all the rooms have controllable Ewart's ventilators in outer wall and fixed openings to the



Ground-floor plan.

corridor, &c. The south side of each dormitory consists of three sheets of glass, one 72 in. × 152 in. and two 72 in. × 72 in., with controlled opening. The verandah, 40 ft. by 16 ft. will accommodate eight beds, and faces south-west, the end being enclosed by glass. *It is so arranged that* a nurse working in the service pantry or the dormitory has a full view of all its area. The dormitory can also be observed from the pantry by day or night.

The main bathroom contains a Shanks porcelain continuous bath with thermostatic control in addition to usual equipment. The pantry contains a hot-closet and two gas-burners, by Main. All w.c. doors are fitted with a light bolt and have a strong handle grip on the outside.

The floors throughout *are of oak*, the doors and *other fittings* of Lagos *mahogany*, and all metal parts are chromium plated.

The building is protected against fire by two outdoor hydrants on the water main, a Norsen automatic hose-reel in the centre, and by a system of automatic electric fire alarms having 23 sensitive points, situated in the attics, connected *to an alarm* bell and indicator in the entrance hall.

The cost of the new hospital, including all new roads, fees, laying *out of* grounds, &c., is approximately £21,500 and the cost of furnishing and equipment is £2800, *making a* total finished cost per bed of just over £600.

PANEL AND CONTRACT PRACTICE

Medical Certification.

We published last week without comment a summary of Memorandum 329/I.G. issued by the Ministry of Health. While it may *not be* easy to realise at a glance the whole significance of the tables it contained, the figures are eloquent enough in proof that *medical* certification has not been an efficient check on claims for sickness benefit. The reader of the memorandum is forced to the conclusion that persons not entitled to sickness benefit, because they were not actually incapable of work, have nevertheless received such benefit. It is natural enough that persons with trivial illnesses should swell the number of claims, and it might be held wise to encourage such patients to cease work. Many minor ailments would thus be prevented from developing *into* disabling conditions; in certain short but acute illnesses complete rest in bed for a week may prevent permanent damag[illegible] from such passing indi[illegible] the present instance the [illegible] pharmacists have [illegible] Apart [illegible] against the Minis[illegible]position the other group of claims the fa[illegible] shows the highest rate of increase is that of married women, in many of whom there may be good and sufficient reason for the demand. Childbearing under present-day conditions, as the Ingleby lecturer has just pointed out, does induce a lowered standard of health, and *one* well-recognised branch of social service is to provide mothers' helps to meet this need. On the other hand, some of these *claims* may be due *to* the acquisitive habits of women with growing families.

No attempt is made in the memorandum to give a lead to practitioners as to the standard *they are* expected to adopt in estimating capacity for work. They must resist the importunities of the benefit seeker, but to do this they must be on the sure ground afforded by a thorough and complete examination. How difficult such an examination may be is well known to every practitioner. When one considers the traditional obstinacy of insured persons, their reluctance to submit to examination, and the difficulty of finding time in a busy surgery for comprehensive work, it is not surprising that the number of claims should increase. It may well be that not enough weight has been given in the memorandum to the change in the attitude of the insured population towards the insurance principle and to the increasing willingness at the present time to get something for nothing. The catch phrases of political controversy have come home to roost, and the cumulative effect of the caption "ninepence for fourpence" is difficult to estimate. Of actual malingering on the part of insured persons there is little evidence. That is admitted on both sides. But there is a lamentable misunderstanding of the nature of the benefits and the conditions necessary to become eligible for them. The objective of *the memorandum* presumably is the enlightening and education of the practitioner, and *who, it may be asked*, will undertake a like task for the insured person? Where carelessness can be *demonstrated* the medical profession has already shown its willingness to apply disciplinary measures. We *reported* last week at some length *proceedings* before the General Medical Council in several cases *of alleged laxity of certification. In this respect* the Scottish Board of Health seems to have stolen a march on the Ministry *in* Whitehall. But the *medical* profession will scan the horizon carefully *for any evidence of similar action on the part* of those *who claim* to represent the insured persons. It is imperative that they should not be misled by the agents of societies into an exaggerated belief in their right to benefit for sickness or disablement. The warning of the Ministry contained in the circular *quoted* in this *column last* week has not come too soon.

decline [illegible]

Essex Public Medical Service.

Dr. C. H. Panting presided at the annual meeting of the service held in London on June 11th. Continued progress, he said, had been made in all directions in spite of the prevailing depression and unemployment in certain parts of the county. The total number of subscribers on the books at the end of last December, after deducting cancellations, removals, and deaths, was 18,533—an increase over the previous year of 1783. Medical members showed an increase of 12 after deducting deaths and removals. The advantages the service had to offer to general practitioners should, he thought, be *more* widely known. The total amount paid out to doctor members during the year was £9533 18*s.* 1*d.*, the largest totals collected for individual doctors in each class of district being:—

	Total.		Total.
Urban	£808	Semi-rural ..	£251
Metropolitan ..	£398	Rural	£318

The service may help practitioners in *taking* over unremunerative clubs. Last year a new member in a rural area decided to transfer to the service *en bloc* a club which had been run for generations by the firm of doctors to which he had succeeded. The transfer was accomplished and the member *found* his income increased by about £100 a year. The excellent work of the paid collectors of the service is shown by the small amount of arrears incurred, averaging under one-half per cent. The *benevolent* fund, started in 1929, to provide appliances, such as belts and trusses, and certain expensive *medicines* excluded from the scheme, has helped 51 cases during the year and has a balance in hand. The report and balance sheet were adopted.

CORRESPONDENCE

A MATERNITY SERVICE.

To the Editor of THE LANCET.

SIR,—I have read with much interest the lectures by Prof. Blair Bell on the subject of Maternal Disablement, and I am emphatically in agreement with him in his conclusion that maternity hospitals should be attached to general hospitals. I should like to have found more emphasis laid on the importance of having senior resident obstetricians on the staff of such hospitals, as I regard these positions as vital, both for the welfare of the patients in the hospitals and for the training of consultants.

Midwifery differs from other branches of medical practice in that it combines long periods of patient watching with moments of intense activity at times that cannot be predicted with any accuracy. These conditions fit in badly with the appointments of a consultant doing private practice, and it is essential that there should be someone more responsible and capable than a house surgeon in continuous charge of the cases in the hospital. Again it is perhaps not going too far to say that tenure of such a position is an essential part of the training of an obstetrician. Midwifery has suffered in the past from the gynæcological attitude to the subject, and the best corrective for this will be a long period of residence in a maternity hospital as part of the training of the consultants in the future.

I am, Sir, yours faithfully,

HENRY H. MACWILLIAM,

June 15th, 1931. Medical Officer, Walton Hospital, Liverpool.

MATERNAL MORTALITY-RATE.

To the Editor of THE LANCET.

SIR,—Two footnotes to Prof. W. Blair Bell's second Ingleby lecture, published in your issue of June 13th (p. 1279) indicate that he does not quite realise how maternal mortality is calculated in this country, and what would be the effect on the rate if the changes were made in that method which he suggests. Prof. Bell states that "We . . . only count maternal deaths in women who give birth to live children." This is not so. The numerator of the fraction which constitutes the maternal mortality-rate includes the deaths of women from all causes during pregnancy, labour, or the puerperium (except criminal abortions) unless they have died from such diseases as do not arise from pregnancy, labour, or the puerperium. Prof. Bell probably has in mind the fact that the denominator of the fraction includes only live births and excludes both stillbirths and abortions, with the result that the rate is not a perfectly true index of the fatality of childbirth and pregnancy. It will be clear, however, that if the denominator were enlarged by the inclusion of these conditions the change would have the effect of lowering our maternal mortality-rate, not of increasing it.

I am, Sir, yours faithfully,

RALPH M. F. PICKEN.

Public Health Department, Cardiff, June 15th, 1931.

To the Editor of THE LANCET.

SIR,—I shall be obliged if you will allow me to correct a misstatement in my second Ingleby lecture, which was published in your issue of to-day's date. I said that the maternal mortality-rate in England and Wales is calculated in relation to live births, and this is true in the sense that stillbirths are not taken into account. I understand, however, that all maternal deaths are counted. It would appear, therefore, that the maternal mortality-rate recorded by the Registrar-General is higher than it should be, and not lower. In either case the mathematics are wrong, and it is high time some correct international standard was adopted for the sake of accuracy and to simplify comparison.

I am, Sir, yours faithfully,

Liverpool, June 13th, 1931. W. BLAIR BELL.

THE CLEAN MILK PROBLEM.

To the Editor of THE LANCET.

SIR,—I am glad to see Dr. Savage's letter in your issue of June 6th, and to find that we are agreed upon two very important aspects of the milk problem concerning which he says:—

> (1) "That any widespread system of pasteurisation will put back the clock as regards the production of clean milk. I think this is a probable and undesirable result and the evil should be minimised so far as possible. (2) I should prefer to see provided a clean safe pure milk-supply without any heat treatment."

If our country were wiser, it would be taking every step to eliminate disease from cattle in the interests of our agricultural community; but the fact that our industrial population is able to obtain large quantities of foodstuffs from distant countries blinds it to this necessity. It seems important therefore to arouse its interest, and this object might be attained if it were proved that the provision of fresh foodstuffs was of real importance, not only to the physique of the nation, but also to its power to resist disease. Concerning the first of these problems, Dr. Savage states:—

> "I do not think that its opponents have demonstrated, when efficiently performed, that it (i.e., pasteurisation) does any material damage to any known nutritional factor in milk, but the last word has not been said on this side and our knowledge is admittedly incomplete."

This is the fairest statement that I have yet seen from any of those who desire compulsory pasteurisation, but it can be said with truth that the problem of the relative nutritional values of different types of milk has never been adequately studied either in this or in any other country. The work of those who are studying the subject all tends to show that there may be a very real difference which is of importance to the nutrition of our people, and it is my opinion that those who wish for further milk legislation must satisfy themselves of the truth or otherwise of this possibility before they advocate a method which has always ended in reducing fresh milk to a minimum in those countries which have adopted it.

Dr. Savage speaks of opponents to the pasteurisation of milk, and apparently assumes that I am one of them. That is not the case. I believe that pasteurisation is rendering a very great service both to the country and to the milk industry, and that we owe a debt of gratitude to the members of the industry who have endeavoured to use it as efficiently as possible. It is doubtful if it ought to be allowed to become a master—and yet it is very important that we should eliminate milk-borne diseases. The question therefore is to what length we can go in view of the present position of the milk industry. I think myself that the following steps might be practicable: make it permissible to sell, in the fresh state, milk which attains to the standard that is now applied to Grade "A," and treat compulsorily all that which fails to do so. To my mind, this method of overcoming our difficulties, although not perfect, would go a long way towards eliminating the dangers of disease, and could be limited to a period of time if, in the interval, sufficiently active steps had been taken to promote the increase of milk from herds which do not react to the tuberculin test.

Moreover, my suggestion could be made much more widely applicable than the one that has been put forward by Dr. Savage, and the possibility of its attainment is well illustrated by the progress that has been made by small farmers in Cornwall in the production and sale of milk of this character. I should be grateful if Dr. Savage could find time to see that work for himself, since it is an admirable demonstration of what might be accomplished throughout Great Britain.

It surprises me that Dr. Savage should throw the responsibility for the study of the nutritional values of the different types of milk upon my colleagues and myself, since it is work which is really within the province of those who are responsible for human nutrition. I believe however we could render them material assistance, particularly by providing them with milk which had been produced under carefully controlled conditions.

I am, Sir, yours faithfully,
R. STENHOUSE WILLIAMS.

Shinfield, near Reading, June 8th, 1931.

SURGICAL TREATMENT OF DUODENAL ULCER.

To the Editor of THE LANCET.

SIR,—Mr. E. R. Flint refers (p. 1321) to the results of the B.M.A. collective investigation into the after-results of gastro-enterostomy as reported by me.[1] He quite correctly gives the post-operative mortality-rate as 4·3 per cent. for the massed cases of duodenal and pyloric ulcers, but if he will refer to the addendum[2] to the investigation he will find that a much lower post-operative mortality is obtained when the operation of posterior gastro-enterostomy is combined with excision, cauterisation, or infolding of the ulcers. In the massed cases of duodenal and pyloric ulcers in which that operation was performed the post-operative mortality is only 1·6 per cent. It is only fair to point out that this particular type of operation was performed on a comparatively small number of cases—viz., 244—but I ventured in the addendum report, writing only as a statistician, to observe that the figures show that the operation, where combined with removal or infolding of the ulcer, is associated with a much lower post-operative mortality than in the cases of the other operations.

I am, Sir, yours faithfully,
Limpsfield, June 13th, 1931. ARTHUR P. LUFF.

To the Editor of THE LANCET.

SIR,—The clinical recognition and surgical treatment of duodenal ulcer owe so much to the genius of Lord Moynihan that the strongest grounds for differing from his appraisement of the value of any particular operation would alone justify a departure from the routine treatment as laid down by him. By his consummate skill and infinite attention to detail in pre- and post-operative treatment he has attained a degree of success with gastro-jejunostomy which, strive how I will, I have not been able to approach. In comparison with his 90 per cent., I cannot claim as cured—in the sense I used the term in my communication last week—more than 69 per cent. of patients who have failed to get permanent benefit by medical means. This measure of success falls so short of the ideal that it is almost compelling in its urge to search for a more satisfactory procedure. This I have attempted to do by exploring the possibilities of resection with the results already communicated. Lord Moynihan, I know, is, in general, in sympathy with surgical research of this kind, though I believe he feels strongly that such experiments should not be extended without adequate safeguard, with which sentiment every thoughtful surgeon must agree.

The points Mr. E. R. Flint brings forward are mostly answered in my paper. Particularly would I refer him to my remarks upon the fallibility of massed statistics. He criticises me for not resecting cases where the lesion was a small soft one which looked as though it might heal. This course seemed to me to be in the best interests of the patients, though resection in them would have been easy and swelled the statistics. His suggestion that the mortality would have been higher if ulcers adherent to the pancreas had been resected is not justified by the facts. Surgeons who resect duodenal ulcers know that the posterior wall is the commonest site for them. Very many of my resected ulcers have been adherent to the pancreas and in a considerable number the floor of the ulcer has been left on this viscus. I claim no more than to have made a serious investigation into the surgical treatment of duodenal ulcer which my results indicated was necessary, and I judged from Mr. Flint's publications of recent years that he also felt the need for it as he seemed to be abandoning gastro-jejunostomy for gastro-duodenostomy. No other English surgeon, as far as I know, has published his comparative results of resection and gastro-jejunostomy. If Mr. Flint would resect a series of ulcers I am convinced he would appreciate the truth of statements I have made.

I am, Sir, yours faithfully,
CHARLES A. PANNETT.

St. Mary's Hospital, W., June 14th, 1931.

AIR MOVEMENT IN SANATORIA.

To the Editor of THE LANCET.

SIR,—As I was on the staff of a chest hospital at the time when the open-air method began (about 1896) to be actively pushed in this country, and have been intimately concerned with sanatorium treatment from that time onwards, I am in a position to answer some of Dr. Macfie's questions in your issue of May 30th (p. 1211).

The effect of open-air methods has in my experience been entirely good. If only common sense is used, I do not believe that harm will ever result from these methods. Our object is to stimulate nutrition and reduce fever (if present) by cooling, but not chilling, the skin; and we must take into consideration both the meteorological conditions and the patient's individual reactive power. Wind and damp always increase the chilling effect. Whether snowflakes on the bed are likely to hurt the patient depends entirely upon circumstances. I have known some patients who remained perfectly comfortable in spite of drifting snow on their beds, and who objected to being brought into a more sheltered place.

---

[1] Brit. Med. Jour., 1929, ii., 1074 and 1125.
[2] Ibid., p. 1212.

So many things affect the progress of the tuberculous that we cannot draw conclusions from Dr. Macfie's Canadian example without knowing much more of the circumstances, but I very much doubt whether an atmosphere which seems stuffy to a healthy visitor is likely to be advantageous to any tuberculous patient in any place. Nor do I believe that we are "overdoing the open-air treatment in this country," although the large size of many sanatoria may make individualisation difficult. Sanatorium methods have varied greatly in England; but the error, if any, has been (I believe) more often on the side of timidity than on that of rigour, because attendant nurses and doctors feel the cold more than a patient in bed suitably covered, especially if the former are insufficiently clad or accustomed to hot rooms. The only safe criterion is the physical effect on the patient at the time, and this needs watching.

The introduction of sanatorium methods here had a very marked effect in improving the faulty ventilation prevalent in private houses; and this was also improved by the return of our soldiers from fresh-air conditions abroad during the Great War. Recently there has been a slight relapse, but not to the bad old standard. The increase of motor traffic, with the noise and dust it causes, may have something to do with this relapse. It appears to me, however, that there are still far more open windows to be seen in cold weather than used to be the case, at all events in this part of England.

I am, Sir, yours faithfully,

Farnham, Surrey, June 9th, 1931. F. R. WALTERS.

TREATMENT OF CEREBRO-SPINAL FEVER.

To the Editor of THE LANCET.

SIR,—During the last few weeks I have been acting as medical officer (infectious diseases) for the county borough of Rotherham, and therefore have come into more immediate contact with the recent cases of cerebro-spinal fever.

The routine treatment so far has consisted of lumbar punctures when necessary, with intrathecal doses of antimeningococcic serum, along with intravenous and occasionally intraperitoneal injections of the serum. The difficulty in obtaining type sera in time to be of use has so far been almost insuperable. After trying all the usual methods with varying doses of serum (from 40 to 180 c.cm.) I felt sure that if it were possible to establish a further reaction in the patient some result might be seen. With this end in view almost three weeks ago I took one case, a girl of 12, meningococci present in cerebro-spinal fluid: four days of illness, progressively getting worse, at this stage comatose, delirium passed and patient sinking, incontinent, &c. At this stage I did a further lumbar puncture and injected 1 c.cm. of thick fluid into the gluteal muscles, as withdrawn. Within 12 hours there was slight improvement; 36 hours later temperature rose about 1° and she was conscious again; temperature came down from 101·2° to normal in about three days further and stayed down; the condition generally improved and the improvement is still maintained.

Case 2.—A man, aged 25 years, was admitted to me four weeks ago. Responded at first to routine treatment, then relapsed slightly and became stationary; after 14 days he became lethargic, incontinent, and after two further days was fully unconscious; I did further lumbar puncture, found thicker fluid than before, and injected 1 c.cm. in the gluteal muscles. His chart shows a slight reaction during the next 12 hours and during the next three days he improved slightly. I then repeated the dose, finding his fluid clear (meningococci still present but attenuated), giving a further 1 c.cm. into the gluteal muscles; he reacted slightly again in the next 12 hours, and since then has improved steadily, temperature running a normal course since 36 hours after the second dose.

Case 3.—A boy, aged 4 years, responded to routine treatment, and after nine days became retrogressive; given 1 c.cm. of his own cerebro-spinal fluid six days ago, he has responded satisfactorily so far.

I have no more cases to try further with, and although this treatment so far has promised extremely well, it cannot be regarded as conclusive. I *propose* to try it out further with any cases we may be unfortunate enough to collect. If, in the meantime, anyone with fresh cases would be good enough to try the method and let me know results I should be extremely grateful. These three cases have been exact parallels of numbers of fatal cases we have had, although differing individually in certain elements. There has been no local reaction to the injections of cerebro-spinal fluid in the muscle. I would suggest that the antiserum should still be continued.

I am, Sir, yours faithfully,

LANCELOT H. COPPING, M.B., Ch.B.,
Assistant Medical Officer of Health, County
June 15th, 1931. Borough of Rotherham.

AFRICAN TICK FEVER.

To the Editor of THE LANCET.

SIR,—In the historical account of this fever in Vol. 8 of the System of Bacteriology recently issued by the Medical Research Council no reference is made to my discovery of the spirochæte. I have no desire to revive the controversy of 27 years ago as to the relative parts played by Castellani, Bruce, and myself in the elucidation of the cause and mode of transmission of sleeping sickness. But in an authoritative work of this kind (and I should like to congratulate the editors on its excellence) justice should be done to the various observers who have worked at a disease. It was in August, 1903, when examining the blood of a suspected sleeping sickness patient that I discovered the spirochætes of relapsing fever on several occasions in the patient's blood. I showed the films to Colonel Bruce, and his comment was that they probably came from the distilled water which had been used in staining the blood film and that they were not in the patient's blood. I pointed out to him, however, that I had stained 20 or more films from other humans and animals that same day and this was the only one which showed the spirochætes. The case is fairly fully described in Part 5 of the reports of the Sleeping Sickness Commission, which was dated Entebbe, Nov. 20th, 1903. This report was, for some reason, withheld from publication until July, 1905, by which time Cook and Ross and Milne, all of Uganda, had rediscovered this spirochæte and obtained the credit for the discovery. The incident is mentioned in the first edition (1910) of Castellani and Chalmers's Manual of Tropical Medicine.

I am, Sir, yours faithfully,

London, W., June 10th, 1931. DAVID NABARRO.

ESTIMATION OF BASAL METABOLISM.

To the Editor of THE LANCET.

SIR,—I read with interest in your last issue the article by the late Dr. A. M. Gale and Mr. C. H. Gale in which they put forward a new formula for estimating the basal metabolic rate (B.M.R.) from the pulse-rate and pulse pressure. They show that this formula gives results closer to the B.M.R., as actually observed by Read in his large series, than does either of Read's formulæ which are also based on the pulse-rate and pulse pressure. On applying Gale's formula to the same series, it is found to give results which approximate closely to the observed B.M.R. when the latter is normal or increased. But when the observed B.M.R. is subnormal, Gale's formula (P.R.+P.P.−111) gives results that are too high, and the lower the observed B.M.R. the greater the error.

Using the same table of results as set out in the Gales' paper, the formula becomes more accurate if the figure subtracted from the sum of the pulse-rate and pulse pressure is increased as the sum of P.R.+P.P. becomes less. For practical purposes I suggest that when P.R.+P.P. is less than 111 (B.M.R. less than 0), the figure subtracted be 111+5, and that when P.R.+P.P. is less than 91, the figure subtracted be 111+10. The following table, taken from Table I. of the Gales' paper, will serve as the best illustration :—

Observed B.M.R. per cent.	Mean values.			Cases.
	P.R.+P.P.	P.R.+P.P. −116	P.R.+P.P. −121	
− 0 to − 9·9	109·1	− 6·9	..	137
−10 to −19·9	104·2	−11·8	..	119
20 to −29·9	93·3	−22·7	..	38
30 to −39·9	88·5	..	−32·5	4

I am, Sir, yours faithfully,

B. BUCKLEY SHARP.

Welbeck-street, W., June 17th, 1931.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

HONORARY FELLOWSHIPS AT THE ROYAL COLLEGE OF SURGEONS.

LAST Saturday the President of the Royal College of Surgeons in Ireland admitted to the honorary Fellowship of the College Dr. George Eli Armstrong, of McGill University, and Sir Hugh Mallinson Rigby, of London. The new Fellows were presented to the President by the honorary secretary of the College, Sir F. Conway Dwyer. He recalled that in Sir Hugh Rigby the College was welcoming an Irishman and a native of Dublin. Subsequently the new Fellows were entertained to dinner in the College.

SWEEPSTAKES : VOLUNTARY AND COUNTY HOSPITALS.

After another somewhat acrimonious debate in the Dáil last week on the report stage of the Public Charitable Hospitals (Amendment) Bill, it was agreed that one-third of the funds distributable to hospitals should, in future, go to the county hospitals. An important suggestion was made in the course of the debate by Dr. Hennessy—namely, that 10 per cent. of the proceeds of sweepstakes should be devoted to medical research. It is notorious that financial provision for research is badly needed in Ireland. The universities have no money to spare, and are not in a position to do much more than they are doing at present, and almost the only provision is certain grants given by the Rockefeller Foundation. It ought not to be beyond the power of the Dáil to insert a clause into the present Bill making, at any rate, some provision for medical research.

A PHARMACOPŒIA FOR THE IRISH FREE STATE.

In moving the second reading of the Pharmacopœia Bill last week, Mr. Richard Mulcahy, Minister for Local Government and Public Health, divulged the interesting fact that since the setting up of the Irish Free State Medical Registration Council the British Pharmacopœia had no longer a statutory authority in the Irish Free State, and he was advised that there was at present no pharmacopœia in force. The Bill proposes to adopt the British Pharmacopœia with such alterations, additions, and omissions as the Irish Medical Registration Council may decide on.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

RESEARCH ON THE BRAIN.

RESPONDING to an appeal by Prof. Wagner-Jauregg, the Nobel laureate, Prof. C. Economo has succeeded in organising an institute for systematic research on the brain. For over 20 years he has been working on these lines, and lately comparative anatomy has received his special attention. He has demonstrated a definite evolution or "progressive cerebration" in the ancestral line of mankind—an evolution manifested not so much by the increase of weight (comparative and absolute) as by increase of gyri and sulci. He believes that we are justified in assuming that the brain of man is still capable of unheard-of development.

Dr. A. Poller has devised a method for obtaining absolutely correct casts of the brain so that study of each separate part is possible. For instance, the anatomical substrate of musical talent can, he thinks, be discovered by comparing the brain of highly musical persons and those with no such gifts. The next object of this new institute will be to study the problem of talent, and for this purpose it is necessary to obtain the brains of eminent persons, excelling in some particular direction. An appeal has been published in the daily press asking for bequest of brains, not only by people who show special musical, mathematical, physical, or other abilities, but also by those who are left-handed or deaf-mutes. Prof. Wagner-Jauregg has already bequeathed his brain to the institute, which is housed in the Vienna Psychiatric Clinic.

STERILISATION OF MENTAL DEFECTIVES.

At a meeting of the Medico-Legal Society in Vienna, Dr. Höpler, the Attorney-General of Austria, made an interesting report on the present trend of opinion and the existing legislation on sterilisation of mentally defective persons. He expressed himself in favour of compulsory sterilisation on eugenic grounds, because the offspring of such people are a threat and a handicap to the human race. In this respect, Dr. Höpler is much further advanced than the new penal code which is under consideration in Germany, and to which Austria will probably consent. In Austria, the existing code threatens to punish any operator who performs any operation for other than therapeutic purposes ; the offence is qualified as : "inflicting serious bodily injury," and the punishment may be imprisonment for a long term, even if the patient has given his consent. It may be recalled that two years ago a certain surgeon in Graz, who performed temporary sterilisation on men, was sentenced to a heavy fine, and only acquitted after two appeals before the Supreme Court. In the new draft of the penal code, which has lately been worked out by the legal committee of the Austrian National Assembly, the consent of the patient to a sterilisation, performed "lege artis" by a qualified surgeon, shall not be deemed an offence, nor shall the surgeon be punishable in such an instance. On the other hand, sterilisation will not be regarded as a penalty or even as an alternative penalty for a criminal offence, and will not serve to shorten a term of imprisonment. Dr. Höpler is, as mentioned before, much more radical. He thinks that sterilisation has nothing to do with the punitive idea, and advocates a clause for the new code requiring that all persons from whom only defective children are to be expected should be subjected to a sterilising operation upon a judicial order. Such an order must, of course, be given only under the strictest control by State authorities and with greatest caution, including the examination of the patient by a committee of qualified medical men, and the right of appeal given to the family or the marriage partner of the person against whom such an order is made. The operation would be performed only in public institutions, and if possible should be centralised.

PUBLIC HEALTH SERVICES

MENTAL HOSPITAL REPORTS.

THE CHESHIRE COUNTY MENTAL HOSPITAL at MACCLESFIELD had 1334 patients on its register on the 1st day of 1930, and was then so crowded that only cute and urgent cases could be admitted. So far, no substantial progress has been made towards providing additional accommodation, although several plans have been discussed. The workhouses have been inspected with a view to using their space, but they were found to be entirely unsuitable. The recovery-rate for the year was 31·8 per cent. and the death-rate 4·8 per cent.—the lowest on record. Apart from a small epidemic of influenza and six sporadic cases of dysentery, the general health was satisfactory. Of the eight cases of general paralysis admitted, four were suitable for malarial treatment, and three of them were discharged fit for work. Light treatment was given to a number of patients, while others had radiant heat, prolonged and Turkish baths, and electrical treatment. The new occupation pavilion is nearing completion and the occupation officer has had six months' study leave for training. The dietary has been improved by the substitution of butter and English meat for margarine and foreign meat, respectively, but there has been no rise in the cost of maintenance. During the year 1876 investigations were carried out in the laboratory, which also undertakes the bacterial work of the Macclesfield public health authority. Two special reports deal with the family history and the relation of the cause of death to the type of insanity. It was found that the proportion of relatives suffering from some degree of mental affliction to the number of patients admitted is nearly 1 to 3; that tuberculosis has been displaced, during the last ten years, from its position as principal cause of death, and that there has been a very great diminution of fatal colitis and dysentery. The largest number of deaths from tuberculosis was found in the schizophrenic group; only 7 per cent. of patients dying from malignant growths belonged to this group. This is not entirely due to the age factor, since 8 per cent. of melancholics and 20 per cent. of paranoid cases died from malignant tumours. No schizophrene died of intestinal catastrophe. The committee have decided to open an out-patient clinic at the institution and to appoint a social worker. The systems of trial and parole are freely used. During the year 15 nurses and five attendants obtained their R.M.P.A. certificate, one nurse with distinction; 83 per cent. of the male nurses and 37 per cent of the female nurses have been in the institution for more than five years. Women are employed for all work, except for some night duty in the male wards.

The GLASGOW ROYAL ASYLUM had 555 patients in residence at the end of last year; of the 150 patients admitted during the year, 74 were voluntary boarders. The directors have acquired an estate in Dumbartonshire which is to be opened as an ordinary nursing-home, without formalities of admission, for patients suffering from incipient nervous and mental disorder. It has been suggested that the former East House kitchen and mess-rooms should be converted into a reception unit with a hydrotherapeutic and electrical department, and a library upstairs. The recovery-rate for the year was 34·8 per cent. and the death-rate 7·4 per cent. A careful study of the malarial treatment of general paralysis has been made; the results have been most encouraging. The occupation therapy department continues to work well. The occupation officer finds that basketry is one of the most useful crafts, as it involves many activities, from the elementary process of sand-papering upwards, and the concentration required for the actual weaving is often just what is necessary to hold the patient's attention. The dental surgeon saw 239 patients during the year. The hospital has also a complete visiting staff of specialists. The convalescent villa at Skelmorlie continues to give great pleasure to those who go there for a change or for a period before discharge. Over 150 patients have parole within the grounds. All nurses now take the examination of the General Nursing Council.

HOSPITAL FOR PRIVATE PATIENTS.

The admissions to THE LAWN, LINCOLN, for the year 1930 included 22 voluntary boarders and 10 certified patients; many of the voluntary patients were definitely psychotic and certifiable, but the medical superintendent finds it perfectly possible and satisfactory to treat them on a voluntary basis. Of the 38 inquiries which did not lead to admission a very large number probably required treatment, but the charitable resources of the hospital were insufficient to meet their needs. The recovery-rate for the year was 66·6 per cent., and five certified patients died from natural causes. The general health was good and there was no epidemic disease. Many patients visited the theatre, concerts, and cinema, and an increasing number go out on parole. A masseuse who worked at the hospital during her summer vacation proved to be of great benefit to the patients, and it is hoped before long to appoint a full-time officer. The valuable work of this institution is hampered by lack of funds, and a special appeal is being made this year for donations and annual subscriptions.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED JUNE 6TH, 1931.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 83; scarlet fever, 1380; diphtheria, 767; enteric fever, 46; pneumonia, 794; puerperal fever, 31; puerperal pyrexia, 111; cerebro-spinal fever, 53; acute poliomyelitis, 2; acute polio-encephalitis, 2; encephalitis lethargica, 13; dysentery, 9; ophthalmia neonatorum, 113. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on June 9th–10th was as follows:—Small-pox, 136 under treatment, 2 under observation (last week 149 and 7 respectively); scarlet fever, 1134; diphtheria, 1381; enteric fever, 14; measles, 175; whooping-cough, 425; puerperal fever, 36 (plus 11 babies); encephalitis lethargica, 195; poliomyelitis, 1; "other diseases," 157. At St. Margaret's Hospital there were 19 babies (plus 0 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was 1 death from small-pox, 1 (1) from enteric fever, 26 (0) from measles, 5 (2) from scarlet fever, 20 (6) from whooping-cough, 18 (2) from diphtheria, 40 (5) from diarrhœa and enteritis under two years, and 30 (5) from influenza. The figures in parentheses are those for London itself.

The case provisionally classified to small-pox was assigned to East Ham C.B. No death from meningococcal meningitis occurred in London. Five deaths from measles were reported from Birmingham, 4 each from Liverpool and South Shields. Diphtheria claimed 3 victims at Hull. Diarrhœa was credited with 10 deaths at Birmingham, 4 at Coventry.

The number of stillbirths notified during the week was 287 (corresponding to a rate of 39 per 1000 births), including 61 in London.

PORT SANITARY AUTHORITY.

IN his first annual report to the PORT OF BRISTOL authority Dr. R. H. Parry mentions that during the year 1930 1160 ships arrived from abroad at the three ports of Bristol, Avonmouth, and Portishead, and 5846 coastwise. Of these 187 were visited by the medical officer, 3378 by sanitary inspectors. No case of cholera, yellow fever, small-pox, or typhus came to notice, but one case of (clinical) plague, an inguinal bubo, in a second engineer, was found on a grain ship from the Black Sea. The case was removed to hospital and did not at this date prove bacteriologically positive. Luckily there were few rats aboard, the grain cargo was discharged under supervision, the one rat trapped was negative; the ship was fumigated with hydrocyanic acid, no further rats being found. The rats on the neighbouring dockside when examined were also found free of plague. During the year 1344 rats were destroyed on vessels, 3107 on shore; 408 were examined, all free of plague. Care is being taken continuously to reduce rat harbourage on ships and ashore. Experiments with an electric rat-guard proved unsatisfactory, for even a direct current of 500 volts merely stunned a rat for a couple of minutes. Of 3378 vessels examined for nuisances, 12 were found defective in original construction, 197 through wear and tear, and 410 were dirty or verminous. Of venereal disease 32 cases came under the notice of the port medical officer; 158 persons made 553 gratuitous attendances to the clinic provided. Much food reaches England through Bristol, and is for the most part (the report says "invariably") in good condition; some 34 tons of wheat, 10 of maize, and 10 of barley were condemned. Bananas, 102,163 tons arrived; none reported unsound. Of 11 samples of water taken from ships (reason for choice unstated) 8 were classed as unfit, 2 reports were indefinite, and only one (from Madeira) was declared perfectly sound. Presumably the water on board merchant ships is generally better than thus appears; in fact only two cases (five years average, 3·8) of typhoid were reported on board all incoming vessels during the year. No insanitary conditions were found among 29 canal boats inspected.

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS.

PUBLIC HEALTH IN MAURITIUS.

ON the second reading in the House of Commons on June 12th of the Mauritius Loan (Guarantee) Bill, Mr. LUNN, Under Secretary for the Dominions (in the absence of Dr. Drummond Shiels, the Under Secretary for the Colonies) said that the position in regard to public health in the Colony of Mauritius was that the island was over-populated. The density of the population was 550 to the square mile. The bulk of the population lived normally on the very limit of bare subsistence, and it was inevitable that in times of depression such as now existed some of them who became unemployed or received a diminishing return from their small holdings should be forced below that limit. The only remedies for this state of affairs were an increase in the productivity of the island or a decrease in its population. Measures for increasing the productivity of the island were under consideration by the Agricultural Department of the Colony and the agricultural advisers of the Secretary of State for the Colonies. On the strictly public health side there was little that could be done to remedy under-nourishment. The record of the Government of Mauritius in public health matters was, he understood, a good one. They had in recent years spent very large sums on public health works, such as antimalarial measures and the improvement of water-supply, and there was no doubt that such efforts would continue to be prosecuted as funds were available. If the measure of assistance now proposed under this Bill had not been given to the Colony the economic position would very rapidly have become worse. Under-nourishment would not only have become more widespread, but might have developed into actual starvation.

After some debate the Bill was read a second time without a division.

WORKMEN'S COMPENSATION ACT.

On June 11th in the House of Lords the Royal Assent was given to the Workmen's Compensation Act, 1931, the Alexander Scott Hospital Order Confirmation Act, 1931, and the Liverpool University Act, 1931.

BETHLEM HOSPITAL BILL.

In the House of Lords on June 16th Lord PONSONBY moved the second reading of the Bethlem Hospital (Amendment) Bill. He said that the Bill was necessary to enable Bethlem Hospital to be used as a war museum. By the generosity of Lord ROTHERMERE, the building and site had been handed over to the London County Council as an open space. It was proposed under the Bill to use the centre part of the building, which contained the dome, as the war museum. The rest of the site would remain in the hands of the London County Council as a garden and open space. The result of the Bill would be to relieve the present overcrowding in the Imperial War Museum at South Kensington. The Bill was read a second time.

HOUSE OF COMMONS.

WEDNESDAY, JUNE 10TH.

Insured Women and Dental Benefit.

Mr. LOVAT-FRASER asked the Minister of Health the number of insured women under the National Health Insurance Act who were entitled to additional benefit, No. 9 (dental benefit), under the valuation schemes of approved societies for the second valuation period, and the number of insured women who were, or would be, entitled to such benefit under the third valuation schemes.—Miss SUSAN LAWRENCE (Parliamentary Secretary to the Ministry of Health) replied: The number of insured women members of approved societies and branches in England having schemes of dental benefit following the second valuations was approximately 4,250,000. The complete results of the third valuation are not yet available, but my right hon. friend regrets to say that from the results already received it is evident that there will be a considerable reduction in the number of women entitled to dental benefit.

Dental and Ophthalmic Treatment.

Mr. JOHN asked the Minister of Health whether he proposed to make dental and ophthalmic treatment statutory benefits for all members of approved societies under the National Health Insurance Acts; and, if so, at what date.—Mr. GREENWOOD replied: No such proposal is at present in contemplation.

Legislation to Amend the Children Act.

Viscountess ASTOR asked the Prime Minister whether, having regard to the need for a new Children's Bill, he could find time for the proposed Government Bill to be taken this session.—Mr. MACDONALD replied: The Government are fully aware of the need of legislation to amend the Children Act, but I am afraid that, in view of the present state of Parliamentary business, I can hold out no hope of time being found this session for the proposed Children's Bill.

Prisoners and Solitary Confinement.

Mr. FREEMAN asked the Home Secretary the total number of prisoners who were in solitary confinement; the maximum period for any prisoner; the main causes for such treatment; and whether he was satisfied with the necessity of dealing with them in this way.—Mr. CLYNES replied: Solitary confinement was abolished long ago. Further, the period of employment in separation was reduced in 1919 to 14 days and was done away with altogether by my Prison Rules of April 4th last. There is now no class of prisoner which as such is excluded from associated labour. For breaches of prison discipline, prisoners are liable to be punished by close confinement, but after the first day on promise of good behaviour are allowed one hour's exercise daily and to attend chapel on Sundays. The maximum period which may be ordered by a prison governor is three days, by visiting justices 14 days, and by boards of visitors or directors of convict prisons 28 days. The modern tendency is to substitute loss of privileges for close confinement.

The Factory Inspectorate.

Major COLVILLE asked the Home Secretary whether he would furnish a statement showing the additional appointments made to the factory inspectorate following upon the report of the departmental committee on the factory inspectorate.—Mr. CLYNES replied: Following the departmental committee's report, the Government decided to increase the general inspection staff from 180 to 243, the medical staff from 5 to 8, the electrical staff from 5 to 12, and the engineering staff from 6 to 10, these increases to be spread over a period of five years. Up to the present the general inspection staff has been increased by 29, the medical staff by 3, the electrical staff by 5, and the engineering staff by 3.

FRIDAY, JUNE 12TH.

Poor-law Relief in Plymouth.

Mr. HORE-BELISHA asked the Minister of Health the number of persons in receipt of poor-law relief in the city of Plymouth, specifying categories for May, 1931.—Mr. GREENWOOD replied: The following statement gives the information asked for: Institutional relief (including casuals, but excluding rate-aided patients in mental hospitals), 576; domiciliary relief (excluding persons in receipt of domiciliary medical relief only), 5411; total, 5987.

MONDAY, JUNE 15TH.

The Grading of Milk.

Brigadier-General CLIFTON BROWN asked the Minister of Agriculture whether, when considering with the Ministry of Health alterations in the regulations for the grading and designations of milk, and before coming to any decision he would consult the advisory committee of the Agricultural Council for England and Wales on this matter.—Miss SUSAN LAWRENCE replied: My right hon. friend has already received a report on this subject which was adopted by the Council of Agriculture for England last year. He will consider it in consultation with my right hon. friend, the Minister of Agriculture and Fisheries, but legislation would be necessary before any alterations could be made in the order as to the grading and designations of milk.

An All-in Insurance Scheme.

Sir GEORGE PENNY asked the Minister of Health whether the Government would consider the possibility of investigating an all-in insurance scheme, including unemployment and health benefits and pensions, to be applicable to a large section of the population.—Miss SUSAN LAWRENCE replied: This was one of the subjects considered by the Cabinet Committee which was set up to make a general survey of the National Insurance and Pensions Schemes, and is dealt with in their report, which is still under the consideration of the Government.

Medical Assistance in Flying Accidents.

Capt. BALFOUR asked the Under Secretary for Air if he was aware that after the flying accident resulting in the death of Mr. Kenneth George Murray at Marshall's Aerodrome during the Cambridge public flying display recently, 20 minutes elapsed before a doctor's services were procured; that when the injured pilot had been extracted, after 20 minutes work in the wreckage, a further period of waiting occurred before the ambulance arrived; if he would investigate the reason why neither medical nor ambulance transport services were available for instant use; whether his department had been consulted or had offered assistance in the organisation of this meeting; and if he would issue immediate regulations to prevent reoccurrence of such lack of safety facilities at all future public flying displays.—Mr. MONTAGUE replied: Inquiry is being made into the points mentioned, but the display at which this regrettable accident occurred was a privately arranged meeting held at an aerodrome licensed for private use only. One of the conditions of the licence is that "adequate first-aid appliances must be kept at the aerodrome."

TUESDAY, JUNE 16TH.

Army Horses Sold for Human Food.

Mr. DAY asked the Secretary for War the number of Army horses that had been cast during the 12 months ended to the last convenient date and sold for human consumption; and to whom they were sold.—Mr. T. SHAW replied: During the year ended May 31st last, 727 Army horses were sold as fit for human consumption. Such animals are destroyed in the presence of a military representative. The purchasers were Messrs. Harrison, Barber and Co., Ltd., London, and Messrs. Smith and Spalding, Ltd., London.

Mental Defectives in Scotland.

Mr. SINKINSON asked the Secretary for Scotland the number of mental defectives under 18 years of age in Scotland; how many were educable and uneducable; and how many were in institutions, criminal and otherwise.—Mr. WESTWOOD (Under Secretary of State for Scotland) replied: The duty imposed upon education authorities in Scotland by the Mental Deficiency and Lunacy (Scotland) Act, 1913, to ascertain what children residing within their areas are mentally defective within the meaning of the Act and to make provision for the education of those who are capable of receiving benefit from special instruction extends only to children between 5 and 16 years of age. According to the last return made by education authorities, the number of children between these ages who were ascertained by them to be mentally defective was 4910, of whom 3993 were ascertained to be educable and 917 uneducable. The number of educable mentally defective children receiving instruction in schools and institutions is 3938. Between the ages of 5 and 18 years there are 192 educable and 696 uneducable mental defectives certified under the Act and in residence in certified institutions, and 110 uneducable mental defectives under guardianship in private dwellings. There are no mental defectives under the age of 18 in residence in the State institution.

Unidentified Bodies in London Mortuaries.

Dr. HASTINGS asked the Home Secretary the number of unidentified bodies taken to the mortuaries in London in any one recent year.—Mr. CLYNES replied: The most recent year for which figures are available without special collection is 1927. Seventy-seven bodies of newly born infants and 74 other bodies found dead in that year remained unidentified two months after the end of the year. It is understood that these numbers fairly represent the average.

DONATIONS AND BEQUESTS.—Mrs. Eleanor Hood-Rowan, of "Rowantree," Warren-road, Blundellsands, left £34,091. After certain personal bequests the residue of the property was left as to: Two-ninths to Liverpool Infirmary for Children, Myrtle-street, Liverpool; two-ninths to the Children's Hospital at Leasowe for Crippled Children; two-ninths to Dr. Barnardo's Homes; two-ninths to the Waifs and Strays' Society; and one-ninth to the Institute for the Blind, Hardman-street, Liverpool.—Miss Ada Bilton, of Yew Tree, Kingswood-lane, Hindhead, Surrey, among other bequests, left her real estate at Shottermill, Hindhead, Surrey, to the Royal Hospital for Incurables, Putney, desiring that it should be used as a country home for patients of the hospital, and £2000 to Florence Nightingale Hospital for Gentlewomen, Lisson-grove, and £500 to the London Hospital for a cot, to be called the "Charles Bilton Cot."

week 149 and 7 respectively); scarlet fever, 1134; diphtheria, 1381; enteric fever, 14; measles, 175; whooping-cough, 425; puerperal fever, 36 (plus 11 babies); encephalitis lethargica, 195; poliomyelitis, 1; "other diseases," 157. At St. Margaret's Hospital there were 19 babies (plus 9 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was 1 death from small-pox, 1 (1) from enteric fever, 26 (0) from measles, 5 (2) from scarlet fever, 20 (6) from whooping-cough, 18 (2) from diphtheria, 40 (5) from diarrhœa and enteritis under two years, and 30 (5) from influenza. The figures in parentheses are those for London itself.

The case provisionally classified to small-pox was assigned to East Ham C.B. No death from meningococcal meningitis occurred in London. Five deaths from measles were reported from Birmingham, 4 each from Liverpool and South Shields. Diphtheria claimed 3 victims at Hull. Diarrhœa was credited with 10 deaths at Birmingham, 4 at Coventry.

The number of stillbirths notified during the week was 287 (corresponding to a rate of 39 per 1000 births), including 61 in London.

PORT SANITARY AUTHORITY.

In his first annual report to the PORT of BRISTOL authority Dr. R. H. Parry mentions that during the year 1930 1160 ships arrived from abroad at the three ports of Bristol, Avonmouth, and Portishead, and 5846 coastwise. Of these 187 were visited by the medical officer, 3378 by sanitary inspectors. King Edward's Hospital Fund for London.

The Prince of Wales presided last week at the annual council meeting of this Fund, when a message was read from the King expressing His Majesty's satisfaction that the fund was able in 1930 to provide the increased distribution of £266,000 out of the current income of the year. In 1929 the distribution was £250,000. The Prince spoke of his fear that the present year would be an anxious one for the voluntary hospitals, but he took courage from the fact that the voluntary system had survived many periods of depression in the past, and that in recent years income had grown steadily. He mentioned "an entirely new and unprecedented item"—a special trust fund of £20,000 given by an anonymous donor, the income of which is to be used primarily to assist a hospital to pay off its building debt. The legacy of £50,000 from the late Sir Otto Beit brought the total munificence of Sir Otto to the Fund to £106,000. It was explained that the new trust fund was to be applied to the reduction of capital charges on hospitals in Deptford, Greenwich, Lewisham, and Woolwich, and that the first beneficiary will be the Miller General Hospital. The management committee is ignorant of the identity of the donor.

Epsom College.

St. Anne's Scholarship.—The council will shortly elect a girl to a St. Anne's Scholarship of £120 a year. Candidates must not be less than 9 years of age on July 20th, and must be orphan daughters of medical men who have been for not less than five years in independent practice in England or Wales. Application must be made by July 2nd, on a form to be obtained from the secretary of the College, at 49, Bedford-square, London, W.C. 1.

London School of Hygiene and Tropical Medicine.

The next series of eight lectures and demonstrations on tropical hygiene, intended for men and women outside the medical profession proceeding to the tropics, will be given by Lieut.-Colonel G. E. F. Stammers from July 6th to 10th. Particulars may be had from the secretary of the school, Keppel-street, Gower-street, W.C. 1.

Diploma in Psychological Medicine.

The University of London has added Stoke Park Colony, Stapleton, Bristol, to the list of institutions recognised for practice under Regulation 3 for the D.P.M. for candidates offering mental deficiency as their special branch under Regulation 4.

Royal Medico-Psychological Association.

The ninetieth annual meeting of this association will be held from July 8th to 11th at the Royal College of Physicians, Dublin, under the presidency of Dr. R. R. Leeper. On July 10th the association will be received at the Vice-Regal Lodge by the Governor-General and Mrs. McNeill.

Royal Society of Medicine.

Nichols Prize.—At the last meeting of the council this prize was awarded to Dr. John Smith, of Aberdeen, and to Dr. R. R. Armstrong and Mr. H. Burt-White (a conjoint contribution), of St. Bartholomew's Hospital. The prize s offered, in accordance with the will of the late Dr. Robert Thomas Nichols, once every three years, for the most valuable contribution by a British subject towards "the discovery of the causes and the prevention of death in hildbirth from septicæmia."

The *Jenner Medal* was awarded to Dr. T. H. C. Stevenson, Medical Statistical Officer at Somerset House. *It is given* o persons whose work has been pre-eminent in the prevenion and control of epidemic disease.

University of Manchester.

The Council have appointed Dr. Stephen Leonard Baker s Procter professor of pathology and pathological anatomy, n succession to Prof. J. Shaw Dunn.

Dr. Baker qualified from the London Hospital in 1913. fter holding various junior appointments in that hospital, he as for three years during the war a temporary surgeon in the oyal Navy. Since 1922 he has held the post of senior assistant n the Bland-Sutton Institute of Pathology at the Middlesex ospital, and in 1928 was appointed Reader in Morbid Anatomy nd Histology in the University of London. His researches over a wide field in bacteriology and pathology. Recently it as been chiefly concerned with problems connected with alignant disease.

Society for Constructive Birth Control.

The medical committee of the Constructive Birth Control linic has arranged special sessions devoted to demonstrating o medical practitioners the practical details of contraceptive echnique, the insertion of various types of pessaries, the etermination of sizes used in various circumstances, &c. hese demonstrations are combined with brief lectures in equence made by the president of the society (Mrs. Marie topes, D.Sc.), various members of the medical committee, nd the midwife nurse-in-charge at the clinic. The leading ethods used in clinical technique will be covered in one fternoon. Sessions will be held from 2.30 till 5 P.M. on he first Wednesdays in each month. Previous application hould be made in writing to the hon. secretary of the onstructive Birth Control Clinic, 108, Whitfield-street, London, W. 1.

Oxford Ophthalmological Congress.

The twenty-first annual meeting of this congress will egin at Oxford on Thursday, July 9th. After the opening y Mr. A. B. Cridland, the Master, a symposium on the iagnosis of Intracranial New Growths will be introduced y Mr. Leslie Paton, the *other speakers* including Sir erry Sargent, Dr. H. M. Traquair, Mr. Norman Dott, nd Prof. Artur Schüller (Vienna). On the same afternoon rof. G. Elliot-Smith, F.R.S., will give an address on the volution of the Instruments of Vision. In the morning f Friday, the 10th, Dr. Baillart (Paris) will speak on Tonometry, and Mr. Philip Adams *will deliver the Doyne* emorial lecture, under the title of an Ophthalmological Mélange. In the afternoon Mr. James Craig and Prof. Schüller will open a discussion on Penetrating Wounds of he Eye. The meetings will end at midday on Saturday.

National Association for the Prevention of Tuberculosis.

On Thursday next the seventeenth annual conference of the National Association for the Prevention of Tuberculosis opens at Margate under the chairmanship of Sir Arthur Stanley. The proceedings, which will continue till Saturday, will be devoted to the Protection of the Child from Tuberculosis.

London Hospital Medical College.

The distribution of prizes will be made by Lord Macmillan on Wednesday, June 24th, at 3 P.M., in the library of the College.

Gloucester Royal Infirmary Extension.

On Thursday last week Princess Mary laid the foundation-stone of extensions which will cost £40,000.

A Memorial Ward at Wells.

There was recently opened at Wells cottage hospital a maternity ward as a memorial to Miss Phyllis Aileen Manning who died, at the age of 25, after six months' work as a medical missionary in Uganda. The ceremony was performed by Mrs. Wynne Wilson, wife of the Bishop of Bath and Wells. Miss Manning was the daughter of the senior honorary surgeon of the hospital.

"Royal" Hospitals.

The committee of the Bolton Infirmary and Dispensary have decided to petition the Home Secretary for the right *to prefix the word "Royal" to the title of the hospital.* The reasons given are that, with such a name, it would be easier to obtain doctors and nurses, and that applicants for positions on resident medical staffs "seem to prefer a hospital which has the word 'Royal' prefixed."

Coventry and North Warwickshire Hospital.

The Hospital Saturday Fund committee has presented to this institution an electrocardiograph apparatus in memory of the late Mr. G. Hadfield, the originator of a movement for its acquisition, and it was recently unveiled by his widow. *At the ceremony it was stated that out of* 1672 deaths in the city of Coventry last year 311 were attributed to heart disease.

Work of Orthopædic Hospitals.

The annual report of the Prince of Wales's Orthopædic Hospital, Cardiff, and its country branch at Crossways, Cowbridge, states that last year a total of 665 patients were admitted; there were 2173 out-patients.—Speaking last week at the cripples' training centre of the Manchester, Salford and District Council for Cripples, at Grangethorpe, Sir Robert Jones commented upon the pressing need for training colleges for those injured at work and in other ways, whose number in the last ten years exceeded the war-time total.

Glasgow Dental Hospital.

The Earl of Home, presiding at the annual meeting of the Incorporated Glasgow Dental Hospital last week, referred to the very great increase in service to the community which would be made possible by the new home for the hospital. They would have 70 operating chairs each with self-contained surgical unit, instead of 35 as before. Children would be *accommodated in a special department and an X Ray plant* would be installed. The laboratory would be twice the size, and provision would be made for research. In response to the appeal for £90,000 to meet the cost of equipping the new hospital, nearly £40,000 had already been received, but he made urgent appeal to the citizens to aid the hospital so that it might open free of debt. £2000 had been promised by the Dental Board of the United Kingdom on condition that £1700 was raised in Glasgow by July 1st, and they were still £400 short of this quota.

Hospital Treatment for the Middle Classes.

Sunderland Royal Infirmary has adopted a scheme to enable middle-class patients to avail themselves of all its private ward facilities on payment of £1 10*s.* per annum. The scheme applies to persons whose incomes fall within the following limits: Single adult persons under £300 per annum; married couples without children under 16, £400 per annum; widows and widowers *with a child or children* under 16, £400 per annum; married couples with a child or children under 16, £500 per annum. Single persons between the ages of 16 and 21 years who are not in receipt *of more than £100 per annum* will be admitted into the scheme on payment of an annual premium of £1. People with incomes above the insurance scheme limits may be admitted to private rooms, the charge for which will be not more than £5 5*s.* per week, with a minimum of £2 2*s.* The premium covers all medical and surgical nursing and maintenance costs while the patient is in the infirmary, but does not cover the cost of any special appliances, drugs, or instruments which may be ordered for treatment after discharge.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lts. J. Cussen, E. O'Reilly, *and* T. G. B. Crawford to be Surg. Lt.-Comdrs.

The following appointments have been made: A. B. Clarke to *Vivid* for R.N. Barracks, Devonport.

Surg. Lt. R. G. Dingwall to *Herald.*

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Comdr. A. G. Reade to *Repulse.*

Surg. Lt.-Comdrs. J. E. Purves transferred to London Divn.; and S. W. Davidson to *Frobisher.*

Surg. Lts. F. W. Chippindale transferred to Sussex Divn.; and F. D. Manners (D). to *Pembroke.*

Surg. Lt. (D).—W. R. Young to *Victory* for Haslar Hospital.

ROYAL ARMY MEDICAL CORPS.

Maj. J. W. Houston is placed on the half pay list on account of ill-health.

Capt. S. Griffin, late 3rd Bn., R. Ir. Regt., is granted a temp. commn. in the rank of Lt. and temporarily relinquishes the rank of Capt.

F. K. Bush to be Lt. (on prob.).

TERRITORIAL ARMY RESERVE OF OFFICERS.

Capt. P. J. Stokes from Active List to be Capt.

ROYAL AIR FORCE.

Lt. R. N. Kinnison (T.A.R.O.) is granted a short service commission as a Flying Officer for three years on the Active List.

RESERVE OF AIR FORCE OFFICERS.

Flying Officer S. S. Proctor relinquishes his commission on completion of service.

Medical Diary

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Thursday, June 25th.—11 A.M.–5.30 P.M., Exhibition of Instruments. Urology. 5.30 P.M., Discussion: The Treatment of Inoperable Carcinoma of the Bladder. Opener: Mr. Ogier Ward.

Friday.—Otology. Summer Meeting at Oxford. 2 P.M., Paper: Dr. W. T. Hillier: The Lateral Line of Sense Organs. 5 P.M., Demonstration: Dr. M. MacNaughton Jones: Models illustrating the Physiology of the Ear. Papers: Mr. E. A. Peters: A Test for Maximum Tuning Fork Hearing. A Case of Cerebellar Abscess Drained Anterior to the Lateral Sinus.

Saturday.—Otology. Summer Meeting at Oxford continued (see above). 10.30 P.M., Open discussion: The Physics of Sound and the Physiology of Hearing.

MEDICO-LEGAL SOCIETY.

Thursday, June 25th (at 11, Chandos-street, Cavendish-square, W.), Dr. T. H. Blench: Crime Investigation in Paris, followed by a discussion.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

Monday, June 22nd, to Saturday, June 27th.—Medical Society of London, 11, Chandos-street, Cavendish-square, W. M.R.C.P. Evening Lecture at 8.30 P.M. Tues., Dr. R. A. Young: Some Lung Conditions Simulating Pulmonary Tuberculosis. Fri., at 10, Beford-square, W.C., at 8.30 P.M., Dr. Knyvett Gordon: The Diagnosis and Treatment of Acute Bacterial Infections, illustrated by epidiascope, and followed by a laboratory demonstration.—Royal Northern Hospital, Holloway-road, N. Tues., 3 P.M., Demonstration of Surgical Cases by Mr. McNeill Love. No fee for attendance.—City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, E. Thur., 2 P.M., Demonstration in O.P. Department by Dr. Burton Wood. No fee for attendance.—Children Clinic and Other Hospitals. A Course of Diseases of Children, lectures and demonstrations. Second week.—Hospital for Tropical Diseases, Gordon-street, W.C. Second week of Course in Tropical Medicine, all day.—Royal Waterloo Hospital, Waterloo-road, S.E. Wed., at 4.30 P.M., Lecture by Dr. Slot on Recent Advances in Treatment of Gastro-intestinal Disease.—Royal Albert Dock (Seamen's Hospital Society), Greenwich. Course of demonstrations on Fractures, Tues. and Fri., Mr. Ernest Griffiths; Wed., Mr. Hope Carlton: time 4.30 P.M.—National Hospital for Diseases of Heart, Westmoreland-street, W. Intensive Course in Cardiology for two weeks.—Prince of Wales's Hospital, Tottenham, N. Intensive Course in Medicine, Surgery, and Specialties. Two weeks.—Further particulars from Fellowship *of* Medicine.

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith, W.

Monday, June 22nd.—10 A.M., Gynæcological Ward Visit, Genito-Urinary Operations, Skin Department. 11 A.M., Surgical Ward Visit. 2 P.M., Surgical Ward Visit. Medical, Surgical, Eye, Gynæcological Out-patients.

Tuesday.—9.30 A.M., Operations. 10 A.M., Medical Ward Visit, Dental Department. 11 A.M., Throat Operations. 11.30 A.M., Surgical Clinical Demonstrations. 2 P.M., Medical, Surgical, Throat Out-patients, Operations, Medical Ward Visit.

Wednesday.—10 A.M., Medical Ward Visit, Children's Medical Out-patients. 2 P.M., Medical, Surgical, and Eye Out-patients, Gynæcological Operations. 4.45 P.M., Venereal Diseases.

Thursday.—10 A.M., Neurological Department. 11.30 A.M., Treatment of Fractures. 2 P.M., Medical, Surgical, and Eye Out-patients, Genito-Urinary Department. Operations.

Friday.—10 A.M., Medical Ward Visit, Skin and Dental Departments. 12 noon, Medical Lecture. 2 P.M., Medical, Surgical, and Throat Out-patients. Operations.

Saturday.—9 A.M., Throat Operations. 10 A.M., Medical Ward Visit, Surgical and Children's Medical Out-patients.

NATIONAL HOSPITAL, Queen-square, W.C.

Monday, June 22nd.—12 noon, Dr. Greenfield: The Cerebro-spinal Fluid. 2 P.M., Dr. Riddoch: Out-patient Clinic. 3.30 P.M., Mr. Symonds: Minor Mental Disorders.

Tuesday.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Dr. Martin: Von Recklinghausen's Disease.

Wednesday.—2 P.M., Dr. Martin: Out-patient Clinic.

Thursday.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Dr. Riddoch: Neurosyphilis (2).

Friday.—2 P.M., Dr. Adie: Out-patient Clinic. 3.30 P.M., Dr. Collier: Muscular Atrophy.

CHARING CROSS HOSPITAL MEDICAL SCHOOL POST-GRADUATE COURSE.

Sunday, June 21st.—10.45 A.M., Mr. Norman C. Lake: Surgical Questions and Answers. 11.45 A.M., Dr. J. Russell Reynolds: Radium.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE, Keppel-street, Gower-street, W.C.

Friday, June 26th.—5 P.M., Sir Thomas Legge: Industrial Poisonings.

INSTITUTE OF PATHOLOGY AND RESEARCH, St. Mary's Hospital, W.

Tuesday, June 23rd.—5 P.M., Prof. Hamilton Hartridge: The Theory of Hearing.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

Tuesday, June 23rd.—3.15 P.M. (at the Royal Chest Hospital), Dr. Saxby Willis: Artificial Pneumothorax (Illustrated by cinema film).

HOSPITAL FOR EPILEPSY AND PARALYSIS, Maida Vale, W.

Thursday, June 25th.—3 P.M., Dr. Douglas McAlpine will demonstrate to Registered Practitioners.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION, St. James's Hospital, Ouseley-road, Balham, S.W.

Wednesday, June 24th.—4 P.M., Dr. Macdonald Critchley: Migraine.

ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY, 49, Leicester-square, W.C.

Wednesday, June 24th.—Annual general meeting. Clinical Cases.

NATIONAL ASSOCIATION FOR PREVENTION OF TUBERCULOSIS.

Thursday, June 25th, to Saturday.—(At Margate): Annual conference. Discussions on the Protection of the Child from Tuberculosis.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.

Friday, June 26th.—4 P.M., Mr. Gill-Carey: Operative Treatment of Sinusitis.

UNIVERSITY OF BIRMINGHAM.

Tuesday, June 23rd.—3.30 P.M. (at the General Hospital). Dr. T. L. Hardy: Colon Spasm and Colitis.

Wednesday.—4 P.M. (in the Large Theatre of the Medical Faculty, Edmund-street), Sir Hubert Bond: Some Correlations between General and Psychological Medicine. (Last Lecture.)

Friday (at the Queen's Hospital).—3.30 P.M., Dr. Cyril Maguire: Demonstrations of Medical Cases.

Appointments

Allen, Dorothy, L.R.C.P. & S. Edin., L.R.F.P.S. Glasg., has been appointed Asst. Medical Officer of Health, Barrow-in-Furness.

Craig, J. C. B., M.D., Ch.B. Edin., D.P.H., Asst. Medical Officer of Health, Carlisle.

Frazer, W. M., M.D., Ch.B. Liverp., D.P.H., Medical Officer of Health, Liverpool.

Sheffield Royal Infirmary: Platt, R., M.D., Ch.B. Sheff., Hon. Asst. Physician; Fawcett, A. W., M.B., Ch.B. Edin., F.R.C.S. Eng., Hon. Asst. Surgeon.

Certifying Surgeons under the *Factory and Workshop Acts*: Worsley, R. C., L.R.C.P. Lond., M.R.C.S. (Mitcheldean, Gloucester); Forsyth, J. M., M.B., Ch.B. Glasg. (Farnborough (No. 1) District); Gibson, G. M., M.B., Ch.B. Edin. (Cromarty, Ross and Cromarty).

Vacancies

For further information refer to the advertisement columns.

Aberdeen County.—Asst. M.O.H. £500.

All Saints' Hospital for Genito-Urinary Disease, 91, Finchley-road, N.W.—H.S. At rate of £150.

Barnsley, Beckett Hospital and Dispensary.—H.P. £200. Also Cas. O. £250.

Birmingham and Midland Eye Hospital.—Res. Surg. O. £150.

Birmingham City Babies' Hospital.—Res. M.O. At rate of £100.

Birmingham, Midland Hospital, Easy-row.—H.S. £150.

Birmingham University.—Walter Myers Travelling Scholarship. £300.

Blackburn Royal Infirmary.—Fourth H.S. £150.

Bolingbroke Hospital, Wandsworth Common, S.W.—H.P. At rate of £120.

Bolton Infirmary and Dispenary.—Two H.S.'s. Each £150.

Bradford Royal Eye and Ear Hospital.—Jun. H.S. £150.

Brighton Poor-law Institution.—Res. M.O. £850. Also Res. Sen. Asst. M.O. £400. And Visiting Surg. Spec. £325.

Bristol General Hospital.—Two H.P.'s, Two H.S.'s, Res. Obstet. O., and H.S. to Spec. Depts. All at rate of £80. Also Cas. H.S. At rate of £100.

Brookfield Orthopædic Hospital, Hale End, Woodford Green.—Anæsthetist.

Bury St. Edmunds, West Suffolk General Hospital.—H.P. and Obstet. O. £150.

Canterbury, Kent and Canterbury Hospital.—H.P. and H.S. Each at rate of £125.

Cardiff, Welsh National School of Medicine.—Jun. Asst. in the Medical Unit. £300.

Central London Ophthalmic Hospital, Judd-street, W.C.—Sen. and Jun. H.S. £120 and £100 respectively.

Central London Throat, Nose and Ear Hospital, Gray's Inn-road, W.C.—Third Res. H.S. At rate of £75.

Coborn School for Girls, 29–33, Bow-road, E.—Doctor. £50.

Connaught Hospital, Walthamstow, E.—Res. H.P. At rate of £100.

Coventry, Coventry and Warwickshire Hospital.—Res. Cas. O. £125.

Derby, Derbyshire Royal Infirmary.—Ophth. H.S. £150.

Dudley, Guest Hospital.—Two H.S.'s. £160–£170.

Durham County Hospital.—H.S. £150.

Eastbourne, Princess Alice Memorial Hospital.—H.S. At rate of £150.

East Lothian, South-Eastern Counties of Scotland Joint Sanatorium, East Fortune.—Asst. M.O. £250.

Elizabeth Garrett Anderson Hospital, Euston-road.—Asst. Radiologist. £100. Also 2nd H.S., and Obstet. Asst. Each at rate of £50.

Evelina Hospital for Children, Southwark, S.E.—Cas. and Out-Patient Officer. At rate of £120.

Exeter, Royal Devon and Exeter Hospital.—H.P. and H.S. to Special Depts. Each at rate of £150.

Folkestone, Royal Victoria Hospital.—Sen. and Jun. Res. M.O.'s. At rate of £125 and £100 respectively.

Gloucester, Gloucestershire Royal Infirmary, &c.—H.S. At rate of £120.

Grimsby and District Hospital.—Res. M.O. £200.

Grosvenor Hospital for Women, Vincent-sq., S.W.—Res. M.O. At rate of £100.

Hampstead General and N.W. London Hospital, Haverstock-hill, N.W.—H.S. and H.P. Each at rate of £100.

Hertford County Hospital.—H.S. At rate of £200.

Hospital for Sick Children, Great Ormond-street, W.C.—Part-time Jun. Cas. O. At rate of £150.

Hove Hospital, Sackville-road.—Res. M.O. £150.

Hull Royal Infirmary.—3rd H.S. At rate of £150.

Indian Medical Service.—Commissions.

Inverness, Royal Northern Infirmary.—Two H.S.'s. Each at rate of £100.

Ipswich, East Suffolk and Ipswich Hospital.—Cas. O. £120.

Islington Institution, St. John's-road, N.—Temp. Asst. M.O. At rate of £600.

Jewish Health Organisation, 19, Dorset-square, N.W.—Hon. Asst. Psychiatrist.

King's College Hospital, Denmark Hill, S.E.—Jun. Ophth. Surgeon.

King's Lynn, West Norfolk and King's Lynn General Hospital.—H.P. At rate of £125.

Leeds, Herzl Moser Hospital.—R.M.O. £200.

Liverpool, Alder Hey Children's Hospital, West Derby.—Sen. Asst. Res. M.O. £400.

Liverpool, Smithdown-road Hospital.—Res. Asst. M.O. £200.

London Hospital, E.—First Asst. and Reg. to Children's Dept. £300.

London Jewish Hospital, Stepney Green, E.—Asst. Gynæcologist.

London University.—Examinerships.

Longton Hospital, Staffordshire.—H.S. £120.

Manchester Royal Infirmary.—H.S. At rate of £100–£200. Also Res. Surg. Reg. to Out-patients. At rate of £150.

Mildmay Mission Hospital, Austin-street, Bethnal Green, E.—Jun. Res. M.O. At rate of £100.

National Hospital, Queen-square, W.C.—Hon. Asst. Radiologist. Also Registrar and Res. M.O. Each £200.

National Hospital for Diseases of Heart, Westmoreland-street, W.—Pathologist. £250.

Newcastle General Hospital.—Two H.P.'s and Three H.S.'s. All at rate of £100.

Newcastle-upon-Tyne, Royal Victoria Infirmary.—Two Res. Anæsthetists. Each at rate of £300.

Newport, Mon., Royal Gwent Hospital.—Jun. Res. M.O. £136.

Norwich City.—Asst. M.O.H., &c. £500.

Nottingham City Mental Hospital.—Jun. Asst. M.O. £350–£400.

Nottingham General Hospital.—H.S. At rate of £150. Also Casualty Officer. At rate of £200.

Oldham Royal Infirmary.—H.P. and Cas. O. Each at rate of £175.

Paddington Green Children's Hospital, W.—Hon. Surgeon to Ear, Nose, and Throat Dept.

Plymouth Central Hospital.—H.S. At rate of £150.

Plymouth, City Hospital.—Radiographer. £240–£280.

Portsmouth City.—Deputy M.O.H. £720.

Queen Mary's Hospital for the East End, E.—H.P., H.S. Also H.P. and Res. Anæsthetist. Each at rate of £120.

Queen's Hospital for Children, Hackney-road, E.—H.S. At rate of £100. Two Anæsthetists. Each £25. Also Res. M.O. £200.

Reading, Royal Berkshire Hospital.—H.P. and Res. Anæsthetist. £150.

Rochester, St. Bartholomew's Hospital.—H.P. At rate of £175.

Rotherham Hospital.—Cas. H.S. £150.

Rotherham, Oakwood Hall Sanatorium.—Asst. M.O. £300.

Royal Free Hospital, Gray's Inn-road, W.C.—Unit Anæsthetist. £150. Also Clin. Assistantships to Spec. Depts.

Royal National Orthopædic Hospital, 234, Gt. Portland-street, W.—Asst. Reg. Surg. for Country Branch. Stanmore. £350.

Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—Cas. O. £200. Also H.S. At rate of £100.

St. Alfege's Hospital, Vanbrugh-hill, Greenwich.—Asst. M.O. At rate of £250.

St. Leonard's-on-Sea, Buchanan Hospital.—Jun. H.S. At rate of £125.

St. Mary's Hospital Medical School, W.—Asst. Director to Surgical Unit.

St. Thomas's Hospital.—Two Surgical Registrars. Also Asst. in Dept. of Psychological Medicine.

Samaritan Free Hospital for Women, Marylebone-road, N.W.—Registrar. £130.

Sheffield Children's Hospital.—Whole-time Registrar-Pathologist. £350. Also 3rd Res. M.O. At rate of £80.

Sheffield, Nether Edge Hospital.—Asst. M.O. £350.

Sheffield Royal Infirmary.—H.S., Ophth. H.S., Asst. Aural and Ophth. H.S. Each at rate of £80.

Stourbridge, Corbett Hospital.—Res. H.S. At rate of £200.

Swansea General and Eye Hospital.—H.P. £150.

Walsall General Hospital.—H.S. At rate of £150.

West End Hospital for Nervous Diseases, Gloucester-gate, Regent's Park, N.W.—Jun. H.P. At rate of £100.

Wolverhampton County Borough.—Asst. M.O. £550.

Wolverhampton Royal Hospital.—H.S. At rate of £100.

Woolwich and District War Memorial Hospital, Shooters Hill, S.E.—H.P. At rate of £100.

The Chief Inspector of Factories announces a vacant appointment for a Certifying Factory Surgeon at Golspie (Sutherland).

Births, Marriages, and Deaths

BIRTHS.

IRWIN.—On June 5th, at Devonshire-street, W., the wife of W. K. Irwin, M.D., F.R.C.S., of a son (prematurely).

STRONACH.—On June 10th, at Nottingham, Marjorie, the wife of Ian D. Stronach, F.R.C.S. Ed., Mansfield, of a son.

MARRIAGES.

DAVIES—MCCALDIN.—On June 11th, at the Presbyterian Church, Monaghan, Ireland, John Llewellyn Davies, F.R.C.S., Wellington Circus, Nottingham, to Dorothy Grace, eldest daughter of Mr. W. A. McCaldin, Glenview, Monaghan.

HEWETSON—GODSON.—On June 10th, at the Parish Church, Cheadle, Cheshire, James Charlesworth Hewetson, M.B., B.S., to Enid Frances Entwistle, youngest daughter of Dr. and Mrs. J. H. Godson, of Cheadle, Cheshire.

SATCHWELL—WEIR.—On June 8th, at the Parish Church, Milford Haven, Thomas Allen Satchwell, L.D.S., to Sidney Marion Weir, B.A., L.D.S.

STARLING—CRACKNELL.—On June 13th, at St. Paul's, Rusthall, Dr. E. C. W. Starling, to Nancy Cracknell, daughter of Mr. and Mrs. Cracknell, of Tunbridge Wells.

WELLISH—MANNERS.—On June 11th, at St. James's Church, Riddlesdown, Gilbert Charrington Wellish, F.R.C.S., of Croydon, to Edith, widow of Mr. Ramsay Manners.

DEATHS.

BRAITHWAITE.—On June 8th, Edward Ashe Braithwaite, M.B., C.M. Edin., J.P., of West Croft, Egremont, Cumberland, in his 64th year.

BROOKMAN.—On June 12th, Hubert Brookman, M.R.C.S., L.R.C.P., D.P.H., of Woodside Park-road, North Finchley, N., and late of Potters Bar, aged 36.

FERGUSON.—On June 8th, at the West London Hospital, Andrew James Ferguson, M.A., M.B., Ch.B., of Holland-road, Kensington, W., aged 44.

GRANT.—On June 11th, at Willesden Hospital, Charles Hamilton Russell Grant, L.D.S. R.C.S. Eng., of Cuckoo-hill, Lodge, Eastcote, aged 50.

MACFIE.—On June 9th, at a London nursing home, Ronald Campbell Macfie, M.A., M.B., C.M., LL.D.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages and Deaths.

GLASGOW ROYAL MENTAL HOSPITAL.—Permission has been given for the name of the Glasgow Royal Asylum for Lunatics to be changed to "The Glasgow Royal Mental Hospital."

is taken and charted on a twice-daily chart at approximately the same hours each day. A half-minute thermometer is used and is left in the mouth for two minutes.

May I beg for insistence by all practitioners that the nurse in private practice shall keep charts? Too often have I been called into consultation on a difficult case to find that the nurse has given up the "silly habit" of keeping charts, years ago!

The morbidity figures for the first three years of my mastership are given below, but in view of the increasing number of complicated cases which seek admission, I have little hope of sustaining these figures. During this period there were 250 cases morbid according to the B.M.A. standard already mentioned. As there were 6075 deliveries in the intern maternity during the time, the percentage rate is 4·1. Of these 250 cases, 128 were operative deliveries, 81 were due to extra-genital causes, and 41 were ordinary cases. That is, 50·1 per cent. of the morbidities were in cases which required some manipulation, while 16·4 per cent. were natural deliveries; surely an argument against interference except when absolutely necessary. Taking the three years together, the greatest number occurred in the three months January, February, March, when the number was 85 of the 250. Taking all in all, there is little to be ascertained as to seasonal activity of sepsis. The following Table shows the numbers in the different months.

Nov.	Dec.	Jan.	Feb.	March.	April.	May.	June.	July.	August.	Sept.	Oct.
10	7	15	11	16	10	10	7	12	9	6	11
8	6	8	9	6	8	6	3	3	4	6	2
2	4	9	8	3	4	5	1	2	9	3	7
20	17	32	28	25	22	21	11	17	22	15	20

Total 250 in 6075 deliveries—i.e., 4·1 per cent.
Of these there were 128 operative deliveries, 50·1 per cent.
" " " 41 non-operative " 16·4 " "

The Private or Hospital Patient.

In considering this whole question, are we dealing with the patient with complete theatre equipment in hospital or in the slum dwelling? Are we catering for the patient in her private house or in the private home? The answer is that it is the duty of those who have control of institutions, and who are teaching post-graduates, to prepare them for every emergency. This has been the object at the Rotunda for many years, and in attaining our results it must be remembered that, unlike some institutions, there is much teaching given to post-graduates, undergraduates, and nurses, and that this necessarily entails added manipulation; in comparing statistics of one institution with another, these facts must be borne in mind. We endeavour to work out a line of treatment which can be carried out in any surroundings.

I do not believe in teaching my students that a midwifery case must be conducted like a surgical operation; this is a catchword spoken by those who cannot realise the difficulties of practice. It is an expression more from the mouth of the gynæcologist than from that of the obstetrician. It is important for the general practitioner, when he requires a consultant on midwifery, to find out if the latter is really a practising obstetrician. I shall probably be castigated as retrograde, unsurgical, and unsound, but in spite of these hard words I refuse to be classified as unobstetrical.

Instruction in Puberty and at Marriage.

Instruction at puberty is all-important for the future mother. A girl should be taught about the onset of menstruation and, according to recent investigations, she should be taught that a healthy body and mind are best obtained by continuing with normal life—games, dancing, and work—during the menstrual period. At marriage there should be knowledge both of the sex act and of sexual relations in general. Especially should it be pointed out that contraception in early marriage is inadvisable. I have been consulted over and over again by women who are anxious to be cured of sterility and who have practised contraception for two or three years. They do not know whether this practice has caused sterility (probably by blocking the tubes through an ascending infection from the vagina) or whether sterility would have occurred in any case. It must also be remembered that contraceptives of certain types may cause an infection which may further cause trouble in labour.

CARE OF PATIENT IN PREGNANCY.

It is all-important that the patient should have a favourable outlook on life. The gloomy forebodings of the pessimist, the growls of the angry or worried husband, the startling tales of abnormal labours by nurses and so-called friends, should have no place in the prenatal armamentarium. I am convinced that depression of any kind lessens resistance, and I have always urged pleasant people and surroundings, with peace of mind, for my pregnant patients.

Fresh air should be insisted on. Daily baths at a temperature of 100° F. should be taken. Coition should be moderate and should not take place, in a normal case, during the last month; if there is any history of abortion it is wiser to avoid it altogether. The word constipation suggests infection; rheumatism is well known to be caused through it. Surely it may be ætiological in sepsis; laxatives and suitable diet must be ordered. Anæmia, too, lessens resistance; if the ordinary organic or inorganic iron, orally administered, is unsuccessful, injections of iron and arsenic should be given. Sepsis and anæmia are boon companions. Various bacteria have been blamed for the toxæmias, so that it is obvious that bacteria are present. In our experience, a mild "sapræmia" is not a rare occurrence in the puerperium of a toxæmic patient. In addition, all debilitating diseases will lower resistance. Gonorrhœa is a definite danger; if the discharge is heavy in pregnancy, antiseptic vaginal douches should be given. In labour complicated by gonorrhœal discharge there should be no manipulation, such as vaginal examination or forceps application, unless the necessity is absolutely imperative.

CARE OF PATIENT IN LABOUR.

Every detail is important. When we remember the excellent results we obtained before the present labour ward was built—results nearly as good as those of the present day, and better than many of the years immediately after the closing of the old labour ward—we believe all the more in our ideas that the doctor and the nurse are the chief factors in obtaining good results.

Excellent results were obtained by keeping all bowls and basins in 1 in 40 carbolic acid, but I have adopted the boiling method as a step in the right direction. Needless to add, a thorough scrubbing and disinfecting has been and always is carried out immediately after use. The gloves are boiled. Dry sterilisation may be better, but the ordinary general practitioner will have no access to an autoclave and he must learn how to boil and how to put on wet gloves in a thoroughly safe manner.

The attendant should wash his hands and wear gloves, but need not wear a mask or a sterile gown. The hands are washed for four minutes with a boiled nail-brush, clean soap, and hot water. The soap is then removed and the hands steeped for one and a half minutes in 1/1000 solution of biniodide of mercury. We do not use sterile water; this is unnecessary, for all general practitioners cannot get supplies of sterile water for washing hands, and certainly we find the water-supply from the Vartry river absolutely safe and reliable. Gloves are always worn and we take much trouble to teach students how to put them on. We have seen so-called trained surgeons who were quite unable to put on gloves cleanly. A long rubber apron is worn, and the hands are kept sacred and clean.

No masks or gowns are worn or advised in a normal case. I am absolutely convinced of the wisdom of this teaching. The man who wears a mask will breathe on it; he may then handle the mask, after which he continues with his obstetrical manipulations. Even if he wears a non-sterile mask he will be more inclined to concentrate on it than to keep his hands clean. When is a man in a private house to put on his gown? How is he to protect it from being soiled? Too often I have seen the gown rubbing unwittingly against some article of furniture; then the "surgeon" allows his glove to become contaminated by the dirty gown, later giving sepsis to the patient. I do not mean to decry the teachers' wish for the sterile gown, but I do not believe it possible to teach their safe usage to the future general practitioner. I advise the gown in operative midwifery, but often the forceps are applied without a gown being worn, simply to show the student that a safe job can be done without it, and that his hands are the really sacred and untouchable part of him which must only be used for the purpose for which he is present—the actual labour.

I have tried various forms of Kocher's sheets and have given them all up. All normal deliveries are carried out in the left lateral position, where a thorough observation can be made and whereby no soiling by bowel matter can occur. If dressings are applied they are inclined to shift to and from the anus with consequent contamination; if the perineum tears, they are in the way. I have given up all dressings on the vulva at normal deliveries, and am satisfied that a cleaner labour results.

THROATS.

It has been the custom to blame the throat where no other cause of sepsis could be found. B. P. Watson, in his extremely interesting and straightforward paper, describes how he could find no other cause for a terrible outbreak. Obstetricians in England delight in proving or disproving the contention. Dr. F. S. Bourke, pathologist to the hospital, assisted by Dr. H. E. Canter—one of our post-graduates—examined swabs and took material for culture from 50 throats. The following list, showing the result obtained, was taken haphazard, with the exception of No. 13, who had a septic throat and was off duty. Are Dublin throats different from others? Is it not strange that there were no hæmolytic streptococci in the 50 throats examined? Does not this examination bear out the futility of counting on the wearing of masks as a real bar to the occurrence of sepsis? In addition it must be remarked that my four assistants and I all harboured some bacteria; yet there was no outbreak of sepsis! And, further, since the investigation one of my assistants has had a pure streptococcus infection with pus exuding from his throat, and still the patients were unaffected.

Sterile	10
Hæmolytic staphylococci and non-hæmolytic streptococci	5
Staphylococcus aureus and *Micrococcus catarrhalis*	2
S. aureus	13
S. albus	1
Hæmolytic *S. aureus*	3
Gram-negative and positive cocci and bacilli	1
S. aureus and *M. tetragenus*	1
Gram-negative and positive cocci and bacilli	1
Gram-negative bacilli and streptococci	1
S. albus and Gram-negative bacilli	1
S. aureus, streptococci, and Gram-negative bacilli	1
Hæmolytic and non-hæmolytic streptococci—	
Staphylococci	1
Contaminated	8

Let this effort cease, and let us concentrate on clear issues. Let those who wish to wear masks do so, provided they are not regarded as a fetish, but only as a very small and possibly necessary link in the chain to be forged for the prevention of sepsis.

FURTHER CARE OF THE PATIENT IN LABOUR.

A hot bath should always be given. In Dublin, the Vartry water is so clean that there is no need to prevent the water from entering the vagina. The trellis arrangement in the bath is not used; the same applies to the shower and needle bath. An ordinary reclining bath is the rule, and is of great advantage to the patient; she takes it after the enema, when she enters hospital. She is then shaved.

Just as the psychological aspect in pregnancy is all-important, so it is in labour. Resistance should be sustained by encouragement, and this is all the more necessary in a lengthy labour. Diagnosis must be made with care. An early diagnosis of abnormal presentation may prevent serious trouble later, and diagnosis should be made nearly entirely by palpation and rectal examination. A knowledge of the mechanism of normal labour is essential for a knowledge of the abnormal; it is important therefore that progress should be noted. With a knowledge of the mechanism of normal labour, failed forceps will be a thing of the past. Post-graduates should be instructed and should be given opportunities to watch normal labour. Credit should be given to the student who describes the normal labours he has seen. This is all far more important than the advanced lectures given in some institutions to post-graduate classes.

Vaginal examinations should be made seldom, but if there is doubt in the mind of the attendant about the presentation, a vaginal examination should certainly be made, and if this does not give the desired information, the half or whole hand should be passed under an anæsthetic. This is rarely necessary; in fact, vaginal examination should scarcely ever be made.

While I am an ardent supporter of the lower segment Cæsarean section after trial of labour, I also recommend the classical section for the clean patient who will quite certainly not be able to deliver herself, and thus prevent morbidity. Any instrumental or internal manipulative delivery tends to increase morbidity; a study of the records of all maternity hospitals confirms this point. Should forceps ever be applied? The percentage rate of forceps application at the Rotunda varies from 6 to 6·5, and these figures include all forceps cases—i.e., they include delivery of moribund patients and many pre-labour morbid cases. We preach from the housetops: no application until all conditions are fulfilled, but in spite of this we sometimes, when fœtal distress occurs, apply while the head is in the mid-strait. The danger of the "drag through" is extreme. I am in absolute agreement with those writers who regard a vaginal trauma as the most likely cause of sepsis, and no matter how carefully the vagina is ironed, and how slowly the delivery is accomplished, the application of forceps other than in the lower strait is attended by an increased morbidity and by some mortality.

We do not teach the use of the Kielland forceps; we are not a radical school except in our ideas of caution. We believe it is iniquitous to teach a method, that may be used with success by a skilled obstetrician, to general practitioners who will neither have the time nor the knowledge to acquire skill in its use. We have already seen at the Rotunda many examples of the misuse of this instrument outside.

After the birth it is obviously of the greatest importance to separate the vulva and look carefully for inside as well as outside tears.

While douching before instrumental labour is the rule, the douche is not used in the normal labour, nor in the puerperium. There has been a vogue lately to teach that secondary repairs should be performed at the *termination* of labour. We believe that this is a dangerous teaching. Imagine a practitioner in a private house starting to do a trachelorrhaphy for a cervical tear sustained in a previous confinement. If this is done maternal mortality will certainly increase.

In every case which is at all suspicious—i.e., where examinations have been made outside the hospital, where manipulations in the hospital have been extensive, especially those causing pain or where there is a questionable discharge—20 c.cm. of antistreptococcal serum is given, and the uterus is activated in the puerperium by the administration of ergotinin phosphate or ergotamine tartrate and quinine grs. 5 three times a day. If the vagina has been traumatised, tincture of iodine 2 per cent. mercurochrome or brilliant green is poured in. Other drugs have been suggested for this purpose, but I think that too much reliance should not be placed on any of them.

The Puerperium.

Immediately after a labour where there has been retention of membranes, the patient is ordered a routine dose of ergot and quinine three times daily. In suspicious cases antistreptococcal serum, 20 c.cm., and quinine, grs. 7½, are given as a prophylactic. Insistence on free movement is the rule and on the appearance of fetid lochia, rising from bed for five minutes twice daily is ordered.

In hospital the hours of the nurses are arranged so that one nurse washes up her patient. Most important of all is the arrangement of numbering the bed-pans, wash-up pans, and bed. Each bed has its own set of utensils. The following are required: (1) cup or small bowl in which to place the pad; (2) small enamel plate for the soap; (3) kidney tray to receive the soiled pad and swabs; (4) douche pan; (5) douche basin; (6) scrubbed bowl in dish of disinfectant; (7) forceps. The bowl, plate, kidney tray, and forceps are sterilised by boiling for 20 minutes. The douche pan and basin are scrubbed with weak cyllin with a nail-brush, and rinsed with warm water. We do not believe it is necessary to boil the douche pan; we must teach our nurses to learn to be as clean as possible in the cottage. The "wash-ups" are done at 7.30 A.M. and 7.30 P.M. Finally, in removing stitches, great care must be taken to clean the perineum properly, or else septic material will be drawn through the tissues. I have seen a sudden septicæmia arise from carelessness in this respect.

Isolation.

Maternity hospitals are being built and altered in the effort to combat maternal mortality, and extravagant notions have been circulated about the necessity for numerous wards. Primarily, it must be stated that all suspect cases must be isolated. This has been the custom at the Rotunda for scores of years, and it is nearly amusing to think that people are still questioning this absolutely necessary aspect of security. Isolation has been the custom, and it has been practised without frills or embroidery. In designing a labour department, one ward where suspect cases can be delivered is a necessity. Wards for puerperal suspect cases are just as necessary. Following the preliminary investigation after admission, the suspect is sent to an isolation ward with a special nurse, and there she is delivered. Small isolation pre-labour wards are better than large. After the birth, the *patient is transferred* to the small puerperal isolation ward, where she is attended by a special nurse. The segregation of suspect cases is a necessity. As for the pre-labour case, so for the puerperal: small wards are better than one large ward, for then the gonorrhœal case can be separated from the tubercular, the septic abortion, the puerperal streptococcic, and from any other infective case of unknown origin.

In the puerperium, immediately a rise of temperature is discovered, the patient is isolated; she may be well in 24 hours, but if she is not isolated, the ward and even the hospital may become a seething nidus for the bacteria which abound. Thus will hospitalisation become condemned, and thus will patients be advised to remain in their own homes—a pernicious habit.

Conclusions.

1. Prenatal care, though important, must not mask the fact that complications of labour will occur in spite of it.

2. There is *a cure for all cases* of sepsis. It is a mistake to concentrate on one method of treatment. The difficulty is to discover the treatment suitable for the case.

3. In a questionaire to a small number of patients who had been morbid in the puerperium, the complaints were found to be surprisingly small; 58 per cent. became pregnant soon afterwards.

4. There should be an international standard of morbidity. At least there should be a national standard. It is suggested that the British College of Obstetricians should give judgment on this.

5. At the Rotunda there were 250 morbid cases in 6075 deliveries, i.e., 4·1 per cent.; of these 50·1 were operative cases.

6. Meddlesome midwifery should be avoided when possible.

7. Figures of hospitals where teaching is not done should be better than those where there is much instruction given.

8. Teaching of post-graduates in hospital should prepare them for general practice, not for work in palatial surroundings.

9. Sepsis can be prevented by care in pregnancy.

10. The obstetrician must know how to put on gloves.

11. It is necessary to wear gloves at all midwifery cases. The wearing of masks and gowns is not essential.

12. Details are given of the examination of 50 throats, which negatives the theory that throats are responsible for sepsis.

13. Aseptic dressings around the vulva are more inclined to be a danger than a preventive.

14. While forceps may be used, such procedures as the delivery of a head in the superior strait by the Kielland or any other forceps is condemned.

15. Small isolation wards for suspect cases in pregnancy, labour, and the puerperium are necessary.

It is a well-known fact that the quickest and safest way to climb a mountain is not to take short cuts, so the best method of combating the scourge of sepsis is not by complicated manœuvres or by working in operating theatres. Success will be achieved, apart from the methods outlined in my paper, by (1) the better education of the student and nurse in hospitals where there is a sufficient amount of material available, (2) by increasing post-graduate facilities for both, and finally, by propaganda with pregnant women themselves.

I have already suggested that doctors and nurses holding public appointments should have compulsory post-graduate training, which should not be included in their leave, the expense of which should be paid for out of the rates.

DIPHTHERITIC HYPOPIESIA.

By C. Fraser Brockington, M.D., D.P.H. Camb.,
ASSISTANT COUNTY MEDICAL OFFICER OF HEALTH FOR WORCESTERSHIRE

Towards the end of the first fortnight in diphtheria a clinical condition develops which may be fatal, and which is clearly separable from early cardiac failure. The chief feature is an extremely low blood pressure, an exaggeration of the fall which occurs in all grades. This extreme diphtheritic hypopiesia has hitherto been confused with early cardiac failure. The syndrome to which it gives rise bears a close resemblance to that of extreme myocardial damage yet is clearly distinct from it. The mode and time of onset of the two conditions differ: early cardiac failure may occur in cases of varying severity; extreme diphtheritic hypopiesia occurs only in the most severe variety of diphtheria. In my series of cases I found that these two conditions accounted for about 50 per cent. of the deaths in the first three weeks of the disease, so that each is of equal importance as a fatal complication.

In support of this differentiation a study has been made of the blood pressure in all degrees of faucial diphtheria, and the main features in relation to severity have been ascertained. The evidence obtained in this way serves to corroborate the clinical evidence in making the distinction.

CLASSIFICATION OF FAUCIAL DIPHTHERIA.

It has been considered desirable for the purposes of this investigation that the cases of faucial diphtheria should be classified into degrees of severity at the outset. In this way the features of the hypopietic curve can best be considered in relation to the presumed absorption of diphtherial toxin. The patients have been arranged into five arbitrary groups and the clinical signs and symptoms determining each are set forth below. The clinical features have been given an order which my experience has led me to believe to be of the most importance in gauging the degree of severity. For example, the presence of an extreme degree of glandular swelling in the neck amounting to "bull-neck" would be an important indication of severity and, in conjunction with other symptoms, would lead to a classification of "severe." The absence of any "pain response" during the administration of the antitoxin denotes in my opinion a severe degree of toxæmia, and those cases in which the needle may be inserted painlessly, as into a pat of butter, I find usually of the severer variety. It is, however, of the greatest importance in gauging the degree of severity to consider the case in all its details, and one or two symptoms alone have not been relied upon for classification. An extreme amount of hæmorrhagic membrane is important, but this alone would not warrant the classification of "severe$_1$" if the patient had an excellent pain response and no nasal discharge nor fœtor. Similarly, membrane might be absent (having separated) and yet other symptoms determine the classification of, say, "severe$_2$."

The following are the groups :—

Severe$_1$.—(1) Bull-neck extreme; (2) membrane extensive (over soft palate), thick and hæmorrhagic; (3) no pain response; (4) marked fœtor—may be extreme; (5) ichorous nasal discharge; (6) late case, fourth, fifth, sixth days; (7) early palatal palsy (first week); (8) toxic appearance; (9) albumin in fair amount in the urine—i.e., a cloud on boiling; (10) temperature low (only in very late cases.)

Severe$_2$.—The symptoms and signs of "severe$_1$" in lesser degree or with some absent. The patient is not "in extremis."

Severe$_3$.—(1) Glandular swellings present in the neck; (2) membrane thick and may be extending on to the palate—it is usually hæmorrhagic; (3) little or no pain response; (4) fœtor present but not extreme; (5) beginning to be toxic in appearance; (6) third or fourth day cases, possibly second if great virulence; (7) albumin in urine; (8) nasal discharge not usually present; (9) early palatal palsy does not usually occur.

Medium.—These are third day cases without glandular swelling and in which the membrane is still confined to the tonsils. They are not toxic in appearance and there is usually a good pain response. Fœtor is absent or very slight; there is no nasal discharge and usually no more than a faint trace of albumin in the urine.

Mild.—First or second day cases without any additional signs of severity.

Hypopiesia and Heart Failure.

An analysis of a series of blood-pressure charts brings out the following points: 1. After a latent period there is a progressive fall followed by a rise of blood pressure in all cases of faucial diphtheria. 2. The pressure does not begin to fall below its normal level (in the absence of early cardiac failure) until the seventh day of the disease. This is irrespective of the severity. The fall most commonly begins on this day, but may be postponed until the eighth, and occasionally the ninth day. There is, in fact, a latent period of seven to nine days. 3. The curve so formed is uniform and, if allowance be made for the irregularities due to excitement, the fall and rise may be assumed to be regular. 4. In many cases the pressure during the first few days is increased above the normal. This may be due to excitement. 5. The lowest point is reached between the eighth and twelfth days. There seems to be a tendency for severe cases to reach the lowest level on the eleventh and twelfth days. 6. In the event of recovery, the normal is reached again on the twelfth to the twenty-second day of the disease. 7. The depth of the curve is in direct relationship to the severity of the disease. Thus :—

(1) Lowest points registered (average) :—

Mild	88
Medium	75
Severe$_1$	62

Severe$_2$ all died with early cardiac failure.
Severe$_3$ all died lowest figure recorded 45.

(2) The depth of the fall (average) :—

Mild	17·6
Medium	19·3
Severe$_1$	35·0

Severe$_2$ died with early cardiac failure.
Severe$_3$ died (hypopiesia), blood pressure unrecordably low at death.

Severe attacks of diphtheria may bring the patient in danger of death at any time during the first three weeks. The chief indication of such a possibility is the onset of vomiting. It has been the practice to group the majority of such occurrences under the heading of myocardial damage. This group in reality includes two different clinical conditions. I have given the name extreme diphtheritic hypopiesia to the condition which must be distinguished from early cardiac failure. The main points of difference are shown in the Table.

	Early cardiac failure.	*Extreme diphtheritic hypopiesia.*
1.	Early onset (average, sixth day).	Late onset (average eleventh day).
2.	Early fall in blood pressure coinciding with onset of symptoms.	Late fall in blood pressure, symptoms coinciding with lowest point of the curve.
3.	Sudden onset, with sudden fall of bloodpressure.	Gradual onset with gradual fall.
4.	Vomiting, with pain in chest and perhaps breathlessness.	Vomiting without pain.
5.	Breathlessness only in the attacks.	Continuous "air hunger"—e.g., sighing, attempts to sit up.
6.	Signs of myocardial damage—i.e.: Rapid pulse 120–140. Dilated heart. Irregular pulse. Apex-beat diffused. *First sound modified.* Pain in the chest.	No sign of myocardial damage—i.e.: Pulse-rate normal. Size of heart normal. No irregularity of the pulse. Apex-beat localised and firm. No modification of the first sound. No pain in the chest.
7.	Symptoms may occur when the blood pressure is still relatively high—e.g., 80 mm. of mercury.	Symptoms only when the blood pressure is very low—e.g., 55–60 mm.
8.	Restlessness only mild.	Restlessness extreme and agonising.
9.	Cold extremities.	—
10.	Subnormal temperature.	—
11.	Occurs in all severe grades.	Occurs only in the severest grade.
12.	In the event of recovery the blood pressure returns very gradually to normal over a period of weeks, with the recovery of the myocardium.	In the event of recovery the pressure is normal by the end of the third week.

It is evident that, as the depth of the fall of blood pressure increases with the severity of the attack, a very low point will be reached in the severest grades. On theoretical grounds, therefore, the severest grades might be expected to give signs of this extreme hypopiesis. The time for the occurrence of symptoms would be between the tenth and the thirteenth days, during which period the blood pressure is normally at its lowest level. In practice the severest grades do present during this period (tenth to thirteenth days) a clear-cut syndrome of restlessness, vomiting and air-hunger, which suggests very strongly that the condition under consideration is a result of extreme hypopiesis.

Representative Cases.

EXTREME HYPOPIESIS.

In the severe cases in which a marked fall of blood pressure ensues, no symptoms arise until the pressure falls to a very low level. In my cases there was a striking absence of symptoms while the systolic pressure remained above 60 mm. of mercury.

A "severe$_3$" case was a boy aged 6, a contact of two fatal cases, admitted on the second day of the disease. He had a thick hæmorrhagic membrane confined to both tonsils, slight nasal discharge, some fœtor and a slightly toxic appearance, but no glands in the neck. There was an excellent pain response, and a little albumin in the urine. He received 40,000 units of antidiphtheritic serum intramuscularly. The membrane spread during the following night in a thin layer over the palate. There was complete early palatal palsy lasting six weeks, and lower limb palsies and eye palsies in the sixth and seventh weeks.

The blood pressure began to fall on the sixth day of disease and reached 60 mm. on the tenth and eleventh days. The pulse at the lowest limit was poor and easily compressible. No symptoms occurred.

Symptoms are not, apparently, to be expected until the pressure becomes as low as 55, when there is a fall in temperature to subnormal and the extremities become cold. At the same time three symptoms arise: vomiting, restlessness, and sighing. The restlessness is persistent and agonising to watch. When once it has been seen it is difficult to forget. The child, unable to remain in any one position for more than a few moments at a time, turns this way and that, while the arms move aimlessly around in never ceasing unrest. Sighing accompanies this wearisome unrest, the child makes frequent efforts to sit up and the breathing is rapid, almost panting, so that the picture presented is one of "air-hunger." The vomiting is persistent, occurring after any nourishment by mouth, and apart from food. It is very frequent and is comparable to that seen in Addison's disease.

CASE 1.—A girl, aged 10, was admitted on the tenth day with every sign of the greatest severity. A dark hæmorrhagic membrane was protruding from the mouth which was locked by reason of the tremendous bull-neck. Fœtor was extreme and there was a blood-stained nasal discharge and extremely toxic appearance with a cloud of albumin in the urine. There was no pain response and complete early palatal palsy. She had 20,000 units of Danish State Institute (D.S.I.) serum intravenously and 40,000 intramuscularly. All the symptoms cleared up in two days, leaving the child normal in appearance.

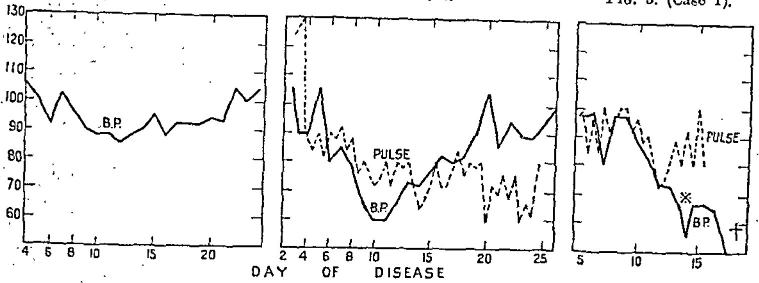
The pressure remained at 95 until the ninth day and then fell steadily to 55 on the fourteenth day (Fig. 1). For two days before this low level it remained just over 60 and the child was to all appearances making excellent progress. As the pressure reached 55, sighing, restlessness, and vomiting began. The heart was within normal limits, the pulse-rate was normal, and there was no irregularity of the rhythm. There was no cardiac pain, and the apex-beat was firm and localised. Ephedrine gr. ½ was given four-hourly and the pressure remained above 65 for three more days. On the seventeenth day the pressure again began to fall, and the last registrable reading was 45. The child lived until the beginning of the nineteenth day, 36 hours after the pulse had become impalpable and the blood pressure unregistrable. To the end there were no signs or symptoms of cardiac failure. The restlessness became more and more marked, vomiting more frequent, sighing continuous, and the extremities cold and lifeless. The child was conscious and talked to me to the end, wishing to be propped up in bed, in which position she seemed easier. She faded away, the exact time of death being difficult to determine.

CASE 2.—A boy, aged 10, was a "severe$_1$" type on the fourth day. He had a hæmorrhagic membrane over the palate and marked fœtor, bull-neck, ichorous nasal discharge, and a toxic appearance. He received 32,000 units of antidiphtheritic serum intramuscularly.

The pulse remained good and full until the ninth day of the disease, when the temperature fell to subnormal. Restlessness, sighing, and vomiting began on the tenth day. The extremities became cold and lifeless and the pulse almost impalpable. The signs of air-hunger became more and more distressing and the child died very gradually on the twelfth day. During the whole period the pulse remained regular and at normal rate. There was no cardiac pain nor dilatation of the heart. (A continuous blood-pressure chart was not kept.)

CASE 3.—A girl, aged 9, had on the fourth day a hæmorrhagic membrane to the front teeth, marked fœtor, ichorous nasal discharge, a very toxic appearance, and no pain response. Albumin was found in the urine for six weeks, and complete early palatal palsy lasted for seven weeks, and lower limb and eye palsies later. There was *ptosis* in the fifth week, and a petechial rash on the back and arms and hæmorrhagic blotches on the arms. She was given 2000 units of antidiphtheritic serum intravenously and 20,000 intramuscularly, and had ephedrine gr. ½ four-hourly

FIG. 1. FIG. 2. FIG. 3. (Case 1).

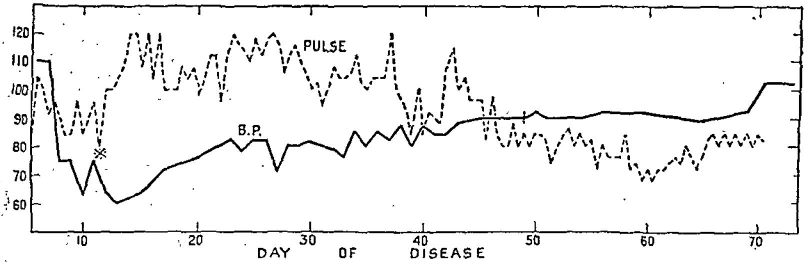


Fall of blood pressure in a mild case (Fig. 1), a severe case (Fig. 2), and a case of extreme hypopiesis (Fig. 3). In Fig. 3 the asterisk shows the time of the onset of vomiting and restlessness. Ephedrine was then given. † = time of death.

from her admission for ten days and six-hourly for a further seven days.

Restlessness, sighing, and vomiting occurred on the twelfth and thirteenth days, at which time the pulse was poor and easily compressible. Restlessness ceased on the fourteenth day. Vomiting continued occasionally until the eighteenth day, when the pulse was full and the child demanded food and began eating voraciously. She was discharged in the thirteenth week. At no time was there any indication of myocardial damage. The pulse-rate never rose above 95 and during the period of air-hunger the beat was regular between 76 and 80. The heart was always in normal limits and the apex-beat firm and localised. Recovery in this girl may have been due to the continuous administration of ephedrine. (No continuous blood-pressure record was kept.)

FIG. 4 (Case 5).



Pulse and blood pressure charts in a case of early cardiac failure. The asterisk shows the time when vomiting began with cardiac pain and breathlessness.

EARLY CARDIAC FAILURE.

As has been previously emphasised, the main features of this condition are the sudden onset at an early date, before the normal fall in blood pressure has begun; the steep fall in pressure due to the dilating myocardium; and the very definite signs of myocardial damage, of which the most important is the increase in the pulse-rate.

FIG. 5.

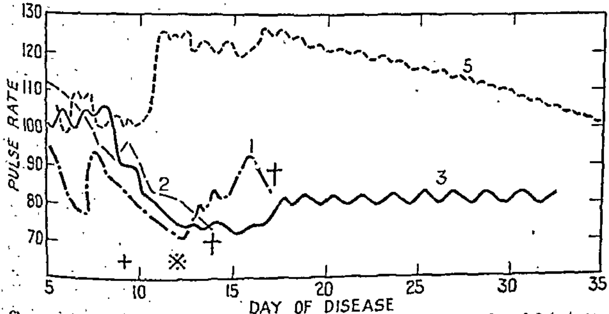


Chart showing pulse-rates in Case 5 (early cardiac failure), and Cases 1, 2, and 3 (extreme diphtheritic hypopiesia). + = the onset of vomiting and cardiac attacks in Case 5. * = onset of vomiting and air hunger in Cases 1, 2, and 3. † = death in Cases 1 and 2.

CASE 4.—A girl, aged 7, was a severe type on the third day. *She had medium* bull-neck, fœtor, a cloud of albumin in the urine, a toxic appearance, and good pain response. The membrane did not extend on to the palate.

At the time of admission (third day) the child was having frequent attacks of breathlessness with cardiac pain. The heart was enlarged, the apex-beat being 1¼ in. beyond the *nipple line, and diffuse.* The pulse-rate was 136–140. The blood pressure on admission was 68. Vomiting with cardiac pain was frequent and continued until death on the fifth day.

CASE 5.—A girl, aged 10, was a "severe$_3$" case on the third day, with a toxic appearance, good pain response, a thick membrane over the palate, fœtor, and some glands in the neck. Palatal palsy began early, lasted one week, and was followed by complete late palatal palsy lasting two months. Lower limb, accommodation and external rectus palsies appeared in the seventh week.

The pressure remained at 105 until the seventh day and fell suddenly to 75 on the eighth day (Fig. 4). The child complained of tightness in the chest and the heart enlarged. The apex-beat became diffuse, the pulse assumed a gallop rhythm, and there were attacks of cardiac pain with breathlessness and vomiting. The vomiting and cardiac pain were frequently present for two days and occasionally for the next fortnight. The heart remained enlarged for six weeks and the rhythm abnormal for eight weeks. Very gradually, as the blood pressure rose to normal during two months, the pulse-rate slowed.

COMPARISON OF PULSE-RATES IN THE TWO CONDITIONS.

No feature allowing of easy comparison is better able to show the distinction between the two conditions than the pulse-rate (Fig. 5). The following chart shows the pulse-rates of four of the cases described.

Whatever may be the cause of extreme hypopiesia, it is clear that it cannot be due to damage to the myocardium, since the enhancement of the pulse-rate which occurs as a result of damage to the myocardium is a very constant feature.

Conclusions.

1. The blood pressure in diphtheria begins to fall after the seventh day, reaches the lowest point about the twelfth day, and rises again to normal about the twentieth day.
2. This fall occurs in all grades of diphtheria.
3. The depth of the fall is in direct relationship to the severity of the attack.
4. In the severest cases the fall may be so great as to occasion a clinical condition which in many cases is fatal.
5. This condition, which occurs late, accounts for about 50 per cent. of the deaths during the first three weeks and is clearly distinguishable from the classical early cardiac failure.

I wish to express my thanks to Dr. Duncan Forbes, superintendent of the Brighton Borough Sanatorium, for allowing me to publish an acconnt of the cases referred to in this paper.

THE PLASMA CHOLESTEROL IN NEPHRITIS.

OBSERVATIONS ON A SERIES OF CASES.

BY CHRISTIAN M. FLEMING, M.D., D.P.H. GLASG.,
HALL TUTORIAL FELLOW IN MEDICINE IN THE UNIVERSITY OF GLASGOW; AND PHYSICIAN TO OUT-PATIENT DEPARTMENT OF THE ROYAL INFIRMARY.

ALTHOUGH cholesterol was first isolated in 1775, little was known about it until a comparatively recent date. In the last 20 years much work has been done on the various problems connected with cholesterol as it occurs in physiological and pathological conditions. Its metabolism unfortunately is not yet fully understood and, until it is, many of these problems will remain unsolved.

Cholesterol is found in the blood in two forms: (*a*) as free cholesterol, which exists mostly in the cellular elements; and (*b*) as cholesterol combined with various fatty acids to form esters. This latter form predominates in the plasma, but free cholesterol is also present. The two forms together constitute the total cholesterol of the blood, and it is this combined value which is considered in the present work.

In numerous pathological conditions, variation in the cholesterol content of the blood occurs. Nephritis is one of the diseases which has excited most interest, and many investigations on the subject have been made. Campbell,[1] in a review of Cholesterol in Health and Disease, comments on the discrepancy in the various results recorded, especially by the earlier workers. He concludes that, on the whole, high values are likely to be found in chronic parenchymatous nephritis and to a lesser degree in chronic interstitial nephritis, and that in the latter a fall occurs with the onset of uræmia. He adds, however, that more work is necessary to determine the exact conditions in nephritis under which an increase takes place. It seemed therefore worth while to investigate a series of cases to confirm results already obtained, and to ascertain the diagnostic and prognostic significance of the cholesterol content of the blood in the various types of nephritis. To elucidate these points estimations were carried out on—

1. A series of healthy control cases.
2. A series of patients suffering from nephritis.
3. A series of patients with renal conditions other than nephritis.
4. A series of cardiac cases with œdema.

METHOD OF INVESTIGATION.

In all the nephritic and in most of the other cases, specimens of blood were taken, for convenience, just before the beginning of a urea-concentration test, so that the same sample served for the estimation of both cholesterol and other substances. In the few remaining cases where this procedure was not adopted specimens of blood were collected three to four hours after a light breakfast.

The cholesterol estimations were made on the plasma after the technique of Myers and Wardell, as modified by McAdam and Shiskin,[2] and each estimation was done in duplicate. Extraction with chloroform in a Soxhlet apparatus was allowed to proceed for three hours. The standard solution used was cholesterol in chloroform. This was found to be much more satisfactory than the solution of naphthol-green B which, it had been suggested, might replace the chloroform standard. Nevertheless, difficulty was often experienced in matching the two solutions owing to a difference in the shades of green of the standard and the unknown. The fact that this difference occurred in some estimations and not in others, while the same chloroform and reagents were in use, suggests that it is due to some difference in the plasmas. It was found that overheating at any point in the procedure or the presence of moisture lowered the readings. Where the duplicate readings were not in close agreement, the estimation was discarded.

1. *Control cases.*—A series of 17 control estimations were made, the maximum, minimum, and mean readings being 227, 138, and 170 mg. per 100 c.cm. These figures are slightly higher than those found by other workers using the same method. McAdam and Shiskin[2] found the range to lie between 191 and 133 mg., while Maxwell[3] gives maximum and minimum figures of 200 and 130 mg. Campbell takes the normal range to be 150 to 200 mg. with an average of 180 mg.

On the whole, the impression gained in this investigation is that the upper normal limit is frequently higher than the commonly accepted value of 200 mg.

2. *Nephritic cases.*—Estimations were made in 60 cases of nephritis. In some instances there was

difficulty in classification, but the following grouping was eventually adopted:

Group.	Cases.
1. Acute glomerular and tubulo-glomerular nephritis	22
2. Chronic interstitial nephritis	11
3. Arterio-sclerotic cases	9
4. Chronic parenchymatous nephritis	13
5. Mixed type of nephritis	5

The results in this series can be most conveniently recorded by giving the general findings in tabular form in the first instance, and thereafter considering the general groups in greater detail (Table I.).

TABLE I.

Group.	Cholesterol content of plasma in mg. per 100 c.cm.		
	Max.	Min.	Mean.
1. Acute nephritis	363	131	223
2. Chronic interstitial nephritis	266	141	182
3. Arterio-sclerotic cases ..	314	166	245
4. Chronic parenchymatous nephritis	408	160	259
5. Mixed type of nephritis ..	333	195	253

GROUP 1.

Acute Nephritis.

In this group there were 22 cases. The characteristic features were: (1) albuminuria, with or without hæmaturia; (2) raised blood pressure; (3) œdema; (4) headache; (5) sudden onset in an apparently healthy individual. The criterion of recovery taken was the absence of albumin from the urine.

The maximum, minimum, and mean readings for the group were 363, 131, and 223 mg. per 100 c.cm. respectively. Second estimations made before dismissal in 21 of the cases gave the following figures: maximum 274, minimum 114, and mean 186 mg. There is therefore a tendency towards a decrease in the amount of cholesterol in the plasma during recovery. The most marked example of this fall in the plasma cholesterol is seen in Case 15, where the cholesterol content decreased by 134 mg. (Table II.).

Three cases, Nos. 7, 8, and 21, showed an increase in cholesterol during convalescence. In Cases 7 and 8 the increase was slight and may possibly be explained by the fact that in both patients there was evidence of an infection. As a reduced choesterol content is found in acute infections, the ultimate rise in these cases might merely indicate a subsidence of the infective process. Case 8 made a good recovery and on examination two years later was found to be in excellent condition, while the cholesterol had fallen to 178 mg. Case 7 has unfortunately not been traced. One cannot draw conclusions from one case, but, in comparison with Cases 47, 49, 54, 55, and 59 of the parenchymatous group, it would suggest that a slight rise in the cholesterol content is not of serious significance, provided that the albuminuria is disappearing. The remaining case, No. 21, which showed a rise in cholesterol during convalescence, was uræmic on admission and had nitrogen retention in the blood. The low initial reading in this case may be associated with the uræmia, in which low values are common. The low readings in these cases have been ascribed to toxic influence, although direct proof is scanty. A certain increase in cholesterol was, therefore, to be anticipated in this case, but in point of fact the value increased to an abnormal extent. The behaviour in this respect resembles, and is probably akin to, that observed in cases of infection where a low reading in the acute stage is followed by an abnormally high reading during convalescence.[4]

With the exception of five cases to be mentioned later, all the patients had œdema in some degree, but in none was it excessive. The four cases showing the greatest œdema, Nos. 1, 7, 16, and 20, gave cholesterol values of 177, 200, 316, and 153 mg. respectively, so that the œdema was not apparently proportional to the amount of cholesterol present in the blood. This is not in agreement with the results of Maxwell,[3] who found that in acute nephritis with œdema the cholesterol content is raised proportionately to the œdema. The possibility of a complication such as anæmia being responsible for the normal cholesterol content in those cases showing considerable œdema has been considered, but in none was any complication found, and the degree of anæmia present was slight. The five non-œdematous cases gave readings of over 200 mg., the maximum being 333 mg. and, as in the majority of cases in the group, a fall in cholesterol occurred with recovery.

Comments.—CASE 6. Albuminuria disappeared five months later. 11. No albuminuria a year later. 13. Convulsions on admission. 15. Convulsions on admission. 16. Convulsions on admission. Slight albuminuria reappeared four months later. 19 and 20. Convulsions on admission. 21. Semi-comatose on admission.

In nine cases the cholesterol content of the plasma at the time of dismissal from hospital was over 200 mg. Of these nine cases, Nos. 7, 8, and 21 have already been mentioned. The remaining six, Nos. 6, 11, 12, 16, 19, and 22, all made a very slow recovery and, with the exception of Case 16, were eventually dismissed with slight albuminuria. Three cases, Nos. 6, 11, and 22, became albumin-free within a year of dismissal, while in Case 22 the cholesterol fell in a period of five months from 244 mg. to 154 mg. In Case 19 albuminuria was still present one month after leaving hospital, but the cholesterol content showed a decrease of 19 mg., the value now being 224 mg. On the other hand, the only case of the six who had no albuminuria on dismissal, Case 16, was found four months later to have a faint trace of albumin in the urine and casts in the deposit. From these six cases, therefore, it would seem that a slowly falling cholesterol content is associated with slow resolution, if not indeed with a chronic lesion.

Six cases of the group had pronounced nervous disturbance. Five of them had convulsions, and their initial readings ranged from 153 to 363 mg., giving an average value of 255 mg. There was no nitrogen retention in these cases, so that they are not comparable to the sixth case, No. 21, or to the uræmic cases of the chronic interstitial group. Although the average of 255 mg. is above normal, the range of values in the five cases is wide, and suggests that there is no direct relationship between the onset of convulsions and the cholesterol content. On the other hand, the only case, No. 21, having nitrogen retention gave a normal value of 143 mg. This is in accord with the normal or low values found in uræmic cases of the interstitial group, which will be discussed later.

It was hoped that by periodic examinations of the acute cases at regular intervals after dismissal from hospital a better idea of the prognostic value, if any, of the cholesterol estimations might be obtained, but unfortunately this has not been found practicable except in a few cases.

GROUP 2.

Chronic Interstitial Nephritis.

Estimations were made in 11 cases of this type, which was characterised by vascular changes, raised blood pressure, and nitrogen retention in the blood. Most of the cases showed also albuminuric retinitis. Five of the patients had uræmia. The maximum, minimum, and mean readings were 266, 141, and 182 mg. respectively. Four cases gave values of over 200 mg., and of these, three, Nos. 26, 30, and 32, had pronounced vascular changes, while the fourth, No. 25, had generalised anasarca and was in extremis on admission (Table III.). Of the cases with slight arterial degeneration, the maximum, minimum, and mean readings were 194, 141, and 170 mg.; that is to say, the values were within the normal range.

Five of the patients died, and subsequent readings are available in only six cases of this group. The average cholesterol content in the five fatal cases was 195 mg. Where a second estimation was made the reading, with three exceptions, showed little change from the initial value, but in no instance did a decrease in cholesterol accompany clinical improvement. Cases 28 and 33, who were uræmic on admission and had cholesterol values of 145 and 182 mg. respectively, showed a gradual rise in the cholesterol content during convalescence. On examination one year later, Case 28 was found to have only a slight albuminuria. Case 33, two months after dismissal, appeared well, though still excreting considerable amounts of albumin; her subsequent history is not known. In these two cases the rise in cholesterol should probably be interpreted as a return to the normal from the low reading which had been found during the period of uræmia. Regarded in this way, the results agree with those in the other uræmic cases of the group, and also with the observation of Maxwell,[3] Henes,[5] and others, who reported low values in uræmia.

It is of interest at this point to recall the fact that in Group 1—acute cases—the only patient showing nitrogen retention gave a low initial reading, which gradually rose during convalescence. On the other hand, the remaining cases of Group 1 which showed marked nervous symptoms but had no nitrogen retention did not have consistently low values. It seems therefore that, where uræmic manifestations are associated with nitrogen retention in the blood such as occurs in chronic nephritis (especially of the interstitial type) and occasionally in acute nephritis, low or normal cholesterol values are the rule. The rise occurring during convalescence (two cases) is interesting in the light of Henes'[5] work on chronic nephritis. He found that cases which were progressing favourably showed a hypercholesterinæmia, and suggested that cholesterol was analogous to an antitoxin. Case 23 is worthy of note. The patient had been treated eight months previously for chronic interstitial nephritis, and the cholesterol content, estimated on two occasions, was then 194 and 192 mg. On readmission, the patient was comatose and the cholesterol was found to be 173 mg. Death occurred within 24 hours and post-mortem examination confirmed the diagnosis. The course of events in this case and also in Case 63 of Group 5, the mixed type of nephritis, shows that the onset of uræmia in chronic nephritis is attended by a fall in the cholesterol content of the plasma. This is in agreement with the results of other workers.[3] [5]

Comments.—CASE 23 on re-admission (R.-a.): uræmic coma, death. 24. Uræmia arterio-sclerosis, death. 25. Uræmia death. 26. Arterio-sclerosis, asthma, death. 27. Progressive anæmia, death. 28. Uræmia. 29, 30, 32. Arterio-sclerosis. 33. Uræmia, asthma.

GROUP 3.

Arterio-sclerotic Cases.

It is convenient at this point to consider a group of cases in whom arterio-sclerosis was the predominant clinical feature. Nine of these had evidence of renal disease. The difficulty of differentiation between arterio-sclerotic cases with renal involvement and chronic nephritis with secondary vascular changes is generally acknowledged. Evans[6] states that there is no accepted clinical distinction between the two, and that a "pathogenic factor simultaneously causes both renal and vascular lesions; a varying incidence on renal or vascular tissue accounts for the unequal change in these tissues in different cases."

For the purposes of this investigation, distinction was made on two points: (1) the very marked cardiovascular signs and symptoms found in arterio-sclerosis; and (2) the absence of nitrogen retention in the blood, with a good response to the urea-concentration test. In general, also, the arterio-sclerotic patient was stout and florid, whereas the chronic nephritic tended rather to be pale and thin.

The maximum, minimum, and mean readings for the whole group were 314, 166, and 245 mg. respectively, while for those having nephritis the figures ranged from 314 to 182, giving an average of 256 mg. Three cases had readings of under 200 mg.; one of these had nephritis, while of the other two one had asthma and the other had hæmoptysis, for which he was sent to hospital as an urgent case. It will be seen, therefore, that the figures for the group are considerably higher than those for the previous group of interstitial nephritis cases.

* mg. per 100 c.cm.

Comments.—CASES 34, 35, 36, 37. Nephritis. 38. Nephritis, myocarditis. 39. Asthma. 40. Myocarditis. 41. Nephritis; myocarditis. 42. Nephritis. 43. Nephritis; myocarditis. 44. Nephritis. 45. Hæmoptysis. 46. Valvular disease of heart.

Two cases of the group, Nos. 40 and 42 (Table IV.), were exceptional in that they showed nitrogen retention. They are included in this group rather than in Group 2 because the clinical picture was that of advanced arterio-sclerosis. Case 40 gave a good response to the urea-concentration test, but was extremely ill and died four days after admission. The cholesterol content was 244 mg. Case 42 had had a mild nephritis eight years before. At that time albuminuria was moderate, there were no casts in the urine and the blood pressure was not raised. On readmission the patient was dyspnœic and had some œdema which was most probably of cardiac origin, being slight and confined to the lower extremities. The cholesterol content was 245 mg. It is probable that in this case there was a recrudescence of the original kidney affection at the time of readmission to hospital, but that in the interval since the first attack the "pathogenic factor," whatever its nature, had affected the vascular tissues more severely than the renal, thus producing a clinical picture of arterio-sclerosis rather than of chronic nephritis.

From consideration of this group, therefore, it is apparent that the presence of arterio-sclerosis is usually associated with a hypercholesterinæmia, particularly if a renal lesion is also present. In cases showing no albuminuria, the cholesterol content seems to vary, but the number of cases of this type investigated is much too small to allow of any deductions.

Difference of opinion exists regarding the association of hypercholesterinæmia and arterio-sclerosis, but the great majority of workers have found that arterio-sclerosis is accompanied by a high cholesterol content. Much experimental and other work has been done in an attempt to determine the nature of this relationship, and also the relationship of hypercholesterinæmia and hypertension. Experiments on rabbits by feeding with cholesterol have been made by various workers[7, 8] and seemed to prove that arterio-sclerosis was the result of hypercholesterinæmia. These results, however, were not confirmed in carnivorous animals. Dewey[9] found that feeding with cholesterol produced not only arterio-sclerosis but definite lesions in the tubules of the kidney. Newburgh,[10] in 1923, found that, by feeding rabbits with a diet rich in protein but with a low cholesterol content, lesions resembling human arterio-sclerosis could be produced. Later, in 1926,[11] he confirmed this, but found also that where arterio-sclerosis was present a hypercholesterinæmia also developed. This elevation of blood cholesterol Newburgh believed to be due to a metabolic disturbance, directly referable to the excess of protein in the diet and not to its cholesterol content. Other workers—Nuzum, Seigal, Garland, and Osborne[12]—produced hypertension and arterio-sclerosis by a high protein feeding and found that these phenomena were most pronounced when the acid-base balance resulting from prolonged feeding with protein was most disturbed.

Recent work by Moscowitz[13] on experimental arterio-sclerosis is of interest. He found that the arterial lesions produced by cholesterol feeding were not permanent; moreover, in investigations in the human subject, he failed to find a constant hypercholesterinæmia in arterio-sclerosis unless a complication was present. He concludes, therefore, that cholesterol plays only a part in the production of experimental arterio-sclerosis, and that the mechanical factor of pressure is important. Waldorp[14] also, from his own work and from a study of the results of various other workers, concludes that hypercholesterinæmia in itself is not sufficient to cause hypertension and arterio-sclerosis, but that in its presence the hypertensive action of certain substances in the blood, such as adrenalin, is increased.

It is therefore evident that the problem is complex and that much work is still necessary.

GROUP 4.

Parenchymatous Nephritis.

Estimations were made in 13 cases of this type, which was characterised by (1) the presence of albuminuria, hæmaturia, and œdema, and (2) the absence of cardiovascular changes and nitrogen retention. In most cases, also, anæmia was a marked feature.

The maximum, minimum, and mean values for the group were 408, 166, and 259 mg. respectively—i.e., there is a definite hypercholesterinæmia in these cases.

A second point of considerable importance is the general tendency to a rise in the cholesterol content during convalescence. This is shown by the following results, which were obtained in nine cases in which of the chest confirmed the clinical finding of an enlarged heart, but no physical signs attributable to an adherent pericardium could be discovered. The pleura showed no abnormality. Microscopical sections of the deposit removed from the surface of the spleen show hyaline fibrous tissue on the free peritoneal surface of the deposit and for the greater part of its thickness. Near the splenic surface the type of fibrous tissue changes and there are signs of considerable activity. Fibroblasts are seen in active mitosis, histiocytes and plasma cells are plentiful, and here and there are deposits of lymphocytes. A few capillaries can be seen in process of formation (Fig. 3).

DISCUSSION.

There is no evidence to suggest that local disease of the parenchyma of the spleen was present in this case and the appearances of the deposit suggest that it belongs among those cases which are rather vaguely grouped together under the name of multiple serositis. Pick,[1] who was one of the first to give his attention to the disease, held the view that in his cases the chronic changes in the peritoneum were entirely secondary, attributing their presence to the influence of ascites, which in its turn was due to circulatory disturbance and tissue hyperplasia in the liver. Harris,[2] however, writing in 1895, speaks of ascites "due to chronic peritonitis which may occur so early as to be probably independent of venous stasis," and Kelly,[3] a little later, advances a theory that elimination of toxins of rheumatic and tuberculous origin from the abdomen may take place by way of the diaphragm which itself undergoes pathological alterations on one or other side during the process. Other cases seem to be certainly primary in the pericardium and several have been recorded which started with a definite known pericarditis.

Hale-White[4] distinguishes a partial and a general perihepatitis and perisplenitis. He quotes nine cases of partial perisplenitis of non-specific origin and a large proportion of these had heart disease sufficient to cause back pressure.

The case here recorded corresponds to Hale-White's "partial" type in that the deposit was patchy and could not be peeled off the spleen. The changes were certainly not due to back pressure as there were no signs of cardiac failure. The history of a definite rheumatic infection some seventeen years previously supplies a possible cause for the condition, and it may be that a similar change is present in the pericardium accounting for the symptomless enlargement of the heart.

In Kelly's words "the striking clinical feature of the disease is ascites." Pain is seldom mentioned, and I have not been able to trace any previously recorded case in which deformity of the stomach was shown to be present.

CLINICAL AND LABORATORY NOTES

PELVIC ABSCESS CAUSED BY BACTERIUM TYPHOSUM.

BY F. T. RANSON, M.B. BELF.,

AND

W. K. DUNSCOMBE, M.D. DURH., M.R.C.S., D.T.M. & H. ENG.,

DIRECTOR OF THE PATHOLOGICAL LABORATORY, SHANGHAI MUNICIPAL COUNCIL.

INFECTIONS of the pelvic area by *Bacterium typhosum* do not appear to be at all common; hence the following account may be of interest.

The patient, Miss A., was admitted to hospital on Nov. 14th, 1929, with a fever, clinically a typical typhoid, which ran a severe but normal course, the temperature becoming normal on Dec. 10th. Two days later there was a slight elevation of temperature which at first was thought to be due to a dietary indiscretion the previous day, but subsequently it kept rising steadily each day and no cause could be found for its recurrence.

On Dec. 21st a white cell count gave the following results: white cells 12,000, polymorphs 70 per cent., and lymphocytes 27 per cent. After prolonged examination a tender lump was discovered in the left side of the pelvis; the lump was about the size of an orange and slowly got larger.

On the 31st a white cell count gave: white cells 15,000 polymorphs 78 per cent., and lymphocytes 20 per cent. The abdomen was opened the same day (by F. T. R.) through a left paramedian incision, and a mass was seen behind the left broad ligament. Accordingly, the peritoneum was closed and stripped back in order to expose the mass extraperitoneally. On opening the swelling a little thin pus and some glairy fluid was extruded, and some loculi were broken down with the finger, but as the patient's condition was critical, a drainage-tube was inserted and the operation completed rapidly.

She made a steady recovery, there was very little drainage, and the temperature and leucocytosis gradually disappeared, a white cell count on Jan. 10th giving: white cells 11,600, polymorphs 71 per cent., and lymphocytes 24 per cent. She was discharged from hospital on Feb. 1st, 1930. Subsequent examination showed that the lump was still there, so the patient was examined at intervals for the next seven months, since it had been decided to wait some time before attempting to remove the tumour. During this period she was in excellent health except for occasional attacks of pain in the lower abdomen.

On Oct. 16th the abdomen was opened again and the tumour was seen to be much bigger than at the previous operation. The uterus was pushed forward under the symphysis, and the Fallopian tubes were lightly adherent to the front of the swelling. There were dense adhesions between the left side of the tumour and the sigmoid colon, and the peritoneum over the tumour was thickened and adherent. It was decided that enucleation was impossible. A needle was inserted into the swelling and thick greenish pus found—a rather unsuspected event. The abscess, therefore, was opened and drained of a large quantity of pus. The tube was removed on the fifth day, as by this time drainage had almost ceased and the patient made a rapid recovery.

The pus which was removed at the second operation was sent to the Municipal Laboratory. It was thick, almost viscid, and tinged with blood. A considerable number of pus cells was present in stained films, but no organisms were seen. Cultures were *inoculated into* veal broth and on to trypsin-agar plates. An actively motile Gram-negative bacillus was found, which on inoculation into the usual sugar media gave the biochemical reactions of *B. typhosum*. Agglutination was positive to a titre of 1/25000.

The results of the Widal tests are as follows:—

Nov. 15th, 1929.	Nov. 21st, 1929.	Oct. 27th, 1930.
T, 200.	T, 240	T, 650.
A, negative.	A, negative.	A
B, greater than 50.	B, 200	B } negative.
C, negative.	C, negative.	C

A sterile catheter specimen of urine was sent at the same time, but no *B. typhosum* was isolated.

The question arises as to what was the origin of this abscess? There are two possibilities: (1) infection of the pelvic lymphatic tissues; (2) infection of a previously existing retroperitoneal cyst. It is very difficult to decide between them. Also the patient was not radiographed, so the possibility of a bony origin is not absolutely excluded; but clinically, there was nothing to suggest that this might be the cause.

We are indebted to Dr. J. H. Jordan, Commissioner of Public Health, Shanghai Municipal Council, for permission to publish this.

LATERAL TRACHEAL DISPLACEMENT.

THE LARYNGOLOGICAL APPEARANCE AND ITS SIGNIFICANCE.

By J. E. G. McGibbon, M.B. Lond., D.L.O.,

AURIST AND LARYNGOLOGIST, LIVERPOOL EYE AND EAR INFIRMARY; VISITING LARYNGOLOGIST, FAZAKERLEY SANATORIUM.

The laryngoscopic appearance described below is caused by lateral displacement of the trachea. Although it will be familiar to all laryngologists, its significance as a possible indication of grave intrathoracic disease does not appear to be defined.

Normally the imaginary chords joining the arcs of the tracheal rings, visible in a laryngeal mirror through the glottis, are at right angles to the glottic axis (Fig. 1). When the trachea is displaced laterally the mirror-view of the direction of the tracheal rings is altered, and the chords then make angles greater or less than 90° with the glottic axis (Fig. 2).

Excluding obvious tumours in the lower cervical region, scoliosis and gross deformities of the chest, lateral tracheal displacement may be caused by fibrosis or atelectasis of the lung, pleural effusion, and mediastinal neoplasm. The fibrosis associated with pulmonary tuberculosis is probably the most common cause of such displacements of the trachea. I have observed it frequently during routine examination of a large number of sanatorium inmates.

FIG. 1.

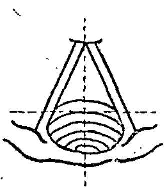

FIG. 2.

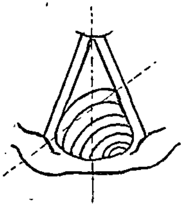
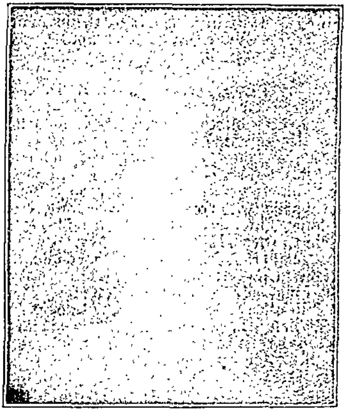


Patients suffering from chronic pulmonary tuberculosis not infrequently seek early advice from a laryngologist. They complain of vague discomfort, irritation in the throat, voice fatigue, or recurrent attacks of loss of voice. Indirect laryngoscopy in such cases may fail to reveal any manifest abnormality in the larynx; or possibly atony of the tensors, adductor weakness, or pinkness of the cords may be present. Absence of objective signs or the presence of such insignificant lesions is disarming. The symptoms may be attributed to functional nervous disorders, bad voice-production, or simple chronic laryngitis. A thorough clinical examination of the patient is not undertaken, or postponed until more serious symptoms develop. The presence of lateral tracheal displacement associated with such indefinite symptoms or signs should arouse suspicion of intrathoracic disease, and calls for an investigation of the thoracic contents.

The following brief notes of three cases illustrate the importance of noting this sign:—

Case 1.—A domestic employed by a medical man was brought for examination complaining of severe paroxysms of coughing. These occurred chiefly in the mornings. There was no expectoration, and the patient's general condition appeared good. Clinical investigation of her chest had been negative. Examination of her upper respiratory tract revealed nothing abnormal except lateral tracheal displacement. An X ray of the chest was suggested, and the radiologist reported X ray evidence of pulmonary tuberculosis. The patient's employer was still unconvinced, owing to the lack of clinical signs. On inquiry a few months later, however, it was found that the patient's sputum had become positive, and that she was under the care of the local tuberculosis authority.

FIG. 3.

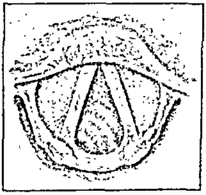


Case 2.—A man, aged 36, complained of an unpleasant taste in his mouth and throat in the mornings. Examination showed slight atrophic rhinitis and laryngitis sicca, with lateral displacement of the trachea. X ray examination revealed healed pulmonary tuberculosis of his right lung.

Case 3.—A woman, aged 54, complained of discomfort in her throat of four years' duration. Examination showed nothing abnormal in her pharynx or larynx; there was lateral displacement of the trachea. X ray showed a light degree of scoliosis.

Fig. 3 shows the X ray appearances of a male patient, aged 44, suffering from chronic bilateral pulmonary tuberculosis, with retraction of the right upper lobe and displacement of the trachea and mediastinal contents to the right side. Fig. 4 shows the laryngoscopic appearance in the same patient.

FIG 4.



I am indebted to Dr. J. H. Mather for the radiological reports in the three cases quoted; to Dr. A. E. Connolly for the radiogram; and to Dr. Claude Rundle, medical superintendent of Fazakerley Sanatorium, for permission to publish it.

of the chest confirmed the clinical finding of an enlarged heart, but no physical signs attributable to an adherent pericardium could be discovered. The pleura showed no abnormality. Microscopical sections of the deposit removed from the surface of the spleen show hyaline fibrous tissue on the free peritoneal surface of the deposit and for the greater part of its thickness. Near the splenic surface the type of fibrous tissue changes and there are signs of considerable activity. Fibroblasts are seen in active mitosis, histiocytes and plasma cells are plentiful, and here and there are deposits of lymphocytes. A few capillaries can be seen in process of formation (Fig. 3).

DISCUSSION.

There is no evidence to suggest that local disease of the parenchyma of the spleen was present in this case and the appearances of the deposit suggest that it belongs among those cases which are rather vaguely grouped together under the name of multiple serositis. Pick,[1] who was one of the first to give his attention to the disease, held the view that in his cases the chronic changes in the peritoneum were entirely secondary, attributing their presence to the influence of ascites, which in its turn was due to circulatory disturbance and tissue hyperplasia in the liver. Harris,[2] however, writing in 1895, speaks of ascites "due to chronic peritonitis which may occur so early as to be probably independent of venous stasis," and Kelly,[3] a little later, advances a theory that elimination of toxins of rheumatic and tuberculous origin from the abdomen may take place by way of the diaphragm which itself undergoes pathological alterations on one or other side during the process. Other cases seem to be certainly primary in the pericardium and several have been recorded which started with a definite known pericarditis.

Hale-White[4] distinguishes a partial and a general perihepatitis and perisplenitis. He quotes nine cases of partial perisplenitis of non-specific origin and a large proportion of these had heart disease sufficient to cause back pressure.

The case here recorded corresponds to Hale-White's "partial" type in that the deposit was patchy and could not be peeled off the spleen. The changes were certainly not due to back pressure as there were no signs of cardiac failure. The history of a definite rheumatic infection some seventeen years previously supplies a possible cause for the condition, and it may be that a similar change is present in the pericardium accounting for the symptomless enlargement of the heart.

In Kelly's words "the striking clinical feature of the disease is ascites." Pain is seldom mentioned, and I have not been able to trace any previously recorded case in which deformity of the stomach was shown to be present.

CLINICAL AND

were through their

PELVIC A iscovery of diphtheria antitoxin, sera been prepared for the treatment and control of scarlet fever, pneumonia, dysentery, and other infections, which were now being more widely used in medical practice. Closely allied was the group of diagnostic agents, such as the Schick test toxin and old tuberculin, and probably others would be added. There were also substances for the active immunisation of man, such as the mixture called diphtheria prophylactic. In the short history of the use of diphtheria prophylactic a number of misfortunes had occurred. Some were due to errors in manufacture, some to mishandling of the product after it was made. The speaker believed that in England, thanks to the cordial coöperation of manufacturers and by the operation of the Therapeutic Substances Act, the possibility of accidents in regard to diphtheria prophylactic had now been reduced to vanishing point.

In experimental physiology and pharmacology a whole chapter of exact information had been added concerning the extract of the posterior lobe of the pituitary gland, so that physicians could now use it in a precise and safe way which had not previously been possible. The characteristics of many of the substances which came under the Act were that they were markedly and sharply specific; that many were dangerous if improperly prepared, or inaccurately standardised, dispensed, or administered; and that they must be given in precise and easily adjusted dosages. A typical example of such a drug was insulin.

Without some agreed system of measurement there was no means of comparing the studies of these substances in laboratories, let alone in different countries. The speaker described briefly the preparation of biological standards. It was found that definite fixed quantities of the substance produced definite effects. Having arrived at a standard,

from other

home products had to be dealt with, the matter would be simplified, but an embargo could not be placed upon the use in Britain of substances made in other countries, provided the requirements were complied with. No licence was issued in this country to foreign manufacturers, but only to the importers resident here. During the past year the licences of several importers had been cancelled owing to failure to satisfy the regulations.

Another activity of the licensing authority was that of control. His own view was that if the physical requirements of the laboratory and selection of the staff were satisfactory, troubles of control were greatly reduced. Not every sample of the substances could be examined, but the regional medical officers were asked to make a collection of a particular article, samples of which were bought in different towns and examined from every point of view. Last year 555 such collected specimens were examined. Fourteen of the samples of diphtheria antitoxin were found to be below strength, and they came from foreign licensees. The licences in question were withdrawn. Vaccine lymph needed careful control. It must be free from gas-producing anaerobes and from hæmolytic streptococci, and must contain no more than a certain number of living micro-organisms per c.cm. It must also pass the test for potency. Seven samples of lymph failed, on some count, to reach the required standard, and appropriate action was taken in each case by the licensing authority. Two defective samples of pituitary extract were found, but as a satisfactory explanation was given, no licences were withdrawn on this account.

Sterilised surgical ligatures were included in the provisions of the Act, for there was no other way of exercising control. Last year 138 varieties of catgut were examined, and 42 (over 30 per cent.) were found to be contaminated. There were nine applications for making the material, but only six were granted. Five of seven applications for import licences were granted.

DISCUSSION.

Dr. R. A. O'BRIEN said that the government staff deputed to carry out the provisions of the Act had helped in every way. It had been shown that there was grave need of control in these matters. Serious irregularities had been found in connexion with some of the substances. Alleged tuberculin was issued which had no tuberculin in it; also diphtheria antitoxin with less than half the units stated on the label, Schick toxin of only half the required strength. Broadly, one must aim at getting biological materials to within 20 per cent. of value; he had seen it done to within 2 per cent. The testing of some of the substances, such as the Schick toxin, was laborious and complicated. It was hoped to make a Schick toxin which would stand room temperature for several days.

Dr. E. W. GOODALL spoke of the value which the Act of 1925 was to the general public, and said he wondered such a law was not brought in many years ago, though THE LANCET Commission inquired into the subject before the Act was passed, that body having included some of the best bacteriologists in this country. That Commission certainly found serious discrepancies.

Dr. J. D. ROLLESTON expressed his gratitude for the paper, the second on a somewhat similar subject he had heard this week, the other by Dr. H. H. Dale at the meeting of the Research Defence Society.

Dr. ALEXANDER JOE said the Act was the result of intensive medical research. Much more work was needed; for instance with regard to antimeningococcal and scarlet fever antiserum.

Dr. HARTLEY, in reply, said inspectors had insisted that those who imported and distributed vaccine lymph should instal cold-storage facilities, and complaints were not so frequent nowadays as formerly.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.

THE annual meeting of this society took place on June 18th, the chair being taken by the President, Dr. G. CARMICHAEL LOW. Before the scientific business was commenced, the President presented to Dr. N. Hamilton Fairley the Chalmers Medal for his work in the domain of tropical medicine.

Dr. ERNEST MUIR read a paper on the

Treatment of Leprosy.

Leprosy, he said, had for ages been regarded as an incurable and hopeless disease, and "once a leper always a leper" had been an accepted axiom. Though Hansen's bacillus was the cause of the disease, it could not be found in many of the patients in the leper asylums of the East, for in them the bacillus had died out, leaving only scars and deformities. Generally leprosy was not in itself fatal, the death of the victims being due to the complications begotten of neglect and exposure; in those surviving long enough the tendency of the disease, qua infection, was to die out. Hence the physician's obvious duty was to study the conditions favouring the automatic eradication of the infection and to supplement them. Treatment in the early stage of leprosy was comparatively simple if the general condition of the patient was susceptible of improvement. Leprosy appeared to be confined entirely to members of the human race, and even man in a healthy state was highly resistant to the disease; hence the importance of the vigour of the general state. When the disease did develop it was because in that person it had found a soil with the requisite lack of resistance. Of those in India who showed slight clinical signs only a small proportion developed sufficient lesions to constitute a disease, yet in them a temporary indisposition would lead to an exacerbation. An idea was prevalent that only some form of injection treatment was of value, but in Calcutta the health factor was constantly being stressed. He had recently been much impressed with the value of the erythrocyte sedimentation test as an index of the resistance of the patient; it was an even more certain test in leprosy than in tuberculosis. All the patients in the Calcutta establishment were regulated by this test. Briefly, it meant that the slower the sedimentation of the red blood-cells, the greater was the resistance of the patient to leprosy; whatever accelerated sedimentation could be regarded as a factor favouring in that patient the spread of the disease. The fact of a patient suffering from leprosy did not mean of necessity that his resistance was low when seen, as he might have had malaria or other disease when the leprosy started, but that since his general health had improved there had not been time for the leprosy to disappear. If the resistance was low, special anti-leprotic treatment should be delayed until there had been brought about some definite improvement in the general resistance.

In the treatment of leprosy the oils of the hydnocarpus or chaulmoogra group and their preparations had been used for centuries, and the modern use of them was by injection into the tissues. Temporarily the resistance was lowered after the injection—i.e., it caused a negative phase. Weekly injections, with careful observation, said Dr. Muir, gave best results; intradermal was better than intramuscular injection, advantage being taken of the anæsthesia and deep analgesia incident to the disease. Ten to twenty square inches of selected skin was thus infiltrated at a time, and his custom was to use a needle whose guard was placed 2–3 mm. from the point, which ensured against too deep a penetration; but it must be deep enough. It had been shown that the drug was taken up by the local cells, and remained in them for several months. Hydnocarpus oil itself was not suitable, because of its viscosity; it tended to push the tissues aside instead of finding its way into the intercellular spaces. The esters, the aqueous solution of the sodium salts, and various mixtures and synthetic preparations, were more useful. Suitably prepared ethyl esters remained in the cells for months. It was important that the esters should have a mild irritative power, and a moderate degree of pain exerted a desirable psychological effect on the native patient. In patients with only a few patches, and in whom a good resistance could be maintained, progressive improvement resulted from infiltration once a fortnight or even monthly.

The lepra reaction sometimes occurred in patients who had passed beyond the first stage of the disease; apparently it was a hypersensitised or allergic state; previously noticeable leprous lesions swelled up and became inflamed, and new lesions appeared. In nerve leprosy it often caused intense pain in the nerves. Sometimes this reaction was brought about by pressing the treatment of leprosy too hard; it might disappear in a few weeks, or might last months, even years, depending on the condition of the resistance. This phenomenon should always be guarded against; when it occurred, the patient must be kept at rest and given light nourishing food. For raising the resistance, the intravenous injection every second day of 0·02 g. of potassium antimony tartrate was valuable, as were large doses of calcium and alkalis given orally. The pain in the nerve cases was greatly relieved by using adrenalin intramuscularly, or ephedrine orally or by infiltration. It was necessary to proceed slowly, keeping watch on the general health.

The mental attitude of the patient Dr. Muir regarded as a very important factor in successful treatment; without the patient's utmost effort and coöperation it would be impossible to maintain the general health at the requisite level. The chief cause of relapsed cases was the discharge of patients from institutions as "arrested" (a term preferred to "cured") without sufficiently careful tests having been carried out. If experts found positive bacteriological evidence at any time within two years, treatment must continue. Any raised or erythematous appearance of the skin caused by leprosy must be considered an active sign of disease. Potassium iodide was a useful auxiliary in clearing up the last remnants of the disease.

The findings of the Bangkok Conference as to prophylaxis had been adopted by the Health Committee of the League of Nations, and at the Manila Conference the 22 experts from all over the world arrived at agreement on every point. These represented large strides forward. It had been decided to run an international journal of leprosy.

DISCUSSION.

Sir Leonard Rogers paid a tribute to the work of Dr. Muir, especially his insistence on the factor of the general health in cure. During ten years Dr. Muir had trained a thousand medical men to treat leprosy, and they were now dealing continually with many thousands of cases in early stages of the disease. Isolation had been practised only in regard to advanced cases which had already infected others when they were taken in hand. The great advancement was the recent establishment of skin clinics, which Dr. Wade had actively promoted, for here were seen cases of leprosy in the most hopeful stage, when probably no infection had been communicated to others.

Dr. R. G. Cochrane contented that leprosy was only just pathogenic to man—i.e., only when his condition was below what it should be. In the native it was important to cause as little pain in the treatment as possible, otherwise he would not continue.

Dr. A. B. Welsh spoke of leprosy work at an island near Port of Spain, where 154 patients could be returned to their homes, as they were mostly "burnt-out" cases. The chief depressing complication was ankylostomiasis. People were now presenting themselves earlier for treatment than formerly.

Colonel N. N. King spoke of the importance of the observation that the lobe of the ear was a seat of predilection for the commencement of leprosy; he also referred to the use of such simple measures as vapour baths, to increase the blood-supply to the lesions.

Dr. Louise Pearse (U.S.A.) said the work on trypanosomiasis confirmed the importance of a high state of general resistance, as also did work on experimental syphilis. If syphilis and vaccinia were both inoculated into an animal, the lesions of each were much more severe than if one disease alone were communicated.

REVIEWS AND NOTICES OF BOOKS

Cancer.

International Contributions to the Study of Cancer in Honour of James Ewing. Edited by F. E. Adair. London: J. B. Lippincott Company. 1931. Pp. 484. £2 5*s*.

It was a happy idea of our American colleagues to invite leading authorities on the various aspects of the problem of malignancy, both in America and in Europe, to contribute to a special volume in honour of Prof. James Ewing. The book is lavishly illustrated and contains over 50 contributions which have been divided into four parts: Cancer in its General Relations, Cancer Research, Regional Cancer, and Radium and Roentgen Ray Therapy. The first contribution, by Sir Lenthal Cheatle, is entitled Natural Law in Pathological Growth. This is followed by a paper on the Present Status of the Cancer Problem by Prof. C. C. Little, President of the American Society for the Control of Cancer. The next two papers by Dr. William Mayo and by Dr. W. Cramer have the same title Susceptibility to Cancer, and both deal with the existence of a constitutional factor in the incidence of cancer. The argument developed is reinforced by the next contribution on Heredity and Cancer from the pen of Prof. Deelman of Groningen. On the basis of a series of carefully collected cases of cancer, the family histories of which were known, he is able to show that there is a definite hereditary factor affecting the incidence of cancer. The existence of such a factor as susceptibility is further emphasised by Miss Maud Slye, who publishes another report on the results of her breeding experiments with mice. She has succeeded in breeding a strain in which trauma is followed with exceptional frequency by the development of malignancy. Mr. Sampson Handley contributes a paper in which he develops his interesting views on the rôle of lymph stasis in the genesis of cancer. Prof. Roussy, of Paris, discusses the subject of epithelial metaplasia and its relationship to new growths. Dr. William B. Coley writes on Multiple Myeloma. He states that these tumours are extremely sensitive to both the toxins of erysipelas and *B. prodigiosus* and to radiation, and that no case of multiple myeloma should be given up as hopeless without a prolonged trial of both toxins and radiations.

The second part of this volume contains three papers on Hodgkin's disease by Dr. F. W. Stewart, Prof. A. S. Warthin, and Dr. E. l'Esperance. Other papers in this section which deserve special mention are by Prof. Maisin, on the effect of different diets on the development of tar cancer in mice; by Prof. Carter Wood, who demonstrates the advantage of using animal tumours as a material for testing therapeutic methods, especially radiotherapeutic methods for the treatment of cancer; and by Prof. O. Warburg, who in two brief pages elucidates a complex biochemical phenomenon concerning the respiratory ferment.

The third section, on regional cancer, contains several contributions on cancer of the breast by Prof. Bloodgood, Dr. Burton Lee, Dr. B. F. Schreiner, and Dr. M. Leu. Of special interest is an illustrated description by Dr. M. Cutler of transillumination of the breast; this method seems to be a really practical aid in the differential diagnosis of pathological conditions of the breast. Dr. Howard Kelly stresses the advantage of electrosurgery in gynæcological operations. Prof. Regaud, of Paris, gives an account of an atypical type of cancer of the uterine cervix, which though observed by him in 8 per cent. of all cases of epidermoid cancer of the cervix, has not hitherto been described. Dr. Barringer writes on carcinoma of the prostate, discussing its early diagnosis and comparing the results of treatment by surgery and by radiation. Dr. H. C. Saltzstein and Dr. D. J. Sandweiss discuss the commoner difficulties in diagnosis and treatment of cancer of the rectum and colon.

The last part of the volume, on radium and roentgen ray therapy, will be of special interest to clinicians. The results of radiation therapy in cancer of the uterus obtained in five different centres are reported in papers by Dr. Heyman, of Radiumhemmet, Stockholm, Prof. Wintz, of Erlangen, Dr. Lacassagne, of Paris, Dr. W. P. Healy, of New York, and Dr. C. F. Burnham, of Baltimore. Sir Charles Gordon Watson discusses to what extent radium can replace surgery for cancer of the rectum. Prof. Lazarus Barlow describes the clinical results observed by him in the treatment of cancer cases by a large amount of radium (5 g.). The application of X ray therapy in breast cancer is discussed in a paper by Dr. G. E. Pfahler and Dr. L. D. Parry, who base their conclusions on a statistical study of 977 private cases treated by them during the period 1902–1927. Their figures show a remarkably high percentage of five-year recoveries and seem to demonstrate a high therapeutic value for post-operative irradiation. Dr. R. E. Herendeen contributes an interesting paper on X ray therapy of giant-cell tumours of the bone.

The subjects dealt with in this volume, while restricted to cancer, include very different aspects of this complex problem, many of them of paramount importance at the present time. The high standard reached by the contributions renders this volume a worthy tribute to Dr. Ewing whose life has been devoted to a study of cancer and who is regarded with affectionate esteem by his colleagues in all countries.

The Concentric Method in the Diagnosis of Psychoneurotics.

By M. Laignel-Lavastine, Professeur Agrégé à la Faculté de Médecine de Paris, Médecin de l'Hôpital de la Pitié. London: Kegan Paul, Trench, Trübner and Co., Ltd. 1931. Pp. 217. *10s. 6d.*

Prof. Laignel-Lavastine's name is familiar to English physicians and psychopathologists largely through his work on the sympathetic disturbances which are registered in the so-called functional nervous diseases. This collection of essays is intended to stress the importance of a clinical approach to the study of the psychoneuroses. The author's thesis is that diagnosis can only be accurately arrived at by regarding the manifestations as a series of concentrically arranged phenomena, psychological, physiogenetic, and organo-lesional; that is to say, we must work from without inwards—through the psychological-behaviour layer to the neural-sympathetical substratum—hence to the endocrine subsoil, and finally to the organic "*morbific kernel.*" This approach is a salutary one. It is good that the general physician should realise in every case a set of psychic determinants—conscious and subconscious, and that the clinical psychologist should not turn his back upon the various physical "sets" from neural to deep organic lesional. The descriptions are diagrammatic, and though they gain in lucidity of exposition, they lose the dynamic interpenetrating processes which unify yet keep fluid the various systematised layers of the organism. This over-simplification in terms is dangerous and shows itself very clearly in the scholarly chapter which relates the mystical states to the mental changes in psychasthenia and the schizoid types. While it is illuminating to bring out the formal relations between neurosis and mystical ecstasy, it is psychologically more important to bring out the dynamic relationships of the states themselves to their deeper roots. The chapter on treatment is very catholic and healthy, though the remarks on the Freudian theories and practices show prejudice. Dr. Vinchon adds a lecture on the Devil, which is not very informative.

The Psychology of Insanity.

Fourth edition. By Bernard Hart, M.D., F.R.C.P. Lond., Fellow of University College, London. London: Cambridge University Press. 1930. Pp 176. *3s.*

Dr. Hart's little book early attained to a popularity that is not likely to diminish with the appearance of this fourth edition; works of the kind are seldom so lucid and compact. It remains essentially unchanged, but an introductory sketch has been added on the development of the chief schools of psychopathology, especially the Freudian. Dr. Hart's method is frankly eclectic; whatever doubts there may be as to the adequacy of such a method for more detailed presentations, there can be none about the simplicity and readableness of this short work.

Le service social à travers le monde.

By Dr. René Sand. Paris: Librairie Armand Colin. 1931. Pp. 250. Fr.25.

The author, who is Technical Counsellor to the League of Red Cross Societies and Chairman of the International Hospital Committee, has taken good advantage of his central international position to study social work. In what may be described as a vertical section, he traces the development of social work from Babylonian times to those of Edwin Chadwick. Then, in a horizontal section, he shows what is being done at the present time in various countries, devoting one chapter to France, another to Germany, a third to Great Britain, and so on. Finally, he shows how all the various social phases through which humanity has passed from ancient to modern times can still be studied to-day in different parts of the world. He rings the changes on happiness and misery with swift dramatic touches; the world is vastly better than it was in many respects, and while in the time of Louis XIV. half of the inhabitants of France, the richest country in the world at that epoch, were crushed by economic misery, only some 3 per cent. of the inhabitants of Western Europe are to-day in need of public support. On the other hand, there are still some 5,000,000 persons living in slavery in our own times, and within two days' journey of Marseilles woman may be studied as a beast of burden, her husband her master, and her children unprotected and untaught. After sketching a programme of social service, Dr. Sand holds it up with a pensive gesture and asks if his critics find it chimerical. He forestalls this objection with the defence that no reform has yet been introduced into the world which has not promptly been condemned as Utopian.

The Vitamins.

Second edition. By H. C. SHERMAN, Mitchill Professor of Chemistry, Columbia University; and S. L. SMITH, Senior Chemist, Office of Experiment Stations, U.S. Department of Agriculture. New York: Chemical Catalog Co. 1931. Pp. 575. $6.

THE new edition of Sherman's Vitamins is essentially a book for students. The account is revised up to 1930 and the history and chief lines of development of knowledge concerning each vitamin are fully but concisely sketched. More than a third of the space is devoted to an extremely full and useful bibliography. The book is not easily readable by the uninstructed reader and it is far too advanced for the ordinary medical student; but the research worker will appreciate it as a valuable work of reference.

Birth Registration and Birth Statistics in Canada.

By ROBERT R. KUCZYNSKI. Washington, D.C.: The Brookings Institution. 1930. Pp. 220. 14s.

THE foundations of Canadian vital statistics were laid in the opening years of the seventeenth century. In addition to a survey of the birth statistics through three centuries of time, this little book provides a discussion of the problems and difficulties which beset vital registration before the (comparatively recent) establishment of the Dominion Bureau of Statistics, and the introduction of more or less uniform methods of procedure. An analysis of the natality data suggests that the fecundity of French-Canadian women has decreased in recent years; fecundity of British-Canadian women is about as low as that prevailing in most other countries of western civilisation, being lowest in Ontario and the Maritime Provinces where the British element predominates.

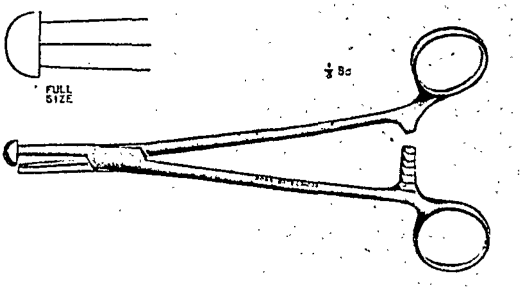
British Journal of Children's Diseases.

Vol. XXVIII. (April-June) contains a paper entitled Is the Hæmolytic Streptococcus Acceptable Epidemiologically as the Ætiological Agent of Scarlet Fever? Drs. T. Toyoda, C. Kuroi, J. Moriwaki, and Y. Futagi, of the Japanese Government Isolation Hospital, Darien, come to the conclusion that the principal factors in the production of scarlet fever are (1) hæmolytic streptococci possessing the capacity of producing Dick toxin, (2) sufficient virulence on the part of the streptococci, and (3) a body with a constitution highly susceptible and suited to the propagation of hæmolytic streptococci.—Dr. E. Ashworth Underwood, who contributes a paper on Early Nephritis in Scarlet Fever, with the report of a personal case, remarks that very few cases have been recorded in which nephritis has supervened within the first three days of the disease. His patient was a girl aged 16, in whom definite acute nephritis developed on the second day of scarlet fever, if not earlier, and showed a recrudescence during each of three attacks of tonsillitis in convalescence. On her discharge from hospital after a stay of 183 days, the urine had been normal for a fortnight. Four year afterwards, however, the patient was reported to be suffering from chronic nephritis. Underwood suggests that the *Streptococcus scarlatinæ* caused the initial nephritis which was of a mild glomerular type and that this lesion was supplemented by acute interstitial nephritis which ultimately became chronic and involved other renal elements.—In a paper on the Onset of Acromegaly before Fifteen Years of Age, Dr. F. R. B. Atkinson has collected in chronological order 32 cases of which he subsequently rejects seven, leaving 25 in which the first signs of acromegaly appeared between the ages of 7 and 14 years. No particular cause seems to have precipitated the onset of the disease, although in one instance it seems to have begun after measles and in another after shock.—In a paper entitled Pædiatric Eponyms III. Koplik's Spots, Dr. W. R. Bett reproduces the original descriptions of this pathognomonic sign of measles with a short life and portrait of the discoverer.—Dr. F. Parkes Weber records a case of Osteochondroma Enclosing the Left Kidney and Suprarenal Gland in a Girl aged 15 Years, in which it was doubtful whether the tumour of the femur or that around the kidney and suprarenal was the primary growth.—The abstracts from current literature are devoted to alimentary diseases.

NEW INVENTIONS

PHRENIC AVULSION FORCEPS.

IN performing the operation of phrenic avulsion the phrenic nerve is exposed in the neck under a local anæsthetic and grasped by fairly strong forceps. The nerve is then divided above the forceps and pulled slowly out from the chest cavity. The avulsion has to be very slowly proceeded with so that the nerve will be removed in as great a length as possible. If it is pulled out too strongly or too quickly the nerve may break. If this breakage occurs above the communicating branches which reach it below the clavicle, the diaphragm will still receive nerve impulses from these branches, so that the operation will be useless. By experience one finds that the best way of controlling this gradual pull on the nerve is to rotate the forceps and wind the nerve on to them very slowly. If ordinary forceps are used, the nerve slips off the end, since the forceps cannot be kept on the same plane as the nerve which lies at the bottom of the fairly deep wound. To overcome this minor difficulty the forceps herewith illustrated were devised. The round tip projects from the edges of the blade, thus preventing the nerve from slipping over it. The blades themselves have longitudinal grooves assuring a good grip of the nerve. The forceps should be of a fairly heavy type as this ensures a firmer and more complete control of the amount of force required.



Messrs. Down Bros., Ltd., 21 and 23, St. Thomas's-street, London, S.E., are the makers.

WALTER MERCER, M.B., Ch.B., F.R.C.S. Edin.
Edinburgh.

THE LANCET.

LONDON: SATURDAY, JUNE 27, 1931.

THE INDIAN MEDICAL SERVICE.

APPLICATIONS are invited by the India Office for permanent commissions to the Indian Medical Service. The terms offered include a gratuity of £1000 on retirement after six years' service or one of £2500 after 12 years' service, together with free return passages for those who no longer desire to remain in the service. The Indian Medical Service, it is stated, offers wide opportunities of medical experience, including clinical, preventive, specialist, and research work. At the beginning of his career the officer is employed on the military side, which has medical charge of the Indian Army; but after one year's service in India he may apply to have his name registered for transfer to the civil side, from which appointments are made to surgeoncies established at the principal centres to provide for the medical needs of officials and for general medical administration. The appointments available include special public health and bacteriological posts, research assistantships, and chairs at the medical schools. Anyone who has seen the work of the I.M.S. in India, or even anyone who has been given the opportunity, as we have been given, of attending year by year the June gathering of senior officers in London, must have been struck by the part which these civil appointments have played in the life and work of the service. They have given variety and fascination to work which would otherwise have been largely of a routine or official character, have provided careers of scientific distinction and renown far beyond the bounds of India or of the British Commonwealth, and have produced habits of mind enabling fine administrative work to be carried on after retirement from the service. It has been said that were civil employ in the service to be abolished there would be a rush of retirement from the already depleted ranks, and a corresponding dearth of recruits. It is therefore an ominous note which has been added to the advertisement to which we have referred: "It is not possible to state at present what, if any, prospects of employment on the civil side will be open to Indian Medical Service officers under the proposed new constitution of India."

The doubt is documented by the report of a subcommittee of the Indian Round Table Conference, appointed to consider the relation of the Services to the new political structure in India. While this subcommittee felt it necessary to provide guarantee in the new constitution for the maintenance of rights and safeguards for existing members of the service, and "to take such steps as are necessary to reassure existing members of the services with a view that they may serve with loyalty and efficiency for their normal term," they express the opinion tersely that in future there should be no civil branch of the Indian Medical Service. As a corollary of this recommendation no civil appointments, either under the Government of India or the Provincial Governments, would in the future be reserved for Europeans as such. It is true two members of the subcommittee, Lord ZETLAND and Sir EDGAR WOOD, expressed a fear that under the scheme proposed neither the Provincial Governments nor the Indian Medical Service would secure European medical officers of the type required. They would prefer to see the present arrangement continued until Indianisation, both in the Indian army and in the civil services, has proceeded further; but these two voices were a small minority in a committee of 34 persons. The Round Table Conference, while admitting the report as provisional, regarded it "as material of highest value for use in the framing of a constitution for India." The Prime Minister was perhaps a little more guarded in describing the subcommittee as having "explored the position as regards the future." It is difficult to think of this abolition of the civil side as being already a foregone conclusion when its retention is regarded by the European officer not only as the sign and seal of his best work, but as equally desirable to whatever extent the service becomes Indianised under the new constitution. It is, we believe, a fact that the many Indian officers now in the service also regard the possibility of transfer to the civil side as a valuable privilege.

It should act as a corrective to any premature feeling of despondency when it is recalled that there has hardly been a period within the recollection of the present generation when the future of the I.M.S. did not appear to be hanging in the balance. Common report had it at one time that Lord KITCHENER, in his exceptionally powerful position as Commander-in-Chief in India, had come to the conclusion that radical alterations in the constitution of the service were essential. The Verney Commission and the Lee Commission have sat in judgment on it, and made divergent recommendations, which, as regards any general reorganisation, were never carried out. In 1925, Lord BIRKENHEAD, as Secretary of State for India, stated the Government's conclusion that the I.M.S. ought to remain for military reasons, its reserve being secured from officers lent by it to the civil administration—that, in fact, the leading characteristics of the service should remain much as of old, it being understood that Indianisation should proceed as rapidly as convenient, and that civil opportunities would necessarily diminish. The service has survived many attacks, some of them from apparently irresistible critics, and the persistent—at times unreasoning—optimism of its friends has on the whole been justified. Great improvements in the conditions of service have been introduced, and most of the evils prophesied have so far failed to materialise. The past year, however, has brought portents the world over, and in India particularly everything seems to have gone into the melting-pot. It is clear that far-reaching burden, her husband her master, and her children unprotected and untaught. After sketching a programme of social service, Dr. Sand holds it up with a pensive gesture and asks if his critics find it chimerical. He forestalls this objection with the defence that no reform has yet been introduced into the world which has not promptly been condemned as Utopian.

The Vitamins.

Second edition. By H. C. SHERMAN, Mitchill Professor of Chemistry, Columbia University; and S. L. SMITH, Senior Chemist, Office of Experiment Stations, U.S. Department of Agriculture. New York: Chemical Catalog Co. 1931. Pp. 575. $6.

THE new edition of Sherman's Vitamins is essentially a book for students. The account is revised up to 1930 and the history and chief lines of development of knowledge concerning each vitamin are fully but concisely sketched. More than a third of the space is devoted to an extremely full and useful bibliography. The book is not easily readable by the uninstructed reader and it is far too advanced for the ordinary medical student; but the research worker will appreciate it as a valuable work of reference.

Birth Registration and Birth Statistics in Canada.

By ROBERT R. KUCZYNSKI. Washington, D.C.: The Brookings Institution. 1930. Pp. 220.

[illegible]sis.
THE foundations of Canadian [illegible]
laid in the opening [illegible] a further contribution to
In a[illegible] of the blood cholesterol in the various
types of kidney disease (see p. 1390). Dr. FLEMING has examined some 60 cases of both acute and chronic nephritis in the hope of finding variations in plasma cholesterol sufficiently constant to be of practical help in prognosis and diagnosis. Briefly summarised, his conclusions are that the blood cholesterol is raised in cases of chronic parenchymatous nephritis (subacute nephritis), frequently in acute nephritis, and "constantly" in arteriosclerosis with renal disease. In other types of nephritis the figures are variable. The association between hypercholesterinæmia and "subacute nephritis" has long been known, although their exact relationship is far from understood. These cases show the picture of œdema, albuminuria, usually a diminished urine output, and a raised blood cholesterol. One type of case with these characteristics is classed as nephrosis by many workers; here the blood cholesterol may be very high indeed and lipoid deposits are found post mortem in the kidneys. Cases are recorded showing figures as high as 780 mg. per 100 c.cm., against a normal of 160–200 mg. The pathological condition does not, however, appear to be produced primarily by the excess of cholesterol, and œdema in particular is not entirely dependent upon this excess. Thus FLEMING notes in his cases the absence of œdema in some patients of this type whose blood has a high cholesterol content, and he notes also the tendency of the cholesterol in the blood to rise as the general condition improves. It is probable that a mere increase of lipoids in the blood is neither the cause nor the effect of the

fortnight. Four year afterwards, however, the patient was reported to be suffering from chronic nephritis. Underwood suggests that the *Streptococcus scarlatinæ* caused the initial nephritis which was of a mild glomerular type and that this lesion was supplemented by acute interstitial nephritis which ultimately became chronic and involved other renal elements.—In a paper on the Onset of Acromegaly before Fifteen Years of Age, Dr. F. R. B. Atkinson has collected in chronological order 32 cases of which he subsequently rejects seven, leaving 25 in which the first signs of acromegaly appeared between the ages of 7 and 14 years. No particular cause seems to have precipitated the onset of the disease, although in one instance it seems to have begun after measles and in another after shock.—In a paper entitled Pædiatric Eponyms III. Koplik's Spots, Dr. W. R. Bett reproduces the original descriptions of this pathognomonic sign of measles with a short life and portrait of the discoverer.—Dr. F. Parkes Weber records a case of Osteochondroma Enclosing the Left Kidney and Suprarenal Gland in a Girl aged 15 Years, in which it was doubtful whether the tumour of the femur or that around the kidney and suprarenal was the primary growth.—The abstracts from current literature are devoted to alimentary diseases.

NEW INVENTIONS

PHRENIC AVULSION FORCEPS.

IN performing the operation of phrenic avulsion the
phrenic nerve is exposed in the [illegible]entally athero-
anæsthetic and grasped [illegible] rich in cholesterol, and
The [illegible]idence of such changes in patients with
diabetes has been attributed to the increase in blood lipoids; the association has, however, not been generally accepted as cause and effect. There are so many pathological and experimental factors which can influence the cholesterol of the blood, either as a whole or in the relation of its "free" and "combined" fractions, that the subject is even more complex than other biochemical ones. Dr. FLEMING confirms the work of others in noting a fall in cholesterol in the blood in uræmia, and believes that a single estimation is of value in the diagnosis of this condition; but the fall is relatively slight and a larger series of cases would be necessary to convince us that this finding has great diagnostic value. It is manifest that the cholesterol variations during the progress of nephritis in general require further study before any final conclusions can be drawn.

◆

THE HEATING OF HOSPITALS.

THE comfort of patients in hospital is much affected by the system of heating which is adopted, and hospital committees are increasingly adopting up-to-date methods. The open fireplace is no longer practicable as a means of warming large buildings, although most people agree that they should be provided as a centre of cheerfulness in a ward or a day-room, in the nurses' recreation rooms, and in the sitting rooms of the matron and the resident medical officers. Low pressure hot water has long been the usual heating system adopted in this country, and it has many advantages. First-class engineers still claim that until some other method has been proved to be superior no committee should be advised to risk a change. There is however a growing feeling that radiators and distributing pipes are unnecessarily ugly and unhygienic. This can be met to some extent by the intelligent placing of radiators, which should be in recesses under windows wherever possible, and by the concealment (as in America) of flow and return pipes in chases or spaces which are accessible but not visible. If these precautions are taken and the radiator is not too near the patient's head there is not much to be said against the method, and the matron of one of our largest hospitals recently gave it as her opinion that the combination of radiator and open window was most conducive to comfort. Fresh-air inlets behind the radiator become a nuisance from trapping dust. The horizontal flow-pipe a few inches above floor level may be economical and even useful as a bed-stop, but it requires constant dusting and spoils the appearance of a ward. These objections can be met by putting the pipes in the thickness of the floor, but a better method is to feed the radiators on the so-called drop system when the vertical pipes can be concealed in piers or chases.

New methods now coming to the front may some day supersede the radiator system. Pipes of small bore may be embedded in the walls or ceiling, more generally the latter. This panel system gives a radiant form of heat in place of the convection of the radiator. The wall or ceiling is gradually warmed, an even temperature is the result, and there are no pipes or radiators to be seen. The advantages of panel heating for hospitals are so obvious that there must be cogent reasons why it is not generally adopted. First the cost of installation is considerably higher than that of the radiator system, and running costs also appear to be higher. There is also a fear that should the panels prove defective they will be expensive to cut out and replace. These objections are partly met by a radiator, which has been placed on the market (known as the Ray-Rad) with a smooth iron surface towards the room and insulating material behind to prevent the heat being absorbed by the wall. These may be arranged as a continuous dado or as panels in the wall. A drawback is the fact that the heating surface must be two or three times as large as the ordinary radiator to produce the same result. In the operating theatre, where it is of first importance to avoid dust-traps, the panel system and the flat radiator should be considered. Here high temperatures are required at short notice, and auxiliary heating with steam or electricity is required.

Electric heating will no doubt come with the cheaper supply of current; hitherto the cost has been against it except in special cases. Such forms as the "Unity" tubular or the "Morgan" panels are suitable where routine methods prove difficult. In private wards a radiator under the window and an electric fire for cheerfulness are the handiest combination, although a gas or coal fire may be preferred. In the hospital kitchen gas more than holds its own. The choice between oil or solid fuel concerns hospital committees very deeply, but can only be settled individually with the advice of competent engineers.

THE GENEVA CONFERENCE ON NARCOTIC DRUGS.

ALLUSION was made in THE LANCET of May 23rd (p. 1146) to some of the difficulties with which the conference, now in session at Geneva, on the international control of the commerce in dangerous drugs would find itself confronted. The conference was opened on May 27th, and in the public discussions which began the next day the nationalisation of the drug traffic trade was advocated by the delegates from Argentina and Roumania. The Italian delegate argued for the right of any country to manufacture for its own needs if it so desired, and to choose the country from which it might desire to import. The British delegate, who was largely responsible for a draft convention which had been prepared, supported what is known as the quota scheme, whereby each manufacturing country should be allotted an appropriate share in supplying the legitimate medical requirements of the world. He urged that no other scheme that was generally workable had been put forward. The Persian delegate pleaded for the application of the quota system to the production of raw opium, a contention which illustrated the difficulty of effectually dealing with the restriction of dangerous drugs to medical uses without paying regard to the limitation of production of their raw materials.

On June 19th the British delegate (Sir MALCOLM DELEVINGNE) announced that it was impossible to frame an agreed text combining the quota scheme, which he supported, and an alternative proposal of Franco-Japanese origin. The latter sought to limit the manufacture of narcotic drugs by any country to its annual estimate for domestic requirement and for export to meet firm orders duly certificated, while provision was to be made for some reserve and for Government stocks. This somewhat complicated scheme was adopted, subject to certain conditions, by the Committee on Limitation as a basis for discussion by 14 votes to 2 with 6 abstentions. Such diversity of opinion on so fundamental a question is not reassuring. Nor does it augur for the chances of reaching general agreement on the form of a convention which would secure ratification by all the Powers concerned. The lamentable results of failure to ratify, or to put in force, the previous opium conventions of The Hague (1912) and Geneva (1925) have been already emphasised in these columns

---

THE INCORPORATED MIDWIVES' INSTITUTE.—The jubilee celebrations to be held next week will include meetings at the Institute on July 3rd, when Mr. Baldwin will be present; at Bedford College, when Lady Salisbury will present the Jubilee Fund to the Institute, and Mr. Comyns Berkeley will speak; and at the house of the Royal Society of Arts, London, W.C., where a conference will be held. The Jubilee Fund, which has now reached the sum of £1400, has been collected by members and friends of the Institute to develop its activities and to provide a nucleus towards new pensions. The conference will discuss the relationship of the midwife under a national maternity scheme to the Central Midwives Board, to the Insurance Committee, and to the British Medical Association. Representatives of these bodies will speak and the subsequent discussion will be open to all midwives.

ANNOTATIONS

COLONIC THERAPY.

THE introduction of substances into the colon by way of the rectum is probably as old as constipation. To introduce fluids two main methods are employed, which may be called the high pressure and the low pressure. The former is more practised on the other side of the Atlantic than in this country, and has an enthusiastic advocate in Dr. Fred D. LaRochelle. He advises[1] colonic lavage with the patient sitting on an ordinary lavatory seat, the fluid entering through a plated brass tube 22 in. long, bent in such a way as readily to adapt itself to the conformation of the body and with a tip which can be detached for cleaning. The liquid, which comes from a three-gallon reservoir, seven feet above the floor level, is forced into the rectum by hydrostatic pressure until a sense of fullness with a desire to move the bowels is experienced; the sphincter is then relaxed and the bowels moved in a very nearly natural manner without moving the tip or shutting off the flow of liquid. When evacuation has taken place the sphincter contracts again around the tip of the tube and the process is repeated. Five gallons are the usual quantity, though two to three times that much can be used. Dr. LaRochelle regards his procedure as assisting nature, and claims that when a mixture of soap and water is forced into the rectum and sigmoid under sufficient pressure the bowel is distended and made to contract; if expulsion is resisted at the sphincter the wave will turn and move up the colon, eventually reaching the cæcum. Although this may be so in many cases, it would appear more probable that when colic spasm is present, the initial downward pressure would cause a relaxation of the sphincter, before the splenic flexure was passed, and the cæcum would not be reached. In any case the use of such large amounts of fluid appears unnecessary. With any enema the cæcum is the slowest part of the bowel to empty, and relies for its evacuation on the natural mass movements of the colon. This clearing is slower than normal in a sluggish bowel. Granted that the cæcum is reached and filled by the first rush of fluid, it is doubtful if real emptying would take place till after the treatment had finished. The main part of the excess fluid would merely pass in and out of the lower bowel, without reaching or disturbing the contents of the bowel between the apex of the cæcum and the splenic flexure. Although the author claims over a thousand treatments without accident, the method can hardly be held altogether devoid of risk. In this country the low pressure method is preferred. The patient lies on the left side and a No. 12 or 14 rubber catheter is inserted 3–4 in. into the rectum, 20–30 ounces of fluid being run in slowly while the patient breathes deeply. The catheter is then removed and the patient lies quietly for two to three minutes before getting into the knee-elbow position and later on his right side, taking eight to twelve deep breaths in each position. About five minutes later the patient clears the bowels in the ordinary position. If there is difficulty in holding the full amount, the flow is stopped when tolerance is reached and the knee-elbow position assumed at once. The fluid is given at a height of 18–24 in. and the procedure is repeated ten minutes later. Given in this way opaque enemata can be seen on the screen to fill the cæcum, often even to invade the terminal part of the ileum, and, what is more important, to empty within a reasonable time. It would seem that this is a safer and more physiological method than the one described by Dr. LaRochelle.

CELL STIMULATION.

CONSIDERING how much of the attention of pathologists is taken up in observing the effects of various agents on the activities of cells, it is rather remarkable that relatively few attempts are made to investigate the matter by the methods of experimental analysis by which alone we can hope to get to the bottom of the phenomena. Some time ago Dr. J. S. Young, of the Cancer Research Department of the University of Leeds, found that active proliferation of the epithelial cells lining the marginal alveoli of the lung of the rabbit could be produced by injecting various electrolytes into the pleural cavity, and he has used this preparation for a systematic investigation. The reaction depends on the anion of the salt used and the efficacy of this varies with the valency, calcium or strontium being more active than sodium and less active than aluminium. The heavy metals also fall into a regular sequence which is, in order of efficiency, mercury, silver, copper, cadmium, lead, zinc, and appears to run inversely with their solution pressures. Taking all the facts together, Dr. Young points out that there is a remarkable parallelism between the stimulation of cell proliferation and the circumstances which determine the precipitation of negatively charged colloids. In his latest paper[1] he deals with the effects of repeated injections and raises questions of great interest to dermatologists and others concerned with chronic irritations. Active hyperplasia of the alveolar epithelium is regularly produced by the injection of a three-quarters normal solution of strontium chloride; the reaction reaches a maximum on the third day and has passed off by the eighth day. If a second injection is given between the second and tenth days there is no intensification of the response though the involution of the primary response is somewhat delayed; between the tenth and twentieth days a second dose has no effect at all. After this the cells become more susceptible again, and after about a month respond as vigorously as to a first dose. This temporary resistance is obviously a curious phenomenon. It is local in that it cannot be caused by injecting strontium chloride intravenously or intraperitoneally, and it is not wholly specific, since a primary dose of calcium chloride induces resistance to a subsequent injection of strontium chloride. On this point of specificity it would be interesting to have more ample information as to the mutual effects of substances differing more from one another chemically than calcium and strontium. It is tempting to suppose that the resistance is an inherent property of young new cells, not yet fully mature and normally reactive. Dr. Young seems to dispose fairly satisfactorily of this idea by showing that by starting a series of injections with very dilute solutions and progressively increasing the strength the cells can be made resistant without having at any time showed any reaction. An alternative hypothesis supposes that a cell is presumably stimulated by any substance because it contains something which can combine with that substance.

---

[1] Jour. Path. and Bact., 1931, i., 357.

In the reaction the receptor material is used up and the cell becomes irresponsive in consequence. In about three weeks the receptors have been regenerated and the cell once again becomes susceptible. These considerations will no doubt be further analysed by Dr. Young, and we await the results with interest.

PICTURES, POPULAR AND UNPOPULAR.

MAGISTRATES and social workers are constantly heard to deprecate the effect of the cinematograph entertainment on the youth of the country; sanitarians deplore the hours spent in dark, crowded, and often ill-ventilated halls when they might be spent in open-air exercise; pedagogues bewail the prostitution of a potential weapon for instruction. Say what they will, the cinema has taken such hold of the public throughout the world that it has almost certainly come to stay. To all complaints about the character of the films exhibited, the business men controlling the industry reply that they must give the public what the public wants. According to them the public wants drama, glitter, and romance, and the cinema is therefore perpetuating the tradition of the Victorian novel which ended: "They married and lived happily ever after." Medical psychologists know some of the appalling damage done to national life and the home by the easy assumption that the wedding bells ring out the period of struggle and anxiety and ring in a halcyon period of effortless delight. The leaders of the cinema world are not likely to be much moved by the plea of the pedagogue or the medical psychologist, but startling changes might follow if it were possible to convince them that they have misinterpreted the real edict of their god, public opinion. A copy of the report of the Birmingham Cinema Enquiry Committee[1] should be sent to every cinema manager in the country. The report contains no argument, no conclusions; it merely consists of the summarised results of a series of questionaires addressed to children, adolescents, and adults. Many interesting figures and comments were elicited. Of 1439 children between the ages of 8 and 14, 780 went once a week to the pictures, 184 went twice a week, 107 went once a fortnight, 302 went once a month or occasionally, while 30 never went and 36 went three, four, or five times a week. A boy of 11 remarked, "You have them on your mind all the time." A report from groups of 150 club girls, past school age, showed an average attendance of once or twice a week. Asked why they liked going, the children replied under four main headings: for interest, for amusement, to pass the time, and for excitement or thrills. The "comics" held an undisputed first place in their affections, followed by adventure pictures and detective films. Love stories are not even mentioned by the boys, except in such remarks as "We like any kind but love," or "Pictures are all now potty love ones." A notable feature is the constantly recurring emphasis on crime and war. A group of girl guides aged 7 to 10 put murder films first in their choice and "comics" second. Many of the children wrote of the fear that crook and war plays had caused them. They did not think the shows were too long—except a few who replied "Only love pictures are too long." In view of Mr. Savin's interesting paper on the incidence of fatigue in the cinema in our present issue (p. 1433), it is worthy of note that 442 of the children found that the pictures tried their eyes. Over 350 had trouble in sleeping afterwards—often on account of fear or nightmare. Asked what they had learnt from the pictures, the children gave a series of replies ranging from "That Quaker Oats is very nourishing," "American slang," "How to talk and to be chilvarus," to "What life really is," "Never to take a big risk," "Discontent," "That actresses do not wear enough clothes," and "That it is a hard job for the police to catch their culprits." One boy of 13 said he had learnt nothing at all except the art of love, and several others gave similar replies, including "How to love and to murder people at the same time." The references to murders are incessant, and many say "I have learnt nothing but murder," or "I have learnt to shoot through my pocket." There are scores of suggestions for improvement: that the entrance should be cheaper and the performance longer, that "rood" pictures should be excluded, that murders should be left out, that there should be more news, more comics, and more fairy tales, and (from several) that babies and smoking should be forbidden. Similar questions were answered by groups of young adults: club girls, guides, factory workers, adult school students, and business people. The majority of these went to the cinema once a week and gave as their reason "recreation." Young men voted for the same films as the boys, and objected to sloppy and suggestive films. They asked for more ventilation, orchestras, and "real" life in the pictures. The girls object to smoking and babies, and suggest that all seats should be booked and queues abolished. They say there is too much sentimentality and too much kissing. They like historical and nature films as well as adventure, comedy, history, and detective pictures. They do not seem to have learnt anything of great educational value, except from travel and nature films and the news. The report closes with the opinion of magistrates, teachers, doctors, business men and women, artisans, clerks, undergraduates, and social workers on 285 films which they have inspected. It forms an interesting supplement to the report on the inquiry addressed to school-children and to teachers in various countries by the International Educational Cinematographic Institute which dealt chiefly with the educational value of films.[2]

CARCINOGENESIS.

THE report of the Yorkshire Council of the British Empire Cancer Campaign for 1930–31 contains accounts by Prof. R. D. Passey and Prof. E. Mellanby on work done at Leeds and at Sheffield. In the laboratories at Leeds Dr. J. S. Young has continued his investigations on the production of experimental hyperplasia by allowing certain electrolytes to act on the cells, and has come to the conclusion that the onset of epithelial hyperplasia conforms to the same principles of physical chemistry as those which regulate the precipitation of negatively charged colloids. A precipitation of such colloids in the cell membrane is therefore considered to be an essential phase in the process which culminates in cell division, and perhaps to initiate cell division. Dr. Berenblum's observations on the anticarcinogenic action of mustard gas have been continued with the object of determining whether this effect is due to an excessive irritation, involving cell damage, or whether there may not be some specific chemical or physico-chemical action of mustard gas on the cell itself to account of the cervix, and (in Cochin-China) of the buccal mucosa, are abnormally common. An interesting point is that epithelioma is four times as frequent as sarcoma. There can be no doubt that careful observations on the incidence of cancer in native races will disabuse our minds of many false impressions founded only on casual statement or copied from one text-book to another. But the difficulties of controlling diagnosis by biopsy and of arriving at accurate statistics among native patients must be remembered before any general conclusions are drawn from such observations.

TUBERCULOSIS AT BREST.

ACCORDING to Médecin-en-chef (Surgeon Captain) Cristol[1] of the French Navy, the great problem of to-day in naval hygiene is tuberculosis. In France, Brest is the port specially concerned, Toulon in the south being much less affected. This, Dr. Cristol thinks, is because Provence has always been a highway constantly exposed to infection, whereas Brittany, away in a corner, only began to be opened up and infected 40 years ago. He quotes the surprise of an old Breton practitioner, recently dead, at the "new disease," much in the same way as native chiefs in German East Africa were registering surprise about 1905 at the phthisis brought to their country by Indian immigrants.[2] Forty years ago, but especially from 1900–10, healthy rustics living on farms, their food poor but fresh, with little risk of infection in the country and so escaping disease, began to flock into Brest, lured by hope of high pay, where they often succumbed when deprived of their fresh food and exposed to an infection against which they had acquired no immunity as children. Auffret was the first physician to appreciate, at Brest in 1896, what was happening. He segregated the tuberculous in wards by themselves, insisted on careful examination of the dockyard men at entry, and got leave to invalid from the dockyard workmen found attacked. In the early stage of Breton infection nearly all the cases were acute (Collis's "natural" type) but now far more are chronic and the mortality is less. Dr. Cristol explains similarly why stokers in the French navy suffer more than other ratings from phthisis; it is because their work requires men of the best physique, and these come in greater proportion from the unimmunised farm hands. Dockyardmen at Brest are received into the naval hospital just as are naval seamen, but when sick at home have to find their own doctoring. Dr. Cristol submits that, as the new French national health insurance is to include care for dependants, the Navy should put naval surgeons in charge of dockyardmen at their homes, thus controlling infection all along the line. These officers would popularise B C G inoculation of infants, the success of which he says (without giving figures) "declares itself more and more." At Brest deaths have fallen off more in the dockyard than in the town. In 1911 the death-rate was 7·1 in the dockyard, 6·0 in the town; in 1926–28 it was higher in the town. Here housing is a difficulty. In 1906, 53 per cent. of families lived in one-roomed houses, of which some (nearly 2 per cent.) had not a single window, and yet lodged up to five persons. Things are better since the war; there are fewer workers in the yard, less pressure on house accommodation, and two housing schemes have been completed; while the generous pensions to men tuberculised in the war have enabled them, as Dr. Cristol has satisfied himself, to live in roomier houses than before. Food too is better since the war; the dockyard canteen feeds, cheaply and well, 1400 men daily. The men drink less and wine is replacing spirits. The growing taste for sports keeps them out of the small dirty cabarets in which they must often have become infected. Dr. Cristol's demographic study, which covers 100 pages of the journal, will no doubt be keenly discussed.

THE NEGATIVE PHASE IN ANTIDIPHTHERIAL IMMUNISATION.

COMMENTING on a paper by Dr. Richard Prigge, to which we recently drew attention,[1] Dr. J. Siegl, of the Vienna University Children's Clinic, maintains that the experiments carried out by Prigge on guinea-pigs do not justify any conclusions as to the absence of increased susceptibility to infection after immunisation in man, as his own observations as well as those of Basch have demonstrated the contrary.[2] According to Siegl, the only conclusion that could be drawn from such experiments was that the inoculation of small doses of the formolised vaccine did not reduce the resistance of immunised individuals, whereas larger doses might be followed by a diminution of resistance. The latter should not be regarded as a negative phase but as evidence of systemic damage. In his reply, which is appended to Siegl's criticism, Prigge retorts that his investigations proved that antidiphtherial inoculation did not involve any increased susceptibility to diphtheria, and that observations relating to the not infrequent oscillations of the antitoxin titre in adequately immunised individuals were of secondary importance, as such individuals always presented a diminished susceptibility to infection. According to Dr. Prigge, the presence of a certain amount of antitoxin in the blood was no proof of an effective immunity to diphtheria, any more than the fall in the antitoxin titre, which might be produced even by non-specific substances, justified any conclusion as to changes in the condition of immunity. The two cases reported by Siegl of diphtheria following inoculation indicated merely that at the time of their attack the patients did not possess any resistance to the diphtheria bacillus or its toxin. No evidence was available to show whether they had possessed any resistance at an earlier date, nor any whether such resistance had been destroyed by inoculation. There was therefore no proof that an increased susceptibility had taken place as the result of antidiphtherial immunisation. And there the matter rests for the moment.

WORKING OF THE SUSSEX PROVIDENT SCHEME.—On May 10th, at the annual meeting, it was stated that during the ten years this scheme had been in operation over £73,000 had been distributed to hospitals and other curative agencies. Through the scheme, £2 4*s.* 6*d.* per week is paid for each in-patient at a coöperating hospital, irrespective of the length of time the patient remains in hospital; 11*d.* for every out-patient; 2*s.* 9*d.* for every X ray treatment, and 7*s.* 3*d.* for every X ray examination. The first year's working of the Queen's Nurses' section of the scheme is held to have been successful, since the number of members who joined the section was 2746, and, including dependants, 6316 people were covered for the free services of the Queen's nurses. The subscription to this section is 2*s.* 6*d.* a year, and the nursing associations in the first year received £311.

SPECIAL ARTICLES

ON THE CAUSATION OF STONE IN INDIA.*

BY ROBERT MCCARRISON, C.I.E., M.D., D.Sc.,
HON. LL.D., F.R.C.P.,

COLONEL, INDIAN MEDICAL SERVICE; HONORARY PHYSICIAN TO THE KING; DIRECTOR, NUTRITIONAL RESEARCH, INDIAN RESEARCH FUND ASSOCIATION.

URINARY calculus is very prevalent in India. During the years 1926–28, 34,325 persons were found to be suffering from the disease—or 1 in 10,000 of the population. These combined records for three years relate only to persons seeking medical relief; as hospital patients form only a small fraction of the population, and as hospitals and dispensaries are sparsely distributed, the disease is more prevalent than the figures indicate.

Distribution of the Disease.

The incidence of stone varies greatly in different parts of the peninsula; it is so prevalent in some localities that they are known as "stone areas," while in others it is rare or unknown. The prevalent belief that India in general is a land of "stone" is erroneous: parts are, others are not. Thus, taking the above figures as our index of its prevalence, we find such variations as the following (in each instance the figures apply to 100,000 of the population): in India generally, 10 in 100,000 of the population; in Dera Ghazi Khan (Punjab), 438; in Hyderabad (Sind), 266; in Sukkur (Sind), 156; in Manipur (Assam), 84; in Dera Ismail Khan (N.W.F.P.), 62; in Saharanpur (U.P.), 25; in Ahmednagar (Lower Bombay), 13; in Benares (U.P.), 5; in Sylhet (Assam), 2·8; in Malabar (Madras), 0·3; in Kolaba (Lower Bombay), 0.

[The lecturer here showed a spot map indicating the distribution of the malady, and pointed out that the great stone area extends from Sind, the North *Western Frontier Provinces, and the Punjab, into* the west of the United Provinces, gradually diminishing eastward towards Bengal and Assam in the south and south-east, the diminution continuing until, in the southern parts of the Bombay Presidency, Mysore, Hyderabad, and Madras, it is relatively rare. The distribution of the disease suggested that there were local factors, geological, geographical, climatic, racial, nutritional or microbic, which exercised an influence on its occurrence. Having given grounds for the view that the physical features of the country were unimportant, he continued :—]

Racial Influences.—It is stated in certain monographs on "stone" that Mahomedans in India are more subject to it than Hindus, and various explanations have been offered to account for this supposed racial difference. But the truth is that no such difference exists. In my series there are 1024 cases in which particulars are given as to the community *of the sufferer; of these* 757, or 73·9 per cent., were in Hindus; 235, or 22·9 per cent., were in Mahomedans; and 32, or 3·1 per cent., were in other communities. Hindus form, approximately, 69·5 per cent. of India's 320 million people; Mahomedans, 21·3 per cent.; and other communities, 9·2 per cent.—percentages which, so far as the two main communities are concerned, are practically identical with the percentage distribution of stone. Mahomedans are, therefore, *no more subject to the malady than Hindus. If* anything, other communities are more afflicted by it than either. The disease appears to be comparatively rare amongst Europeans in India; in my series they formed 0·44 per cent. of the whole.

Nutritional Influences.—In the plains of the Indus and the sub-Himalayan regions fed by the upper reaches of the Ganges most wheat is grown, and the cultivation of maize is considerable; while in Sind the chief crop is millet. As we pass eastward along the Gangetic plain the cultivation of rice increases, reaching its acme in the Delta; southward, also, through lower Bombay to Malabar and Madras, and south-eastward to the deltas of the Godaveri and Kistna rivers, the cultivation of rice increases. In Burma, too, rice is the principal, and often the only, cereal produced. In these places rice is the staple article of diet. The suspicion thus arose in my mind that the gradual decline in the incidence of "stone," from regions where wheat is the principal cereal grown to those where rice is the chief crop might be associated in some way with the cereal forming the staple article of diet of the people.

Experiments on animals showed that this was so. Groups of young albino rats were fed on a diet of the same composition, but in which the cereal, forming 90 per cent. of the diet, differed. It was found that cereal foods ranged themselves in the following descending order of stone-producing potency: whole wheat flour, oatmeal, North Indian millet (bajra), white flour, rice, and South Indian millet (cambu). The result of this experiment provided a partial explanation of the peculiar distribution of "stone"; its great frequency in the wheat-growing areas of the north-west and its relative infrequency in the rice-growing areas of the south and east. But this association is not invariable. Thus stone is as common, even commoner, amongst the rice-eating Manipuris *(Assam) as in the wheat-eaters of Dhera Ismail Khan* (N.W.F.P.). There is more in the occurrence of stone than the cereal which happens to be the staple food in this or that part of India; other dietetic factors are concerned. What these factors are has been revealed, in some part at least, by experiments on animals.

Experimental Production of Stone.

My first experiment was begun early in 1926. It lasted 157 days. The diet consisted of oatmeal (53 parts), linseed meal (20 parts), cornflour (25 parts), calcium phosphate (1 part), sodium chloride (1 part), and distilled water ad libitum. It may be wondered why I used "oatmeal," since it does not enter to any considerable extent into the dietaries of the Indian people. I confess at once that chance determined my use of it. The original object of the experiment was not to produce "stone," but to learn the effect on the thyroid gland of an iodine-poor diet such as this one was. But as things turned out the experiment taught me three things: (1) that this so-called iodine-poor diet did not cause thyroid enlargement; (2) that it did cause stone and its sequelæ; and (3) that it also caused a very grave form of anæmia which subsequent investigation in my laboratory, by Dr. Lucy Wills, showed to be due to *Bartonella muris*, carried by the lice with which my rats were infested. I may draw attention to this last result. Here we of the cervix, and (in Cochin-China) of the buccal mucosa, are abnormally common. An interesting point is that epithelioma is four times as frequent as sarcoma. There can be no doubt that careful observations on the incidence of cancer in native races will disabuse our minds of many false impressions founded only on casual statement or copied from one text-book to another. But the difficulties of controlling diagnosis by biopsy and of arriving at accurate statistics among native patients must be remembered before any general conclusions are drawn from such observations.

---

* Being an abstract of the second of two lectures delivered at the Royal College of Surgeons of England, on May 18th and 20th. The first lecture, entitled Some Surgical Aspects of Faulty Nutrition, appeared on May 23rd.

TUBERCULOSIS AT BREST.

ACCORDING to Médecin-en-chef (Surgeon Captain) Cristol[1] of the French Navy, the great problem of to-day in naval hygiene is tuberculosis. In France, Brest is the port specially concerned, Toulon in the south being much less affected. This, Dr. Cristol thinks, is because Provence has always been a highway constantly exposed to infection, whereas Brittany, away in a corner, only began to be opened up and infected 40 years ago. He quotes the surprise of an old Breton practitioner, recently dead, at the "new disease," much in the same way as native chiefs in German East Africa were registering surprise about 1905 at the phthisis brought to their country by Indian immigrants.[2] Forty years ago, but especially from 1900–10, healthy rustics living on farms, their food poor but fresh, with little risk of infection in the count y and so escaping disease began to flock into Brest, lured b where they ofte fresh

have enabled them, as Dr. Cristol has satisfied himself, to live in roomier houses than before. Food too is better since the war; the dockyard canteen feeds, cheaply and well, 1400 men daily. The men drink less and wine is replacing spirits. The growing taste for sports keeps them out of the small dirty cabarets in which they must often have become infected. Dr. Cristol's demographic study, which covers 100 pages of the journal, will no doubt be keenly discussed.

THE NEGATIVE PHASE IN ANTIDIPHTHERIAL IMMUNISATION.

COMMENTING on a paper by Dr. Richard Prigge, to which we recently drew attention,[1] Dr. J. Siegl, of the Vienna University Children's Clinic, maintains that the experiments carried out by Prigge on guinea-pigs do not justify any conclusions as to the absence of increased susceptibility to infection after immunisation in man, as his own observations as well as those of Basch have demonstrated the contrary.[2] According to Siegl, the only conclusion that could be drawn from such experiments was that the inoculation of small doses of the formolised vaccine did not reduce the resistance of immunised individuals, whereas larger doses might be followed by a diminution of resistance. The latter should not be regarded as a negative phase but as evidence of systemic damage. In his reply, which is appended to Siegl's criticism, Prigge retorts that his investigations proved that antidiphtherial inoculation did not increased susceptib

---

to vary in their stone-potency, and experiment fixed them in the following descending order: whole wheat flour, millet grown in the north of India, white flour, rice, and millet grown in the south of India. The last did not cause "stone" at all within the 515 days of the experiment. The significance of this in the distribution of stone in India has already been referred to, but another possibility arises. Millet grown in one part of India may be stone-producing, while that grown in another may not: soil, manure, and irrigation conditions—which I had already shown to be capable of causing variations in the nutritive quality of food grains (McCarrison, 1926 and 1928)—may thus be concerned in the production of stone, an aspect of the matter not as yet investigated.

Would additions to the stone-producing diet prevent the malady? One group of rats was now fed on a diet of known stone-producing potency; another on the same diet to which whole milk was added, the milk being given in the proportion of two-thirds of an ounce per rat per day. Stone, and its sequelæ of cystitis, hydronephrosis, and pyonephrosis, were completely prevented by milk containing "something" which counteracted the stone-producing action of the diet. In further experiments butter or cod-liver oil was added; when the butter and the cod-liver oil prevented stone, the vegetable oils in common use in India did not. This narrowed the issue down to deficiency of vitamin A-bearing ingredients as a chief food-fault concerned in stone-production.

[The lecturer here acknowledged the help at this point derived from the work of Osborne and Mendel (1917), and Fujimaki (1926), and described his experiments indicating that the addition of lime to diets deficient, amongst other things, in vitamin A caused a greatly increased incidence of calculus, cystitis, hydronephrosis, and pyonephrosis; while it was

uction and almost universal use of white flour. We have seen also that the distribution of "stone" in India can, to a certain extent, be correlated with the kind of cereals in use in various parts of India; and we have seen, further, that milk and butter, if used in sufficient quantity, afford complete protection against stone in rats. Now the great fault of all Indian dietaries, amongst the poorer classes, who are the chief victims of stone, is that their diets do not contain anything like enough milk and milk products; and I postulate that according to the kind and quality of the cereal grain they use as the staple article of their dietaries, and according to the poverty of these dietaries in milk and the products of milk, so they will be more or less likely to suffer from stone. Milk, and the products of milk, are amongst the greatest of India's needs at the present time. I do not contend that this is the whole story; indeed, I know it is not, but it represents certain chapters of it.

Dietetic Factors Causing Stone.—There appear to be two categories of dietetic factors concerned: (*a*) *positive* factors, including excess of lime in the diet, and some unknown agent present in whole cereal grains; and (*b*) *negative* factors, including deficiency of vitamin A derived from animal sources, and deficiency of phosphates relative to the amount of lime in the diet. I say "vitamin A derived from animal sources" because millions of people in India are dependent for their supply of this factor—whatever that factor implies—on vegetables; I am not yet certain that the latter source of vitamin A is, from the point of view of stone-prevention, as good as the former; I do not think it is, and I notice that de Langen (1929) of the Dutch Indies is of a like opinion.

I must make my position clear in regard to the value of whole wheat flour and oatmeal as articles of diet. Because I have found that whole wheat flour and oatmeal, when they compose the major part of an imbalanced diet, are stone-producing, this is part in the genesis of stone, and in designing its architecture: on occasion, in certain individuals or in certain places, the star part may be taken by one or by the other. In India the "star part" is taken by diet.

The President and the Council of the College have signally honoured me by their invitation to tell something of my research activities in India, and I have been deeply conscious of the responsibility this honour has imposed upon me. I have purposely chosen to refer only to those of my activities which I have thought might be of special interest to surgeons. Even with this limitation much has had to be omitted or passed by with but a few words. But if what I have said may serve to indicate directions in which the newer knowledge of nutrition touches upon the art of surgery—to indicate lines of investigation which hold out the prospect of the solution of certain surgical problems—then I shall have fulfilled, in some small measure, the duty imposed upon me by the invitation to address this great College.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

THE CONGRESS ON INTERNAL MEDICINE.

THE German Congress on Internal Medicine was held in Wiesbaden, Prof. Bergmann, of Berlin, being in the chair. Among the many papers read before the congress, that on angina pectoris was of special interest. Dr. Edens, of Dusseldorf, pointed out that the anatomical condition underlying angina pectoris can be thrombosis or spasm of the coronary vessels, arteritis, or spasm associated with a nervous condition. The sudden obstruction of a coronary artery produces a severe attack and a tendency to these attacks may persist. A spasm of anatomically healthy arteries may lead to an infarct in the heart, and to angina pectoris; an obstruction of a coronary vessel may develop slowly and painlessly. Syphilis of the aorta leads to aortalgia with permanent pain but without oppression and attacks. That angina pectoris can arise from the aorta alone has not yet been demonstrated. Coronary sclerosis alone does not produce angina pectoris without other exciting factors; such factors are abuse of tobacco, over-strain, high tension of the vessels, and adiposity. The prognosis of angina pectoris is better than is generally supposed; it depends on the strength of the heart, ascertained by the electrocardiogram. The treatment must aim at relieving the spasm and combating spasmodic attacks by the administration of sedative and vasodilatory compounds, with due regard to the blood pressure and to the occasional need for the suitable cardiac stimulants. A definitive opinion on the value of modern organic preparations, of X ray treatment, and of operative measures cannot, in Dr. Edens's view, yet be given. Prof. Morawitz, of Leipzig, said that the principal symptom is the pain, of which the cause is not always the same. Conditions predisposing to pain are disorders of the circulation of the coronary vessels, an increased excitability of the vegetative nervous system, and other factors which include over-exertion, cold, psychic influence, nicotine, and overfilling of the stomach. A statistical record of 100 cases of angina pectoris showed that infarct of the myocardium has a mortality of 50 per cent., syphilitic aortitis somewhat better with a mortality of 30 per cent., whilst cases of hypertension are more favourable. The diagnosis of a myocardial infarct is made by clinical observation and the electrocardiogram. Prof. Morawitz showed diagrams to demonstrate the action on the heart of certain compounds such as amyl nitrite and calcium.

SHORTAGE OF CLINICAL AND SCIENTIFIC ASSISTANTS.

Notwithstanding the overcrowding of the medical profession, it has been stated that hospitals, and, still more, scientific medical institutes, have difficulty in finding candidates for appointments as assistants. Those appointments are often advertised in vain, and in consequence foreigners who have studied in Germany, without having acquired a German qualification, have sometimes been appointed, a fact which has led to some protest in medical circles. Prof. Zieler, head of the clinic for skin diseases at the Wurzburg University, states that at his clinic two posts had been vacant long enough to handicap the work of the clinic. He has, therefore, been compelled, for the time being, to give those appointments to foreigners. This remarkable shortage of applicants for posts which used to be popular is attributed to the fact that according to existing regulations medical men desiring to enter into club practice in any district must have resided for several years in that district. Since a period as clinical or laboratory assistant is not counted as residence, young medical men settle as soon as possible in the place where they wish to acquire a club practice.

DELIVERY AFTER CÆSAREAN SECTION.

Dr. Hornung reports in the Centralblatt für Gynäkologie on his experiences of conducting labours in women who have had Cæsarean section performed at a previous delivery. In 57 out of 111 cases the delivery took place in the natural way. To avoid a rupture of the uterine scar, forceps had to be applied in 18 per cent. of the cases. After the birth of the child manual interference often became necessary because of a partial or total fixation of the placenta on the scar; this happened especially in cases where a deep cervical section had been performed. The fixation of the placenta on to the old scar led to profuse hæmorrhage and to a lesion on the uterine wall which might produce severe complications. Owing to the insufficient elasticity of the scar it might be stretched unduly and even ruptured. This complication was observed not only at the end of pregnancy, but also as early as the third month. A rupture of the scar need not be due to a fault in the technique of the suture; it is more likely to be due to repeated pregnancies at short intervals so that the scar has no time to become organised. Repeated Cæsarean section is, in Dr. Hornung's view, even more dangerous and should not be performed without very definite indications.

PYÆMIA AFTER TONSILLITIS.

A paper on pyæmia following tonsillitis was recently communicated to the Berlin Medical Society by Dr. Claus, who described 100 cases. Often a thrombosis of the facial, sometimes of the jugular, vein was present. A characteristic symptom, he said, is pain on pressure at the angle of the jaw, and rigor, not at the onset of the illness but when the local symptoms begin to disappear. Besides the pain in the jaw a deterioration of the general condition, a subicteric and cyanotic colour, a dry tongue, and a frequent and weak pulse are characteristic of this complication. By post-mortem research it has been ascertained that a phlegmon of the retrotonsillar tissue, leading to thrombosis, is the cause. The prognosis is held to be bad, but in Dr. Claus's series about 70 per cent. of the cases were saved by operative measures. The operation consists in laying open the vessels from the clavicle to the tonsils and in ligaturing the facial and the jugular veins.

FUR DYES.

Rabbit furs are often dyed with ursol, commonly termed fur-black, a substance which may be harmful to the workers in and to the wearers of the fur. Dr. Pernice, of the Hospital for Industrial Diseases in Rummelsburg, near Berlin, reports cases where working with the fur for a quarter or half hour only was sufficient to produce in the workmen an acute very painful eczema of several weeks' duration. The cause in these cases is not a fault in the technique of dyeing, but the eczema is a reaction to some product of the dyeing process.

PARIS.

(FROM OUR OWN CORRESPONDENTS.)

THE FOURTH CENTENARY OF THE COLLÈGE DE FRANCE

LAST week there was commemorated in Paris the four hundredth anniversary of the Collège de France, which was originated in 1530 by the institution of royal lecturers. With some changes of name the institution has pursued a continuous, though somewhat chequered, career from that date to this. Imbued with the spirit of the renaissance and of the unfettered and disinterested pursuit of science, letters, and the arts, the College bears on its roll of lecturers through the centuries some of the most illustrious names in the intellectual history of Europe. Alongside the names of Budé, Lascaris, Sainte-Beuve, Champollion, Quinet, Michelet, Rénan and Bergson are to be found those more familiar to students of science and medicine, such as: Ampère, Marey, Regnault, Laennec, Magendie, Flourens, and Claude Bernard. In a historical collection, put together in the "Bibliothèque Nationale," are to be seen portraits, manuscripts, publications, and scientific apparatus associated with the work of the lecturers at the College. The physiological instruments employed by Claude Bernard are exhibited and also a cast taken after death of his distinguished features. The new President of the Republic presided at the great commemoration function which was held in the amphitheatre of the Sorbonne on the afternoon of June 19th. Representatives of 37 nationalities and of more than 300 academies and universities attended at this memorable celebration. Among British institutions represented were the Royal Society by Prof. Armstrong, the British Academy by Lord Chalmers, the University of Oxford by Dr. Allen, the University of Edinburgh by Sir E. A. Sharpey-Schafer, and the University of London by Sir William Collins.

IMMUNISATION AGAINST DIPHTHERIA IN THE FRENCH ARMY.

In a communication to the Academy of Medicine on May 19th, Dr. C. Dopter presented figures showing how serious the ravages of diphtheria have become in the French Army since the war. In 1913, the incidence of this disease among the active forces was only 0·94 per 1000. By 1920, this ratio had risen to 2·28, and in one of the following years it was as high as 8·78. In 1929 it was still as high as 6·39 per 1000. A similar state of affairs has been observed in the armies of other countries. As the usual methods of combating diphtheria, such as ascertainment and isolating of carriers, did not assure an adequate control of the disease in certain highly infected regiments, it was decided early in 1930 to inoculate the Schick-positive recruits with Ramon's anatoxin at the same time that they were inoculated against typhoid and paratyphoid fever with T.A.B. After referring to the experimental work of Ramon and his associates, and showing how it justified the conclusion that immunity to all the diseases concerned can be achieved by a simultaneous poly-vaccination, Dr. Dopter gave a detailed report of his experiences with five regiments. In all of them diphtheria had been endemic for years, taking a heavy toll among the recruits in particular, but not always sparing the older soldiers. The results were strikingly successful. With only two exceptions, the cases of diphtheria breaking out in these regiments after the introduction of this measure were confined to soldiers who had not been inoculated, or whose inoculation had been incomplete. The curious fact that the incidence of diphtheria among the older soldiers not treated with Ramon's anatoxin also showed a marked decline, was interpreted as a consequence of their not being repeatedly exposed to infection by cases of diphtheria in recruits. In other words, being no longer exposed to super-infections, these soldiers were left free to develop a natural immunity. The simultaneous inoculation against typhoid and paratyphoid fever was so effective that no case of typhoid occurred among the troops thus treated, although one of the regiments concerned was stationed in a badly infected district.

AN EXHIBITION OF SANITARY AVIATION.

The authorities of the Colonial Exhibition have authorised the organisation of an exhibition of sanitary aviation between July 25th and 30th. A trophy has been offered for the best system for converting any type of aeroplane or hydroplane into an air ambulance. Lectures will be given on colonial sanitary aviation, and discussions will follow in which foreign as well as French delegates may participate. Demonstrations will be given of ambulance aeroplanes in flight, and visits will be organised to certain factories. This demonstration will coincide with the conferences on colonial medicine to be held between July 22nd and 30th. Those who desire further information can obtain it from the Secretariat of *La Ligue des Amis de l'Aviation Sanitaire*, 52 rue des Martyrs, Paris, 11.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

THE ALLOCATION OF HOSPITAL SWEEPSTAKES.

THE Senate of the Irish Free State gave a second reading last week to the Public Charitable Hospitals (Amendment) Bill, not without considerable criticism. Most of the criticism was against the principle of permitting the rate-supported institutions to benefit from the sweepstakes. There was also criticism of the way in which some of the hospitals which have already benefited largely were proposing to spend their funds, particularly in undertaking further building. Pleas were put in for amalgamation of the smaller hospitals. In particular, Sir Edward Coey Bigger, a former medical administrator of great experience, pointed out that if the sweepstakes of the next three years were as successful as those conducted up to the present, a sum of about £4,000,000 would be available for the hospitals. There were too many general hospitals in Dublin; Cork had three hospitals, and Limerick two. It would be an advantage if these were amalgamated in each city. The plans for the next sweepstake, to be held in connexion with the Manchester November Handicap, are now complete. At least 38 hospitals will share in the benefits, 19 being in Dublin, 6 in Cork, 4 in Limerick, 3 in Waterford, 2 in Drogheda, and 1 each in Galway, Ballyshannon, the Curragh, and Arklow. If the present Bill passes without further amendment some seven other institutions may be permitted to share.

IRISH MEDICAL ASSOCIATION.

The annual meeting of the Irish Medical Association was held in the Royal College of Surgeons, Dublin, on June 17th. Mr. P. E. Hayden, outgoing President, and subsequently, Dr. Eugene Byrne, his successor, took the chair. The annual report stated that the register at the beginning of the year 1930 showed a membership of 388. There were 32 deaths, 29 names were removed for non-payment of subscription, and some resignations. The membership at the end of the year was 303. The council had recently sent out an invitation to medical men who were not members of the Association asking them to join it. Dr. Byrne, of Slane, County Meath, was declared President, and Dr. J. T. Daniel, of Dublin, Vice-President. A committee was appointed to consider the revision of the Articles of Association. Mr. R. R. Leeper, a former honorary secretary of the Association, was elected an honorary member.

MEDICAL BENEVOLENT FUND.

The annual meeting of the Royal Medical Benevolent Fund Society of Ireland was held on June 17th in Dublin, Dr. T. G. Moorhead, President of the Royal College of Physicians of Ireland, in the chair. The annual report stated that 87 grants were made during the year, being one more than in the previous year. The amount disbursed was £2154, as compared with £2104 in the previous year. The beneficiaries included 6 medical men, 15 orphans, and 66 widows. With the issue of this year's support Sir John William Moore completes half a century of service as one of the honorary secretaries of the Fund. During the year Mr. A. B. Clery has succeeded Dr. A. E. Boyd as secretary.

THE SERVICES

INDIAN MEDICAL SERVICE.

THE QUESTION OF CIVIL APPOINTMENTS.

At the final plenary session of the Indian Round Table Conference on Jan. 19th reports of nine subcommittees were received and noted. Subcommittee No. VIII., which was asked to consider the relation of the Services to the new political structure in India, met six times between Jan. 6th and 13th and authorised its chairman, Sir William Jowitt, to present the report which appears in a blue-book (Cmd. 3772. H.M. Stationery Office. 1*s.* 3*d.*). Paragraph 4 of this report deals specially with the Indian Medical Service and paragraph 1 applies to all the Services, including the medical.

§ 1.—*Existing Members of the Services.*—Inasmuch as the Government of India Act and the rules made thereunder by the Secretary of State in Council guarantee certain rights and safeguards to members of the Services, due provision should be made in the new constitution for the maintenance of those rights and safeguards for all persons who have been appointed before the new constitution comes into force.

When the new constitution is drawn up suitable safeguards for the payment of pensions (including family pensions) and provident funds, should be provided.

As it is important that those responsible for the working of the new constitution should not at its initiation be embarrassed by the economic waste and administrative difficulties which a change of staff on a large scale would entail, it is desirable to take such steps as are necessary to reassure existing members of the Services with the view that they may serve with loyalty and efficiency for their normal term.

To this end the subcommittee agreed that the right to retire on proportionate pension should be extended, but opinion was divided as to whether the extension should be for an unlimited term or for a definite period of years, not exceeding five years.

§ 4.—*The Indian Medical Service.*—Subject to paragraph 1, the subcommittee are of opinion that in future there should be no civil branch of the Indian Medical Service; and that no civil appointments either under the Government of India or the Provincial Governments should in future be listed as being reserved for Europeans as such.

The Civil Medical Services should be recruited through the Public Service Commissions. In order to provide a war reserve, a clause should be inserted in the contracts of service of a sufficient number of officers that they shall undergo such military training and render such military service as they may be called upon to do. The extra cost involved should be borne as an Army charge.

Further, the Governments and Public Service Commissions in India should bear in mind the requirements of the Army and the British officials in India and take steps to recruit a fair and adequate number of European doctors to their respective Civil Medical Services, and should be prepared to pay such salaries as would bring about this result.

It is suggested that agreement might be reached between the Central Government and the Provincial Governments whereby the latter in selecting their European doctors might grant a preference to those members of the Indian Medical Service who have performed a period of service with the Army. We contemplate that such members would sever their connexion with the Indian Medical Service during the term of their employment in the Provincial Medical Service—subject only to the acknowledgment of a claim by the Army authorities in time of emergency. The practical details of any such arrangement would have to be a matter of agreement between the Army authorities and each Provincial Government.

(Major Stanley wishes to make it clear that his acceptance of this section is contingent upon the possibility of securing satisfactory agreements under paragraph 4.

Lord Zetland and Sir Edgar Wood fear that under the scheme proposed neither the Provincial Governments nor the Indian Medical Service will secure European Medical Officers of the type required, and they would prefer that the present arrangement should continue until Indianisation both in the Indian Army and in the Civil Services has proceeded further.)

The Conference, in its final resolution, described this report along with those of other committees as provisional but affording material of the highest value for use in the framing of a constitution for India. The Prime Minister, in his speech at the final session, said that the subcommittee dealing with the Services had affirmed the necessity of continuing the guarantees given to existing members and had explored the position as regards the future.

I.M.S. ANNUAL DINNER.

THERE was an exceptionally large attendance at the annual London dinner of the Indian Medical Service held at the Trocadero Restaurant on June 17th. The chair was taken by Colonel R. A. Needham, and there were present as guests: Mr. F. H. Brown (*Times Correspondent for India and the East*); Dr. N. G. Horner (*British Medical Journal*); Dr. Egbert Morland (*The Lancet*); and ten officers now on probation at the R.A.M. College, Millbank.

Proposing the toast of "The Service," Colonel Needham welcomed the presence at the dinner of ten officers on probation, and read a message he had received from the Director-General of the Service in India to the effect that though conditions in India had changed, and would continue to change, new entrants would still find excellent prospects of a career. The I.M.S. flag was still flying, and recruits of the right sort were needed. The faint-hearted should stay at home. Colonel Needham suggested that a reply in the same tone should be sent to the Director-General and their fellow-officers in India. He went on to refer briefly to the various evidence and findings of commissions and committees which had, during the past 20 years, considered the constitution of the medical services in India and possible changes in their organisation. He described the present constitution as a military service with a proportion of officers withdrawn for civil duties to form a war reserve and to provide attendance on Europeans. A constitution of this kind had always been found necessary, and would be just as necessary under a new federal government, whether the name Indian Medical Service was retained or not, should the new Government desire to retain an efficient medical service for the Indian army, and to discharge its essential civil obligations. It was, he thought, too readily assumed that a central service was incompatible with autonomy in the provincial medical services already in being, or with progressive Indianisation. He did not hold that view. The Services Subcommittee of the Round Table Conference had reported that in future, in their opinion, there should be no civil branch of the I.M.S. This opinion implied a complete reversal of policy. Abolition of the civil branch would leave the I.M.S. as an Indian army medical service, to which few, if any, European recruits would be attracted. The Army authorities had not been consulted. They were vitally concerned in a policy which might affect recruitment of British officers for the combatant branches of the Indian army. Perhaps, said Colonel Needham, the wide implications of this innovation had not been fully stated or appreciated in the political atmosphere of the Round Table Conference. The Simon Commission was well aware that a failure of recruitment for the I.M.S. would be disastrous for India, and that a medical service recruited provincially would be no substitute for one with the standards and traditions of the Indian Medical Service. Lieut.-Colonel J. K. S. Fleming proposed "The Chairman" in a few well-chosen words, and Colonel J. J. Pratt made it clear how much was due to the hon. secretaries, Colonel T. A. Granger and Sir T. Carey Evans, for the organisation of a successful evening.

The following is a list of the officers present at the dinner:—

Major-Generals: Sir Havelock Charles, Bart., G.C.V.O., K.C.S.I.; A. A. Gibbs, K.H.P.; J. D. Graham, C.B., C.I.E., K.H.S.; Sir Courtenay Manifold, K.C.B., C.M.G.; Sir Leonard Rogers, C.I.E., F.R.S.; G. Tate, C.I.E.

Colonels: H. Ainsworth; R. F. Baird; J. Fuller-Good, V.H.S.; C. M. Goodbody, C.I.E., D.S.O.; T. A. Granger, C.M.G.; J. A. Hamilton, C.M.G.; J. Husband; I. Davenport Jones; W. H. Leonard, K.H.P.; R. A. Needham, C.I.E., D.S.O.; J. J. Pratt; A. Spitteler, O.B.E.; F. Wall, C.M.G.; C. N. C. Wimberley, C.M.G.

Lieut.-Colonels: A. W. Alcock, C.I.E., F.R.S.; G. P. Alpin, O.B.E.; J. Anderson, C.I.E.; F. A. Barker, O.B.E.; G. T. Birdwood; H. H. Broome, C.I.E.; S. H. Burnett; J. T. Calvert, C.I.E.; H. P. Cook, D. G. Crawford; J. M. Crawford, O.B.E.; H. J. M. Cursetjee, D.S.O.; E. E. Doyle, C.I.E., D.S.O.; H. R. Dutton, C.I.E.; S. Colin Evans; J. K. S. Fleming, C.B.E.; B. Gale; C. A. Gill; A. E. Grisewood; D. Heron, C.I.E.; E. V. Hugo, C.M.G.; M. L. C. Irvine; S. P. James; H. C. Keates; L. H. Khan; H. H. King; R. Knowles; J. C. G. Kunhardt; W. B. Lane, C.I.E., C.B.E.; E. C. G. Maddock, C.I.E.; W. A. Mearns; F. O. N. Mell, C.I.E.; G. McMillar, O.B.E.; A. Miller; T. R. Mulroney; F. O'Kinealy, C.I.E., C.V.O.; A. H. Proctor, D.S.O.; Norman R. J. Rainier; A. J. H. Russell, O.B.E.; G. M. C. Smith, C.M.G.; R. Steen, J. Stephenson, C.I.E.; T. G. N. Stokes; Ashton Street; W. A. Sykes, D.S.O.; C. Thomson; Sloane G. Thomson; R. S. Townsend, M.C.; E. L. Ward, C.B.E.; D. P. Warliker; W. L. Watson, O.B.E.; W. E. R. Williams, O.B.E.; N. M. Wilson, O.B.E.; H. R. Woolbert; H. G. L. Wortabet.

Majors: F. J. Anderson, M.C.; A. C. L. Bilderbeck; Norman Briggs; H. C. Brown, C.I.E.; Sir T. Carey Evans, M.C.; E. S. Goss, M.C.; J. H. Hislop, M.C.; R. N. Kapadia, M.C.; A. C. Macrae; J. J. Rooney; H. M. Ullah Salamat, M.C.; W. J. Webster, M.C.; R. L. Vance.

Captains: J. L. Donnelly; T. A. Doran; G. M. Irvine; M. Taylor; S. C. H. Worseldine.

Officers on Probation: Lieut. M. Kirk Bryce; Lieut. G. K. Graham; Lieut. J. Guthrie; Lieut. H. B. Macevoy; Lieut. M. M. Mansfield; Lieut. J. L. O'Neill; Lieut. M. H. Shah; Lieut. W. J. Stewart; Lieut. B. Temple-Raston; Lieut. A. W. West.

APPOINTMENTS.

INDIAN MEDICAL SERVICE.

Lt.-Col. F. E. Wilson to be Col.

Lt. J. S. McMillan to be Capt. (prov.).

Lt. (T.C.) A. N. Malhotra to be Capt. (T.C.).

Lt.-Col. J. R. J. Tyrrell retires.

Capt. E. P. Carroll relinquishes his probationary appt.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lt. H. W. Strong to be Surg. Lt.-Comdr.

H. E. B. Curjel to be Surg. Lt.

ROYAL NAVAL VOLUNTEER RESERVE.

The following appointments are notified: Surg. Lt.-Comdr. H. E. Hall to *Iron Duke*. Proby. Surg. Sub.-Lt. H. R. Vickers to *Victory* for Haslar Hospital.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. A. A. Meaden, having attained the age for compulsory retirement, is placed on retd. pay.

Maj. (temp. Lt.-Col) A. C. Elliott to be Lt.-Col.

Maj. W. B. Purdon to be temp. Lt.-Col.

Lt. D. C. McC. Ettles to be Capt.

J. M. Gibbon to be Lt. (on prob.), and is secd. under the provisions of Art. 213, Royal Warrant for Pay and Promotion, 1931.

ARMY DENTAL CORPS.

Lt. S. D. Badman to be Capt.

ARMY RESERVE OF OFFICERS.

Lt.-Col. T. F. Ritchie, having attained the age limit of liability to recall, ceases to belong to the Res. of Off.

TERRITORIAL ARMY.

Capt. W. E. A. Buchanan to be Maj.

Capt. C. A. D. Mitchell (late T.A. Res. of Off., 4th Bn. Devon R.) to be Lt. and relinquishes the rank of Capt.

TERRITORIAL ARMY RESERVE OF OFFICERS.

2nd Lt. G. D. Kersley, from Gen. List, T.A., to be Lt.

ROYAL AIR FORCE.

E. A. Gudgeon is granted a short service commission as a Flying Officer for three years on the Active List.

THE MISSION TO LEPERS: ANNUAL REPORT.—The annual report states that of the 6350 inmates who have been under treatment at 47 stations in India, China, Korea, Siam, and Africa, 4370, or over 68 per cent., have more or less improved, while 442 have become symptom-free, of whom 310 have been able to return to normal life in the healthy communities. In addition, more than 2600 lepers had been treated as out-patients of the different centres; of these over 61 per cent. improved and 19 became symptom-free. The principal drug used in the treatment is still a derivative of hydnocarpus, or chaulmoogra, oil. A very considerable amount of medical work is being done at over 100 centres in 20 different countries, and in the missions' own homes and hospitals there are about 8200 leper inmates and over 800 healthy children. The report adds that recent investigations in India, Africa, and other parts of the world have discovered vast numbers of lepers as yet unrelieved, and that there is a constant demand for extension of the mission's efforts.

CORRESPONDENCE

INSULIN AND PRESERVATIVE.

To the Editor of THE LANCET.

SIR,—Dr. O. Leyton, Dr. E. P. Poulton, and Dr. Izod Bennett have drawn attention in your columns to the desirability of making the inclusion of antiseptic in insulin optional and not compulsory as is contemplated in the draft regulations of the Therapeutic Substances Act. We would like to produce the following evidence in support of this.

In the first place, the acidity of the insulin is sufficient to prevent the growth of pathogenic organisms as shown by the following observations. Two brands of insulin were tested for their antiseptic properties. Brand B was an insulin of bovine origin containing 0·3 per cent. tricresol. Brand L was an insulin made from pigs' pancreas without any preservative added. The pH of the latter was approximately 4·0. The organisms chosen for testing were hæmolytic streptococci, *B. coli*, *Staphylococcus aureus*, and a mould (*Penicillium glaucum*). Neither the streptococci nor the mould grew in any of the experiments in either of the insulins used and are therefore not included in the table.

In the earlier experiments measured amounts of broth cultures were added to the insulins. This caused a turbidity, and was sufficiently alkaline to raise the pH considerably and diminish the antiseptic qualities of the insulin. In the last experiments (see further) three colonies from a plate were emulsified in 5 c.cm. of the insulin, and two standard loopsful transferred to another 5 c.cm. of insulin, and one loopful of this emulsion was plated on to agar. This procedure was carried out with each organism in each insulin.

—	Control = immediate *plating.*	AFTER 48 HOURS AT— 37° C.	Room temperature.
	Colonies.		
B. coli.			
Insulin B (bovine + 3 per cent. tricresol)	25	0	2
Insulin L (pigs: no preservative)	2320	0	38
Saline	2416	123	3304
Staph. aureus.			
Insulin B	62	0	0
Insulin L	1520	0	0
Saline	1082	2	539

It will be seen that the tricresol in B was sufficient to prevent almost completely the growth of *B. coli* immediately, and also after 48 hours at 37° C. or room temperature. Insulin L, without tricresol, showed that the number of organisms inoculated was high (2320), and yet after 48 hours at 37° C. there was no growth. Left at room temperature there were still 38 colonies after 48 hours. In this case the saline controls showed an *increase* of nearly 1000 organisms at room temperature.

Even more marked was the result obtained with the *Staphylococcus aureus*. Here the insulin L gave no growth either after 48 hours at 37° C. or room temperature, although the original inoculation grew 1520 colonies. We would lay most stress on the room temperature experiments, as these more nearly simulate the conditions of any accidental inoculation.

In the second place the following observations support the suggestion that injection of tricresol is capable of causing a certain amount of irritation.

Intradermal injections of 0·2 c.cm. of insulin B and of insulin L were made into A. S. and W. P. There was an equal immediate painful reaction due to the acidity. In the case of A. S. insulin B left a small nodule which took three to four days to disappear, while insulin L left no lump. As the purity of the two insulins is at least equal, the difference was probably due to the antiseptic. In the case of W. P. an intense reaction of 2–3 in. diameter and lasting seven to eight days was caused by insulin B. Insulin L caused only a transient response, as in A. S. It was evident that W. P. was sensitive to insulin of bovine origin irrespective of the antiseptic, so 0·2 c.cm. of a 0·3 per cent. tricresol solution in saline was injected intradermally. A slight immediate reaction resulted, and a small nodule palpable for over a week, similar to that occurring in A. S., was produced. It is thus evident that tricresol is capable of producing a definite tissue response.

Finally, from the clinical aspect we have used insulin containing *no tricresol* for 13 months and have had less tissue response, a factor of importance in children in whom the area available for injection is less, and who usually have a marked prejudice against using fresh sites for injections. In the *only* case of local infection occurring after injection of insulin not containing an antiseptic the insulin and syringe the patient was using were both found to be sterile; also this patient had previously had an infection while using insulin containing an antiseptic.

To sum up: we find no evidence that absence of preservative is dangerous and definite evidence that the presence of preservatives may be harmful.

We are, Sir, yours faithfully,

W. W. PAYNE.
A. G. SIGNY.

Hospital for Sick Children, Great Ormond-street, W.C.,
June 20th, 1931.

To the Editor of THE LANCET.

SIR,—The views expressed by Dr. O. Leyton, Dr. E. P. Poulton,[1] and Dr. T. Izod Bennett[2] about the addition of antiseptics to insulin are shared by many Hungarian scientists. I should myself regard the compulsory addition as injurious. There may be reason for the addition of an antiseptic to a single hypodermic injection when there is some risk of infection from outside, but this should certainly not be done in the case of a preparation given it may be several times daily over a long period. However small the dose, the antiseptic is then cumulative and no longer indifferent to the organism. In fact, if it has to be given frequently, the dose must be so small as to be ineffective. If the rules of antisepsis are neglected the risk of infection from outside is present in a single injection; careful technique will avoid the risk in repeated injections.

We do not possess an antiseptic which is active and yet does no harm to the organism when frequently injected. The question now raised in connexion with insulin was discussed all over the world in connexion with vaccine therapy when that was new. But vaccines are not as a rule injected daily into the body. We cannot overlook the fact that insulin injections do sometimes give rise to secondary effects, due to what component we know not. The Danish insulin "Leo" was one of the first reliable brands and no such secondary effects have been reported from its use, although they have followed the use of some of the new and very trustworthy brands to which antiseptics have been added. R. Priesel and R. Wagner, assistants in Pirquet's clinic in Vienna, suggested[3] the tricresol content of insulin as the cause of lipodystrophy, after excluding all other possibilities. As a bacteriologist who has had opportunity of controlling theory on a large material at the Institute for

[3] Zeitschrift für Kinderheilkunde, Nov., 1925.

Social Assurance in Budapest, I am satisfied that any quantities of phenol or tricresol which can produce an antiseptic effect are definitely injurious to the organism, locally and generally. This I have noticed in vaccine as well as in insulin therapy. Antiseptics other than phenol and tricresol hardly count. I am therefore an advocate of insulin without antiseptics, and I have never observed any harm from its use. It seems to me wrong to enforce the addition of an antiseptic; the physician should be at liberty to carry out his principles.

I am, Sir, yours faithfully,

DR. FORBATH SANDOR,
Chief Physician, Editor of "Magyar Orvos."

Budapest, June 15th, 1931.

*** Among the Draft Rules and Orders (dated June 2nd, 1931) proposed to be made by the Joint Committee constituted by Section 4 (1) of the Therapeutic Substances Act, 1925, is the following provision: Part III., Section 9 (2). When any therapeutic substance is issued in liquid form in containers which are sealed in such a manner that portions of the contents can be withdrawn for use on different occasions, the liquid shall contain a sufficient proportion of some antiseptic to prevent the growth of any organism which may be accidentally introduced in the process of removing a portion of the contents of the container.—ED. L.

A MATERNITY SERVICE.

To the Editor of THE LANCET.

SIR,—I write to support the plea of Prof. Blair Bell in his second Ingleby lecture (THE LANCET June 13th) that no new maternity hospitals should be built, as is now being done in many municipal areas. These hospitals are being erected by municipal authorities. It is, so far as I know, the intention of those authorities that they shall be staffed by their own medical officers. I believe, and I know that my opinion is shared by other teachers, that such arrangements will help to perpetuate, rather than diminish, the present maternal mortality- and morbidity-rates. Such medical officers are unlikely to have either the training or the experience necessary to deal adequately with obstetrical problems and difficulties. Far better that, in university cities at least, the money were spent in extending where necessary the already existing maternity departments at the teaching hospitals, where really trained and experienced people are available. Such training is not a matter of six months' residence in a maternity hospital, or of a short post-graduate course in obstetrics.

Further, unless these hospitals are to be used for teaching medical students, their multiplication will tend to diminish the already too small numbers of cases available at teaching schools. If they are to be available for teaching, who is to teach there? No medical school, already so careful in making appointments to its staff, is likely to send its students to be taught by any Tom, Dick, or Harry at a municipal hospital. If the teaching is to be done by the already existing staffs of medical schools then they obviously must have control over methods and technique, for the student, like other people, learns more from example than from precept. In other words, if the new municipal hospitals are to be used for teaching students they must be staffed by the medical school, or at least the medical school must have a predominating voice in the appointments. Will the municipalities allow this? Even if they do, what of the waste of time in going from one institution to another, and of the money needlessly spent in duplicating equipment? Bad as the policy is which sanctions the erection of new maternity departments at municipal *general* hospitals, it is much worse when it encourages the erection of maternity units entirely separated from a general hospital. Every obstetrician knows how essential is constant coöperation between him and his colleagues in the medical, surgical, and other special departments in the management of many of his cases. This close coöperation simply cannot be obtained in the isolated maternity hospital.

It seems almost incredible that the Ministry of Health, genuinely concerned about the maternal mortality-rate, and medical education in obstetrics, should sanction policies so utterly reactionary at a time when coöperation, coördination, and centralisation are essential to progress. It will soon be too late to call a halt.

Since writing the above, I have seen your admirable leading article on the same subject. It puts most ably the argument for "pooling of available resources, intellectual, material, and financial." It is to be hoped that the warning will not go unheeded.

I am, Sir, yours faithfully,

F. J. BROWNE.

University College Hospital, W.C., June 20th, 1931.

MORTALITY AFTER PROSTATE OPERATIONS.

To the Editor of THE LANCET.

SIR,—No urologist in London can have read the article by Dr. R. J. Minnitt in your issue of June 13th (p. 1292) without interest or emotion. His reference to the mode of anæsthesia is valuable, if for nothing else than for bringing up once again the important subject of the optimum method in prostatic surgery. For the rest, one must regard it as bristling with provocations.

The first point that must strike the reader is that ether is made the scapegoat for the post-operative rise of blood-urea. Are there not other factors? It is well known that in the majority of prostatics with a degree of renal deficiency the mere opening of the bladder, or perhaps even the passage of a catheter, is sufficient to send up the blood-urea in virtue of a degree of "kidney shock" occasioned thereby, the cause of which is not fully understood. Such rises of blood-urea may occur after operative drainage, though performed under local or spinal anæsthesia. One must presume, therefore, that when Dr. Minnitt increases his series of gas and oxygen administrations for this purpose he will meet with the same phenomenon.

The second point is that too high a value appears to have been placed upon the blood-urea percentage assessment of operative risk. Many of us have come to rely upon the results of a carefully carried out urine-urea percentage according t
of MacLean as furnishing a more a

deftly and courteo

At a discussion on the results of prostatectomy recently held in the Section of Urology, Royal Society of Medicine, a meeting representative of British urology, the average mortality given was under 10 per cent. All surgeons taking part in this discussion held urological appointments at the larger hospitals, chiefly in London. The figures given were, in the great majority, gathered from hospital practice. I am not in a position to say exactly how many of these surgeons allow some ether administration; I feel I might venture to suggest that 90 per cent. would not be an exaggeration. For my part, having tried most of the known methods of anæsthesia in prostatic surgery, I have come to regard ether inhalation as the safest means of producing unconsciousness, relying upon nerve block (with ½ per cent. novocain introduced into the depth of the rectus sheath) to procure relaxation of the rectus abdominis, the only muscular obstacle in the technique of suprapubic prostatectomy. I have used this method in upwards of 300 cases and have had no case of uræmia in the absence of such complications as hæmorrhage, sepsis, and myocardial deficiency.

I do not feel that an apology is needed for digressing from the primary subject, anæsthesia, to the subordinate one which must appeal acutely to the surgeon performing prostatectomies almost daily, the mortality figure. The chief cause of a high mortality in prostatic surgery is still to be laid at the door of the patient or of his medical adviser, —namely, procrastination. Were patients to seek skilled advice as soon as symptoms arise and to take it, as they have learnt to do in appendicitis or cancer, their earlier presentation for operation would serve their best interests and I venture to think would help the prostatectomist to realise his ambition to keep under the 5 per cent. figure. The publication of such unfortunate results must give rise to an acute wave of unjustifiable pessimism, frightening off those subjects who thus lose the opportunity of being restored to a life of joyous activity, allowing themselves to drift into a state where their existence cannot be worth enduring. One is reminded of the feelings of the sufferers from the stone in the old days, as referred to by Cheselden quoting the words of Rosset the anatomist, who, in 1590, endeavoured to stimulate surgeons to abandon the perineal for the suprapubic route "pitying . . . the perpetual anxieties of those persons who ought to be cut, but were deterred from trying the operation, as the fox was from visiting the lion, by seeing the tracks of abundance of feet towards the Lythotomists, but a few back again."

I am, Sir, yours faithfully,

Portland-place, W., June 20th, 1931. JOHN EVERIDGE.

To the Editor of THE LANCET.

SIR,—In your issue of June 13th Dr. R. J. Minnitt gives a report on the unfavourable effect of ether anæsthesia on the blood-urea. Further investigation on this would be of interest with a view to general surgery as well as prostatectomy, but my immediate concern is with the death-rate of 50 per cent. that he quotes for this operation. This rate is very high in comparison with the results obtained in the hands of some genito-urinary surgeons, and it would be unfortunate if the quotation of a high death-rate should prevent patients from undergoing one of the most beneficent and successful operations in the practice of surgery.

In May, 1915, I published a report in THE LANCET on spinal anæsthesia for prostatectomy, and in 1921 a further report in your paper on a modified method I had been using for some years—namely, a very small quantity of the spinal drug with a very light general anæsthesia. In this report I gave the death-rate as under 5 per cent. Since then, owing to the kindness of Mr. Sydney MacDonald, I have been able to add largely to the number of my anæsthesias, and can now report 402 operations for prostatectomy done under spinal anæsthesia. Of these 402 cases, 382 were cured of their trouble, and 20 died. This is a death-rate of just under 5 per cent.

I have notes of all these cases, and have followed the subsequent result. They are consecutive cases. I should like to give the causes of death in five cases met with in this series, as they are so accidental that they lower the risk of the operation for the individual patient.

1. Patient did well for two days. Then some distension, followed by acute obstruction. Mr. MacDonald diagnosed acute intestinal obstruction, not ileus. A general surgeon did a cæcostomy. At the autopsy an old inflammatory band constricting the splenic flexure was found.
2. Death from cerebral hæmorrhage occurring more than a month after the operation, the patient being very well at the time it occurred.

3 and 4. Pulmonary embolism.

5. Patient over 80. In very good condition when back in bed. Was given gr. ¼ of morphia hypodermically. Became gradually comatose and died of morphia poisoning. He had had no narcotic previously, and was evidently a case of idiosyncrasy.

I am, Sir, yours faithfully,

H. M. PAGE.
Consulting Anæsthetist, West London Hospital.

June 22nd, 1931.

THE VITAMIN B_1 CONTENT OF LIVER EXTRACT.

To the Editor of THE LANCET.

SIR,—It appears to be generally accepted that all commercial liver extracts are deficient in the antineuritic factor (B_1) of the vitamin B complex although they are rich in vitamin B_2. In a recent article[1] Dr. Lucy Wills quotes cases in which pernicious anæmia of pregnancy and tropical anæmia have been cured alike by liver extract and by a yeast extract (marmite). The question arises as to what these extracts have in common. At first glance this would appear to be the B-vitamins, but Dr. Wills quotes a verbal communication from Dr. Harriette Chick to the effect that to produce a vitamin B_1 effect in the rat at least ten times as much liver extract are needed as to produce a vitamin B_2 effect, and concludes that liver extract cannot therefore be called a rich source of vitamin B_1. Certain experiments carried out in this institute during the past six months bear on this question, for they make it clear that the vitamin B_1 content of liver extracts varies to an extent which renders any generalisation in this connexion inadvisable. The results obtained indicate that proprietary liver extracts are divisible into two sharply defined groups, those which contain considerable quantities of the antineuritic factor B_1, and those in which B_1 is present in negligible amount. There is no intermediate class, if equivalents of fresh liver are compared, and the first category includes the majority of the extracts tested.

Eight different liver extracts, as used for the treatment of pernicious anæmia, were tested for their ability to promote normal growth in rats on a diet deficient in all water-soluble vitamins; of these eight extracts, six were found to be efficient sources of vitamin B_1 as well as B_2. Three stomach preparations were also examined for their vitamin content, and all were found to be effectual in correcting a deficiency in both factors of the complex; presumably the stomach preparations, therefore, contain both B_1 and B_2.

---

[1] Brit. Med. Jour., June 20th, p. 1059.

The full experimental data will be published in due course. The results suggest that those liver extracts which are rich in B_1 as well as in B_2 should be included in the list of medicaments available for use in cases in which administration of the vitamin B complex is indicated. Clinical evidence can indeed be adduced that such extracts are of practical value as general tonics, a fact which may be partly attributable to their vitamin content.

I am, Sir, yours faithfully,

ESMÉ GILROY.

Institute of Animal Genetics, Edinburgh, June 22nd, 1931.

VENTILATION OF THE HOUSE OF COMMONS.

To the Editor of THE LANCET.

SIR,—I can add a few words to the position as set out in your leading article (p. 1355). The ventilation of the debating chamber can be easily improved by bringing the air in at the front of the gallery and by stopping up the inlets in the floor where the Members sit, leaving open the inlets in the floor of the central gangway. This was the plan suggested by me in 1913 and confirmed by the National Physical Laboratory after the war. The cost would be about £4000 and there is no hope held out by Mr. Lansbury of this sum being available. Complaints are also made of the ventilation in the division lobbies, library, committee rooms, &c. I suggested that without any expenditure of money the conditions in the House of Commons might generally be improved in the winter months by increasing the heating of the air during the hours when the Members are not there, so as to warm up the structure, and by sending in cool air in comfortable volume when the Members are present. The warmer walls and cooler air would then give them better conditions. In the chamber the floor inlets under the benches can be closed by matting. The trial of this plan next winter will, I hope, lessen complaints. I am, Sir, yours faithfully,

LEONARD HILL.

Chalfont St. Peter, Bucks, June 20th, 1931.

THE BOX RESPIRATOR.

To the Editor of THE LANCET.

SIR,—Your annotation last week on Lord Trent of Nottingham contains a statement which I feel should be corrected. It is that "Sir Jesse (Boot) himself in collaboration with Colonel E. F. Harrison devised the box respirator for which the firm supplied all the chemicals required." As one of the officers in the anti-gas department I happen to be in possession of the actual facts, which are these. The design of the first box respirator used by the British army was worked out almost entirely by Colonel Harrison and Captain J. A. Sadd. It became known as "Harrison's tower" and was based on a principle first described by Mr. B. Lambert of Oxford. It is true that Sir Jesse Boot placed his organisation at the disposal of Colonel Harrison and that the manufacture of the respirator was at first entirely carried out at Nottingham. I feel sure that had Lord Trent been alive he would have been the first to deny that he had any part in the design of the box respirator. I am not desirous of minimising in any way the great help which Messrs. Boots' organisation gave in manufacturing the respirator—it was extremely valuable—but in justice to the late Colonel Harrison and others of my former colleagues in the anti-gas department, I think that your statement should not go uncorrected.

I am, Sir, yours faithfully,

H. S. RAPER.

The University, Manchester, June 22nd, 1931.

THE PRICE OF RUBBER APPLIANCES.

To the Editor of THE LANCET.

SIR,—The price of rubber at present is about 3*d.* a pound; 1s. 6*d.* each is charged for rubber finger stalls. It would require about 50 of these to weigh a pound. They are a standard article, capable of being turned out on mass production lines, so that the manufacturing costs must be slight. This discrepancy between the price of the raw product and that of the finished goods surely calls for some explanation. If it were a purely economic question the matter might be allowed, without protest, to solve itself; but if the wearing of rubber appliances prevents infection spreading from attendant to patient and vice-versa, and if their expense acts as a barrier to general use it takes on a public health aspect. It is a far cry from the planting of tiny seedlings of the rubber tree in the East Indies half a century ago to the reduction of maternal mortality, and yet, if the full advantage of the abundance of the raw material created by British enterprise were allowed to be reaped in a reasonably priced manufactured article, the credit which is its due as a factor in the diminution of the death-rate would be assigned to the plantation industry.—I am, Sir, yours faithfully,

Belfast, June 23rd, 1931. R. M. FRASER, M.D.

STAFFORDSHIRE GENERAL INFIRMARY.—The Earl of Harrowby, lord-lieutenant of the county, recently opened new out-patient and casualty departments at this Stafford hospital which have cost £6000.

ROYAL MEDICAL BENEVOLENT FUND.—During the first six months of this year the Committee has been called upon to vote grants amounting to £6349, which is £1161 in excess of the amount voted in grants during the corresponding period of last year. Unfortunately the income received from subscriptions and donations this year does not show a corresponding increase over last year, but a decrease; unless new subscribers will come forward in support of the Fund before the end of this year, the Committee will be forced to curtail its activities.

At the last meeting of the Committee 26 grants were voted, amounting to £562. The following are particulars of two of the cases helped:—

Widow, aged 68, of M.R.C.S. & L.R.C.P. Her husband was professor of Clinical Surgery in a medical school in the Near East. It was brought to the notice of the Fund that this lady, who had enjoyed a good social position with all the ordinary comforts of life, and had lived for many years in a warm climate, had during last winter been living in a bed-sitting room and had often been unable to afford a fire in her room. Owing to unfortunate investments her income had gradually diminished until last year she had only £89 to live on. She had to pay 9*s.* a week for her room, which left only £66 a year for her maintenance, clothes, light, and warmth. Fund voted £36.

Widow, aged 51, of M.B. Husband died in August, 1930, abroad, at the age of 47, having been in private practice abroad for 12 years. The Ex-Service League paid the widow's passage money to England, where she landed at the end of May this year. When debts and outstanding expenses have been paid, it is expected that the husband's estate will yield to the widow an income of £70. Since the death of her husband the widow has had a severe illness, from which she is now only just recovering. When she landed in England she had only the clothes which she had travelled back in. The Fund voted £26 payable during the next six months, as it is hoped as soon as the widow has recovered her health she will be able to undertake some employment. The Guild have supplied clothes.

Subscriptions should be sent to the Hon. Treasurer, Royal Medical Benevolent Fund, 11, Chandos-street, Cavendish-square, London, W. 1.

OBITUARY

JOHN CARSWELL, F.R.F.P.S. Glasg., L.R.C.P. Edin.

Dr. John Carswell, J.P., who died on June 20th at the age of 75, was a pioneer among those who, in the latter part of last century, insisted on the abolition of coercive methods in the management of the insane. His interest in the subject began when, shortly after qualifying from the Anderson College, Glasgow, in 1877, he became assistant to Dr. James Rutherford, at that time medical superintendent of Woodilee Asylum. Rutherford was inspired by ideals which, though they influenced Scottish procedure, could not be effectively pursued in this country until recently when the law has been amended to allow mental hospitals to admit voluntary patients. Dr. Carswell actually put these ideals into practice. He described in his Maudsley lecture in 1924 how he had persuaded the parish of Glasgow, with a population of 600,000, to place the certification of alleged insane persons in charge of one medical officer, and to make provision for the treatment of suitable cases, without certification, in observation wards. It was necessary to convince not only the authorities but the public that numbers of patients could thus be treated successfully who would otherwise have had to be certified, and also that the departure from conventional methods of dealing with the mentally deranged would not menace the community as a whole. Dr. Carswell was able to make his influence widely felt in medical and lay circles, since he held the posts of lecturer on mental diseases to the Anderson College Medical School, certifying officer to the parish of Glasgow, and physician to the mental wards established in the East District Hospital. In 1914 his work was recognised in his appointment as a medical commissioner to the General Board of Control in Scotland, and from that time onwards he took an important part in elucidating medico-legal aspects of lunacy. His Maudsley lecture, referred to above, was on sociological considerations bearing upon the occurrence, prevention, and treatment of mental disorder. He surveyed the opposing points of view—that the betterment of bad social conditions would improve the mental health of the community, and, on the other hand, that better social conditions would lead to the preservation of the unfit and therefore produce more insanity—concluding that the existence of much the same degree of constitutional instability in good and bad districts damaged both arguments. Dr. Carswell's pronouncement on uncontrollable impulse in connexion with responsibility for crime opened a discussion by the Royal Medical Psychological Association on the report of the Atkin Committee which cleared up several issues.[1] His last important public duty was the delivery in 1928 of the Morison lectures before the Royal College of Physicians of Edinburgh. In these lectures, entitled psychology and medicine, he entered a plea for the closer union of psychological and physiological research, believing rather unfashionably that advances in psychological medicine are most likely to come from investigations such as are directed to ascertaining the causation of physical disease. Dr. Carswell's productive work for improved conditions for the insane and for the prevention of insanity by early treatment of mental abnormality will provide a notable chapter in the history of psychiatry and his name will long be remembered.

RONALD CAMPBELL MACFIE, M.B., C.M., LL.D. Aberd.

Dr. R. C. Macfie who died on June 9th at a nursing home in London at the age of 65 years was a man of wide sympathy and high ideals. He had a big circle of friends, the present Prime Minister amongst them. He was first and foremost a poet. His prowess and position in this direction were recognised a couple of years ago by the invitation he received and accepted to deliver a series of lectures on the art of poetry in the land of his birth. He qualified in medicine at Aberdeen in 1897 and received later an honorary degree of his own university largely in recognition of the charm of his poem Granite Dust, written in commemoration of her foundation. His ode War has been hailed as the greatest poem that war had produced and as one of the greatest odes in the language. Besides poetry he wrote extensively in prose both as an author of such books as The Romance of the Body, and Heredity, Evolution and Vitalism, and as a journalist.

DR. MACFIE.

[Photograph by E. O. Hoppé.

Macfie's poetic temperament, intolerance of anything having even the semblance of being sham or mean, his occasional shortness of temper, and his unselfishness often militated against worldly success. These qualities sometimes terminated friendships which would undoubtedly have been more lasting if the recipients of his friendly strictures had been more penetrating, or the strictures less outspoken. His high ideals were unfortunately for him not often mixed with that business shrewdness usually ascribed to a Scot. Many of his numerous projects for bettering mankind while aiding himself to make a living came to nought. At one time he would be about to found a truly useful international open-air school, at another to exploit for the health of invalids the climatic advantages of some resort on the south-west coast of Ireland. But few of such schemes were of a lasting success in spite of his quite extensive medical experience and his true human sympathy for the sick and needy.

As a Conservative pacifist with some strong Radical leanings, with friends in many nations and experience of living in many lands, he had a variety of strange experiences during the war both as a doctor and as a writer. His chief rôle in medicine was as a sanatorium physician. At one time or another nearly all the best-known sanatoriums in the United Kingdom opened before the war had his services as resident officer or as locum tenens. But his heart was always more in writing than in medical practice.

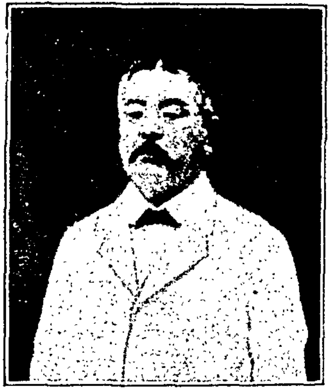
Sir Arthur Thomson writes: "Ronald Campbell Macfie was well known to lovers of poetry and to those interested in the *magnalia naturæ*, but few of us knew him intimately or realised his greatness. From a conventional point of view, which has of course its admitted shrewdness, Macfie was a philosophical physician, who specialised on pulmonary troubles, and wandered from one sanatorium to another, or had occasional compliments as consultant, or enjoyed holidays abroad in one or other of the great caravansaries. He never told us much about this medical experience, but we gathered that it engendered in him a deep sympathy for human frailties, and that it never inhibited his impulse to blurt out the truth. He was always 'daring himself' to be outspokenly sincere. But we must not be thinking of Macfie in any pitying way, as if he did not make a success of his life. He had more red letter days in his hardest and loneliest year than most of us have in our lifetime, for he had a poet's visions and he was ever on the quest after truth—whose pursuit is even more rewarding, Lessing said, than its capture. His was a high-strung, breezy nature, loving much and fighting well, dreaming dreams and helping his fellowmen, very gentle and very fierce, a devotee of beauty and a passionate defender of the faith.

"Ronald Campbell Macfie—his full name seemed to suit him—was an Aberdonian, but far from typical, in being so largely a man of feeling. He graduated in arts as well as in medicine at Aberdeen, and afterwards extended his medical discipline at other schools and in foreign parts. He told us that he had greatly enjoyed some of the locum-tenens posts he had held—at Teneriffe, for instance. He had a high standard of health—an ascetic, with a great respect for his body. Intensely religious, he reacted almost too violently from materialism and from mechanistic analysis of life; and there is a white-hot expression of this in his last published book Science Rediscovers God, or The Theodicy of Science. Many of his poems, such as that on the Quatercentenary of Aberdeen University and his Song of Labour, seem to us pure gold, and he had in his prose, as in The Romance of the Body, many a poetic flash that made a commonplace fact a wonder of the world. He had a grateful love for his alma mater, and it was a great pleasure to him to return after many years to be laureated, and to come back, just the other day, to give the Thomson lectures in the Theological College. He made us all better by his presence."

SHIBASABURO KITASATO, M.D.

A LINK with Robert Koch is broken by the death on June 13th of Prof. Shibasaburo Kitasato, the founder of the bacteriological institute at Tokyo which bears his name. Kitasato was among the fathers of bacteriology. He was the first to obtain pure cultures of the tetanus bacillus, and his classical work, published jointly with Emil v. Behring in 1890, on immunisation against tetanus, provided the basis on which modern serotherapy is founded. In 1894 he discovered the cause of plague. (Yersin)

Kitasato was born in 1856 at Ogunigo, a mountain village in Southern Japan. He received his medical education in the newly established medical school in Kumamoto, under Prof. Mansfeld. Later he studied in the Government Medical School at Tokyo, qualifying in 1883, when he entered the Central Public Health Service. In 1885 he was sent to Germany by the Japanese Government to study bacteriology under Robert Koch. He worked at first on *B. tuberculosis* and then on the tetanus bacillus, isolating it in pure culture, and producing tetanus in animals with his cultures. His great contribution to medicine was his discovery, jointly with Behring, that the cell-free blood serum of animals inoculated with tetanus toxin neutralised the toxin so as to render it inert.



BARON KITASATO.

He continued his work in Germany until he returned to Japan in 1892 to establish a private laboratory for the study of bacteriology, which was the first institute for scientific research in the country. This laboratory was subsequently brought under the control of the Hygiene Society, later subsidised by the Government, and finally, in 1899, the institute, which had been rebuilt, was taken over by the State under the Minister of the Interior, and its work was linked with that of the Government vaccine lymph farm and the serum institute under the general direction of Kitasato. New buildings for this Imperial Institute for Infectious Diseases were erected at Shirokane-daimachi in 1905. During this period Kitasato had not confined his attentions to administrative work, but with his pupils had published several important researches in bacteriology. He himself was ordered abroad periodically to investigate epidemics or to attend congresses; it was on one such mission, during an epidemic of bubonic plague at Hong-Kong in 1894, that he discovered *B. pestis*.

In 1914 the Imperial Institute for Infectious Diseases was transferred suddenly to the control of the Minister of Education, and later was amalgamated with the Tokyo Imperial University. Resenting this change, in regard to which he had not been consulted, Kitasato resigned his directorship, and his pupils followed him to a private institute, known as the Kitasato Institute. He was not long allowed to withdraw from public life, since the Keio-Gijiku University pressed him to organise a new medical faculty. Kitasato accepted the offer, and acted as dean of this faculty, which attained great prestige, for some years, being eventually succeeded by his lifelong associate, Dr. Kitashima.

In 1917 the Emperor of Japan appointed Kitasato a Member of the House of Peers in virtue of his distinguished public service, and thereafter he took some part in medical politics. It was largely owing to his efforts that some ten years ago a medical practitioners' association was organised on a legal basis, all the doctors in Japan being united in the organisation. Kitasato was the first president of this association. In 1924 he was made a baron. Kitasato was honoured by learned societies in many countries, among which was the Royal Society of London, of which he was a foreign Member.

We are indebted to Prof. Mikinosuke, of the Kitasato Institute, for many of the personal details noted above, and also for the following appreciation: "All of us who have associated with him in his life work hoped that Kitasato might yet live long years, and guide us with his master mind to greater progress in medical science and public health. His sudden death has deprived us of one of the most distinguished and influential leaders in scientific as well as social circles in modern Japan. In recollecting the dominant characteristics of this great man, I may mention some of his traits, which have left on us the deepest impressions. Kitasato was a man of filial affection toward his parents and a devoted follower of his teacher. While Koch was in Japan, Kitasato always attended his teacher with the utmost care as though serving his own father. When Koch died, Kitasato built a shrine in the inner court of the institute in remembrance of his great teacher. Each year, on the day of Koch's death, Kitasato commemorated with an appropriate Shinto ceremony the memory of the departed soul. Now, he himself passed beyond the horizon of life, the two great souls may meet in eternity."

PUBLIC HEALTH SERVICES

REPORTS OF SCHOOL MEDICAL OFFICERS.

—	No. on roll.	Average attendance.	Routine inspections.	Special exams. and reinspections.	Percentage of defects.
Hull	47,375	42,628	15,471	58,488	18·6
Birmingham.	—*	—*	42.724	79,895	24·10
Wigan	13,327	12,110	3,508	9,923	20·6

* Not stated.

Hull.

IN a table Dr. J. Morrison shows that the school clinics in the city treated, besides the scholars, 1855 patients, such as infants, nursing and expectant mothers, tuberculous patients, and blind trainees. School-children were given artificial light at a maternity centre, X ray and orthopædic treatment at a combined clinic; scholars with scabies and dirty heads went to a disinfecting station, and swabs from school-children's throats were examined by the city analyst. In addition there is a special liaison with the tuberculosis department. A spectacular result of the efficiency of the medical and nursing staff, and of the value of the X ray installation, is the reduction in cases of ringworm of the scalp from 440 in 1927 to 82 in 1930. Dr. W. M. Frazer, in his introductory note as medical officer of health, says there seems to be no reason why this disease should not virtually disappear in a few years. The city authorities have realised the great need for open-air education, for which nearly 1000 children have been classified as suitable. There are open-air classes and a plan is given of an excellently designed open-air school which was to be ready in April. A nursery school will also be available this year. Attention is being devoted to the hygienic condition of the schools as a whole, the programme of educational reorganisation having emphasised the desirability of altering some of the old schools. The practice of teaching hygiene in the schools has been investigated with the usual result: the teachers' efforts are praised, but the efficiency of the instruction is found to vary much. Hygiene should of course form a definite part of the curriculum in every school. In an appendix is given an account of the X ray treatment which has cured every case of ringworm of the scalp. It is observed that very young children may need only half or even a quarter of the adult dose; the degree of epilation should be such that at the end of 14 days all the hairs are loose. If not, the dose has been insufficient. On leaving the clinic the child is provided with two linen caps and a box of ointment containing salicylic acid grs. xx., precipitated sulphur grs. xx. in soft paraffin 1 oz., and told to keep quiet for 48 hours after the irradiation, since headache and slight sickness may ensue, though they quickly subside.

Birmingham.

In the year under review the city council took over the duties of the guardians of the poor, and Dr. G. A. Auden asks that the work of the school medical service should be looked at very widely. Not only must defects be sought out and remedied; the underlying causes must be determined, else the work fails of its task as part of a preventive service and remains palliative. One child may need to go to hospital, another to a convalescent home, in others the home conditions may require consideration or poverty have to be dealt with. The service becomes the nexus of ameliorative agencies in the city.

One type of agency for remedial work is the school clinic, and the report contains a description and plan of the new clinic at Bordesley Green. Another is the system of cottage homes and the supervision of boarded-out children. These children need care because their parents could not or did not give it; many of them bear marks, physical and psychological, of their earlier life. At the cottage homes they are placed under advantageous conditions, and it is instructive to note how rapid is the physical recovery from the effects of an unhealthy environment compared with the lasting results of psychological maladjustment. At these homes special attention is given to the teeth, a fact that recalls a recently growing type of remedial activity in the schools—namely, orthodontic treatment. It is estimated that at least 5 per cent. of Birmingham children are in serious need of regulative treatment for malformed jaw and misplaced teeth. A note on absentees brings to light another source of benefit to these city children. In acknowledging the information on medical causes for absence from school courteously supplied by busy practitioners, Dr. Auden says it is their reports which have led to the provision of special treatment (ultra-violet, artificial sunlight) and of appropriate schooling (open-air classes). The nexus reaches out again to the three nursery schools whose benefits in poor areas have been so marked that an increase in accommodation is being considered.

An example of an agency not belonging to the city authority is the residential home at Haseley Hall established by the I.C.A.A. It is, however, recognised by the Board of Education as a special school, and close relation is maintained with the school medical service. It is intended to receive children with well-marked rheumatism, whose hearts are unaffected or so slightly involved that there is a prospect of substantial restoration. Since care of the mind is as essential as care of the body, mention should be made of the work at the remand home, where observation and medical report facilitate the task of magistrates in doing their best for delinquent children. Wider still is the scope of the special inquiries which in the long run may be of even greater benefit to the community. Examples are one on the influence of vitamin D on the teeth, and another on the after-results of tonsillectomy.

Wigan.

Dr. H. Whitehead and his assistants are fighting an uphill battle. Though the report describes good progress made with orthopædic and dental schemes, yet the facts and figures show a great deal more to gallant friend a copy of the *report of the* proceedings of a conference of local *governments* which considered the reports of these inquiries. Following upon the *deliberations* of this conference the Government of India have recommended all local *governments to* make an analysis of the figures of consumption in districts where it is known to be high; to obtain more exact information as to the extent to which opium is *given to* children: to experiment with rationing and registration of *consumers; to attempt* to equalise the sale price of opium on *inter-provincial boundaries*; and to consider the possibility of *propaganda* and welfare work in connexion with the administration of opium to children.

Child Labour Convention.

Mr. BROCKWAY asked the Home Secretary what was the attitude of the British Government's representatives at the recent International Labour Conference at Geneva to the resolutions *regarding* the inclusion within the Child Labour Convention of children *now* excluded from protection in various works, the prohibition of overtime and *night work in the case of* young persons under 18, the inclusion of domestic workers within the *convention*, and the prohibition of street trading in the case of girls under 18. Mr. SHORT (Under Secretary to the Home Office) replied: *The Conference only concluded towards the end of last week* and full information is not yet available. If the hon. Member will repeat his *question* later, my right hon. friend will endeavour to give him the information.

Under-nutrition in Mauritius.

Mr. MCSHANE asked the *Under* Secretary for the Colonies if he would have a special medical *report* prepared on the incidence and area of under-nutrition in Mauritius, *and* especially upon the Indian population, particularly since the hurricane of March last.—Dr. SHIELS *replied*: Yes. *I will ask the Governor* to obtain a report on the subject from the Director of the Medical and Health Department of the Colony. I understand that when this question of the existence of under-nutrition was first brought to *notice* an *investigation* was ordered by the Acting *Governor. The report* is not yet to hand, but I am *taking* steps to secure it.

TUESDAY, JUNE 23RD.

Cost of Maintenance in Military Hospitals.

Mr. MIDDLETON asked *the* Secretary for War the total overhead cost of maintenance *per capita per diem* in military hospitals at home during the financial years 1913–14, 1920–21, and 1930–31.—Mr. T. SHAW replied: *I* cannot give figures for the year 1913–14, since *at* that time no cost accounts were kept of military hospitals. In 1920–21 the *estimates show (page 60) that the average* cost per *diem* for each occupied bed was 9*s.* 7·45*d.* For 1930, figures are given on page 72 of Army Estimates showing the gross *cost of* five of the largest military hospitals at home and the number of equipped beds maintained *at* each hospital. For other hospitals at home cost accounts are no longer kept.

Experiments on Living Animals.

Mr. FREEMAN asked the Home Secretary whether he would arrange to publish in *future annual* reports of experiments on living animals and the full *names of all* licensees.—Mr. CLYNES replied: *The names of all* licensees with their degrees and the *registered places* for which their licences are available are published every year in Table II. of the Annual *Return*. It would be impracticable to include reports of experiments in the Annual Return.

Slum Clearance in Scotland.

Mr. McGOVERN asked the Secretary for Scotland the numbers of ordinary, *intermediate*, and slum-clearance houses built in Shettleston *parliamentary* division from June 1st, 1920, to June 1st, 1931, and the number of houses closed *and demolished*.—Mr. ADAMSON replied: The numbers of ordinary, *intermediate*, and slum-clearance houses built by Glasgow Corporation in the Shettleston parliamentary division *from* June 1st, 1920, to June 1st, 1931, are 184, 438, and 612 respectively, and the number of houses closed and demolished during the same *period* is 391.

Miss LEE *asked* the number of condemned houses in Scotland which were at *present* occupied; and what percentage of these would be replaced by slum-clearance houses within six months, a year, two years, and three years respectively.—Mr. WESTWOOD (Under Secretary for Scotland) replied: Complete figures of the number of unfit houses in Scotland *are not* yet available as a number of local authorities have not yet submitted the statement required by Subsection (2) *of* Section 22 of the Housing (Scotland) Act, 1930. According to the statements that have been submitted by 180 *local* authorities, the number of houses *estimated to be* required to replace unfit houses is 37,840, and the *number of houses* likely to be provided by these local authorities within three years *to* replace unfit *houses is 24,321. I am unable to state* what percentage of the unfit houses *will* be replaced by these new houses within the periods mentioned in the question; this will *depend* upon the rate of progress made by the local authorities during *these* periods in carrying out their three years' programme.

Cost of Housing in Scotland.

Mr. MCGOVERN *asked the Secretary* for Scotland the *cost* of three-apartment *and four-apartment* houses which were built in 1923 and 1924 *at* Sandyhills, Glasgow; the cost of the latest houses built on the *same site* during 1930; and the respective rents.—Mr. ADAMSON replied: The costs of the three-apartment and *four-apartment* houses built by the Glasgow Corporation at Sandyhills in 1923 and 1924 were £439 and £553 respectively, while the costs of the houses of the *corresponding types built by the Corporation* on the same site during 1930 were *£335 and £102* respectively. The rents of the houses built in 1923 and 1924 are £27 and £35 per annum for the three-apartment and four-apartment houses *respectively*, and the rents of the houses built in 1930 are £28 and *£35 for the three*-and four-apartment houses respectively.

MEDICAL NEWS

Society of Apothecaries of London.

At recent examinations the following candidates were successful:—

Surgery.—O. A. P. Clark, Westminster Hosp.; A. J. P. Coetzee, London *Hosp.*; *S. D.* Jouhar, Univ. of *Durham*; J. L. F. King, *Charing* Cross Hosp.; R. Pakenham-Walsh; Univ. of Oxford and St. Mary's Hosp.; and T. L. O'C. Ryan, Univ. of Edinburgh.

Medicine.—O. A. P. *Clark*, Westminster Hosp.; A. K. Guha, Univ. of Manchester; S. D. Jouhar, Univ. of Durham; D. M. Nightingale, *King's Coll. Hosp.*; S. H. Thaler, Guy's Hosp.; and C. F. Williamson, Univ. of Birmingham.

Forensic Medicine.—G. R. Germany, Univ. of Sheffield; A. K. Guha, Univ. of Manchester; S. D. Jouhar, Univ. of Durham; D. M. Nightingale, King's Coll. Hosp.; T. L. O'C. Ryan, Univ. *of Edinburgh*; and E. S. St. John, Guy's Hosp.

Midwifery.—A. K. Guha, Univ. of Manchester; O. L. Matthews, Univ. Coll. Hosp.; B. Rivlin, Univ. of Frankfort and Middlesex Hosp.; R. Schauder, King's Coll. Hosp.; E. Teplitzky, Univ. of Berne and St. Mary's Hosp.; and K. G. Wrigley, Univ. of Leeds.

The following candidates, having completed the Final Examination, *are granted the Diploma of the Society* entitling them (upon *registration under the Medical Acts) to practise* medicine, surgery, and midwifery: A. J. P. Coetzee, S. D. Jouhar, D. M. Nightingale, R. Pakenham-Walsh, T. L. O'C. Ryan, and S. H. Thaler.

University of London.

At a meeting of the Senate held on June 17th the Rev. *J. Scott Lidgett* was re-elected Vice-Chancellor for the year 1931–32.—Mr. H. L. Eason, M.S., was appointed a member of the Court for a period of five years.—Dr. Millais Culpin was appointed to a university chair of *medical* industrial psychology, tenable at the School of Hygiene and Tropical Medicine.

Medico-Legal Society.

The annual general meeting of the Society was held at 11, Chandos-street, Cavendish-square, W.1, on June 25th. The *following* officers were elected or re-elected:—President: Lord Riddell. Vice-Presidents: Dr. A. S. Woodwark, Dr. F. J. McCann, and Mr. W. A. Chadwick. Hon. Treasurer: Sir Walter Schröder. Hon. Editors of Transactions: Dr. Gerald *Slot and* Mr. Everard Dickson. Hon. Auditors: Mr. H. B. Wells and Colonel C. T. Samman, M.B. Members of Council: Mr. A. A. Romain, Mr. B. A. Levinson, and Dr. J. S. *Fairbairn*. Hon. Secretaries: Mr. Ernest Goddard and Sir Bernard Spilsbury. At the conclusion of the annual general meeting a paper was read by Dr. T. H. Blench on Crime Investigation in Paris.

Royal Free Hospital Appeal.

The present portion of the Nurses' Home, built on freehold land, is unable to provide sufficient accommodation for the number of nurses required to meet the growing needs of the hospital. The beds in the hospital cannot be increased until *there* is accommodation for a larger nursing staff. The estimated cost to extend and equip this Home is £68,000; of this, £21,000 has been subscribed, leaving £47,000 yet to be found. In order to aid the hospital an appeal for this sum *and for* funds for general maintenance has been issued; Miss Ruth Draper is giving a special matinée at the Vaudeville Theatre on Tuesday, June 30th, at 2.45 P.M., which it is hoped will be largely attended.

University of Liverpool.

Dr. H. Leith Murray, M.D. Aberd., F.C.O.G., has been appointed to the chair of midwifery and gynæcology in succession to Prof. W. Blair Bell.

University of Manchester.

Mr. Stephen Leonard Baker, M.R.C.S., L.R.C.P., D.P.H. Lond., has been appointed Proctor Professor of Pathology and Pathological Anatomy in succession to Prof. J. Shaw Dunn. Since 1922 he has held the post of senior assistant in the Bland-Sutton Institute of Pathology at the Middlesex Hospital, and in 1928 was appointed Reader in Morbid Anatomy and Histology in the University of London. He received his medical education at the London Hospital, where he worked in the pathological department under Prof. H. Turnbull. The Council have appointed Prof. J. S. B. Stopford as Dean of the Medical School in succession to Prof. Raper.

National Conference on Maternity and Child Welfare.

This conference, held under the auspices of the National Association for the Prevention of Infant Mortality, will meet next week at the City Hall, Cardiff. On July 1st debates will be held morning and afternoon on an effective maternity service for the whole population. On July 2nd a debate on the mental health of the normal child in the morning will be followed in the early afternoon by one on the physical health of the child from 1 to 5, while in the late afternoon the best practical means of combining antenatal and postnatal care of the mother, especially in rural areas, will be discussed. On July 3rd the conference will discuss problems connected with children in institutions and boarded-out children.

Glasgow Post-Graduate Medical Association.

The following arrangements have been made for post-graduate teaching in Glasgow during the summer of 1931: (*a*) A general medical and surgical course from August 17th to Sept. 11th. (*b*) Clinical assistantships in general and special hospitals. Further information may be obtained from the Secretary of the Association, The University, Glasgow.

A Coöperative Mental Hospital.

The town councils of East Ham and Southend-on-Sea have agreed, subject to the consent of the Board of Control, to build a joint mental hospital for their respective patients. A site of 500 acres has been found at Runwell, 12 miles from Southend, and 24 from East Ham. The ultimate provision will be 1000 beds, but in the beginning there will be 500 for East Ham and 350 for Southend. At present East Ham has to board out patients as far afield as Gateshead, Taunton, and Worcester.

Royal Hospital for Incurables.

The festival dinner of this institution last week produced a record collection of £16,361, including £3000 from a single donor. There are 109 names on the waiting list, but no beds are vacant, and the annual expenditure of £50,000 is raised with difficulty. The majority of the patients are suffering from rheumatoid arthritis. It was stated at the meeting that "the Board have secured the services of an eminent physician to see what modern science can do to alleviate their suffering."

Fellowship of Medicine and Post-Graduate Medical Association.

The following free demonstrations in out-patient departments will be given: June 29th, at 1.30 P.M., Royal National Orthopædic Hospital, by Mr. Rocyn-Jones; July 3rd, at the Prince of Wales's Hospital, Tottenham, at 2.30 P.M., by Dr. B. H. Jones, and at 3 P.M. by Mr. Dickson Wright, on the Treatment of the Complications of Varicose Veins. A ward round on June 30th, at 2.30 P.M., at the Victoria Hospital for Children, by Dr. R. C. Jewesbury, may also be attended free. For the following lectures and courses fees are payable: A lecture on Recent Advances in Treatment of Disorders of Calcium Metabolism and Calcium Therapy will be given by Dr. Gerald Slot at the Royal Waterloo Hospital on July 1st at 4.30 P.M. A special course in Proctology will be given for one week, June 29th to July 3rd, at St. Mark's Hospital, City-road; it will include operations, demonstrations, and lectures. A special course in Diseases of Children will be given by Dr. John Gibbens at the St. John's Hospital, Lewisham, for two weeks, commencing June 29th, occupying every afternoon. Forthcoming courses include medicine, surgery, and the specialties at the Prince of Wales's Hospital, Tottenham, July 6th to 18th, and a similar course at the Miller General Hospital, Greenwich, July 20th to August 1st. Each course will occupy the whole day from 10.30 A.M. to 5.30 P.M. Syllabuses and tickets can be obtained from the Fellowship of Medicine at 1, Wimpole-street, London, W. 1.

Alexandra Rose Day.

Instead of the £60,000 that had been hoped for, the amount collected in London and Greater London on Alexandra Rose Day, which was marred by bad weather, fell to £50,000. Two years ago £58,000 was collected.

Radium for Nottingham.

With the help of Mr. W. G. Player, Nottingham General Hospital has acquired an additional gramme of radium from the National Fund; hitherto the hospital has possessed three-quarters of a gramme. The hospital now becomes one of the National Radium Centres.

Frenchay Sanatorium, Bristol.

Sir George Newman, chief medical officer of the Ministry of Health, last week opened the completion of Frenchay Park Sanatorium and Orthopædic Hospital for Tuberculous Children belonging to the corporation of Bristol. There is now accommodation for 100 patients.

Royal National Pension Fund for Nurses.

At the annual meeting last week it was reported that 1930 had been a very satisfactory year. The new policies numbered 855, as compared with 721 in 1929, with a new premium income of £19,000. There are now 3847 nurses receiving annuities averaging £30 7*s.*, and the invested funds exceed two millions and a quarter.

Royal Society of Tropical Medicine and Hygiene.

This Society has moved into its new home at Manson House, 26, Portland-place. At present only the office and library are ready for occupation, but the necessary alterations are being carried out as soon as possible, and a small hall for meetings is being erected at the rear of the building. As a result of the appeal issued last year by the President (Dr. G. Carmichael Low) and Sir Austen Chamberlain, a total of nearly £12,000 has been reached, but a further £17,000 is required to equip Manson House as a suitable headquarters for the Society in order that its Fellows visiting England can meet and discuss with those at home the problems of tropical medicine and hygiene. Donations should be sent to the President, at the house of the Society, *26, Portland-place, London*, W.1.

London Light and Electrical Clinic.

The governing body of the clinic, which has recently been reorganised, is the Order of St. John of Jerusalem. On the recommendation of the medical advisory committee honorary consultants have been appointed, by whom all new patients are examined. A staff of specialists in the methods of physical medicine control the treatments, which are carried out under their direction by trained State-registered nurses. Sir Leonard Hill, who is the director of research and teaching at the clinic, will henceforward act as medical supervisor. Payments for treatment are regulated by the means of the patients, and are arranged by the Lady Almoner. To meet the requirements of those able to pay higher fees a private department is available. Some 2500 treatments are given every week at this clinic, which is situated at Ranelagh-road, S.W. 1.

Children's Hospitals.

A meeting was held at St. Pancras town hall recently in connexion with the reconstruction scheme of the Hospital for Sick Children in Great Ormond-street. Mr. J. G. Ketchen, the financial secretary of the hospital, said that the present administration was suffering from the failings of those who had preceded them and had built so that there were wards which excluded the sun and there was no space for a lift, and children who were operated on had to be carried back to their wards. The hospital had no observation beds, and had insufficient accommodation for research work, which had to be done in underground passages. A new nurses' home as well as new hospital buildings was needed.—The Lord Mayor of Liverpool last week opened extensions of the Royal Liverpool Children's Hospital, Heswall, which is now the largest children's hospital in the country with 390 beds—240 at Heswall, 124 at Myrtle-street, Liverpool, and 26 at Thingwall. The extensions have been made possible by a gift of £15,000 from Mr. Andrew Gibson. The whole cost, exclusive of equipment, will be about £23,000.—At the annual meeting of the Liverpool Hospital for Consumption and Diseases of the Chest, it was stated that the Torpenhow open-air school for children at Frankby, Wirral, is "practically a new effort to tackle consumption at its source." In a country house overlooking the Dee 50 potential consumptives, boys and girls, are having six months' schooling under medical supervision. Last year 165 children received the benefits of the school, and in no single case has a scholar fallen back.

100 adults were more sophisticated and 26 complained of fatigue.

The pet dislikes of my subjects were interesting in connexion with psychical fatigue: 10 adults disliked love scenes; only 3 children actively expressed dislike. A stay-at-home population dislikes foreigners, and 17 people bitterly hated Americanisms. Seventeen children complained of blurred sound in the talkies. Other dislikes specially specified included murder (7), wild west scenes (7), comics (7), sentiment (8), bad acting (3), jazz (4), vocal quartets (2), instruction, war, religion 1 each.

These reasoned dislikes were not so interesting as the instances of morbid fears. One man was in a fever of apprehension at the pictures lest he might see blood shed; a boy was terrified of shooting; a man seldom went to the pictures as he once heard a child scream in the audience; a lady feared murder films as she dreamed and had nightmares; a man felt that when at the pictures he was surrounded by the offscourings of the gutters and wanted to get out of the crowd.

I have emphasised the minor psychical abnormalities of a few of my subjects, but on the whole my investigations showed the extraordinary commonsense and tolerance of the London masses.

Flicker.

The optimum-rate of projection of a film is often said to be 16 pictures a second with a duration of 1/32 second per picture. In fact, the most smoothly moving pictures are run at about 25–30 pictures per second. If the film is run too slowly, flicker is produced. Large picture houses run their films at 5000 feet per hour. Smaller theatres wishing to reduce renting costs of their film programmes may run films at 4000 feet per hour or even slower. If the slowing is excessive, flicker may be produced. Such flicker may be somewhat minimised by the use of a revolving, interrupted shutter with accessory vanes.

The film runs through the projector in a series of intermittent jerks, the intermittent motion being due to a device known as a "Maltese cross." Teeth fit into perforations along the sides of the film and pull it through the machine in jerks. Formerly irregularities in the perforations were a common source of trouble but modern film manufacture has improved this defect. Mr. G. B. Bowell maintains that a source of "eyestrain" still remains in the elasticity of the film. The intermittent movement makes the film alternately stretch and relax so that it is never quite stationary at the moment of projection.

Another cause of flicker is the use of alternating current for the arc light which projects the film on the screen. Variations in light intensity may produce flicker. Direct current should be obtained by using a transformer if only alternating current is supplied at the mains.

Vibration.

Vibration of the picture projected is another very trying phenomenon. Lateral and vertical movements may occur from loosening of the "gates" or grooves through which the film runs in the projectors. This is especially trying when printed captions are thrown upon the screen. Projectors should be firmly anchored to the floor or the projector motor may cause vibration. Projector motors should be run off the special power circuit and not the lighting circuit.

"Rain."

"Rain" or floating spots on the projected picture may annoy the audience. "Rain" has various causes. Film is used over and over again, starting at the larger houses and descending in due course to the barns and tin shacks used as country picture theatres. The film inevitably gets scratched and the scratches projected cause "rain." When celluloid film is run fast through projectors, static electricity is generated, and this attracts dust, which shows as "rain" on the screen. In theory the film [illegible] houses are supposed to clean used film; duty is often discharged in a perfunctory Old film often catches in the projector and the tears out the offending segment. The film i sequently stuck together with some missing, omission of the intervening piece causes discontinuity at subsequent projections. film should be discarded.

"Dazzle."

"Dazzle" is another ill-effect of which often complain. Here the individual is very variable and is much increased by suc diseases as conjunctivitis. Every film needs a minimum amount of light for optimum. Animated black-and-white cartoons such as of Mickey Mouse require some dimming of th jector light to avoid unpleasant glare. On the hand, colour films require more light and more projection than the normal. The front of the is undoubtedly the worst place for those to dazzle, which worried the musicians in the of a large cinema very much until they were with tinted glasses.

The eyes of an audience take some time used to changes of light in the intervals films. On this account all the lighting of the torium should be fitted with dimming apparatu the lights turned on and off gradually, not

Bad Vision and Excessive Concentrati

Uncorrected errors of refraction produced fatigue in those persons who attempted to see by narrowing their palpebral fissures or by accommodation. Refractive errors in themselv not necessarily seem to cause fatigue. children with refractive errors and atropinise were sent to the cinema but they experience discomfort save not seeing clearly. In my ow I found fatigue in watching colour films due to excessive accommodation. This was demonstrated by watching a colour film in red and blue-green tints predominated. The the normal eye focuses blue-green sharply in of the retina, while red images tend to focus at an imaginary point just behind the retina own eyes are very slightly hypermetropic. watching a blue-green and red colour film I a tended to focus the blue-green most sharply images of this colour became blurred and red became progressively sharply focused. This menon, the basis of the well-known refraction test, showed I was getting a accommodation and at the same time I expe headache. Perhaps my knowledge of the menon made me look for it and there may be alternative explanation such as "suggestion." patients experienced much relief from fatigue cinema after their refractive errors were

Effects of Distance.

Many patients said that sitting too near screen worried their eyes. The head had to be to an uncomfortable angle in order to see. and dazzle were more noticeable near to the Statistical information was difficult as the c a seat was complicated by financial factors in cases. Of 200 consecutively interviewed 27·5 per cent. habitually sat at the back, 62 per in the middle, and 10·5 per cent. in front. people complaining of cinema discomfort, 2 cent. sat at the back, 48 per cent. in the m 24 per cent. in front. These percentages ar based upon large enough numbers to draw clusions. A cinema proprietor with whom I t thought distance had a great effect on fatigue interspersed films with variety turns which popular because the people in the front temporarily exchanged the worst seats in the for the best.

Uncomfortable Seats.

Uncomfortable seats are becoming rariti modern cinemas which have much in this
